A *literal* is a Boolean variable or its negation. A *clause* is a finite set of literals that does not contain a variable together with its negation. By a *formula* we mean a Boolean formula in conjunctive normal form (*CNF formula*) defined as a finite set of clauses. The number of literals in a clause is called the *length* of the clause. A formula F is called a k -*CNF* formula if every clause in F has length at most k .

Throughout the chapter we write n , m , and l to denote the following natural parameters of a formula F :

- n is the number of variables occurring in F ;
- m is the number of clauses in F ;
- l is the total number of occurrences of all variables in F .

We also write $|F|$ to denote the length of a reasonable binary representation of F , i.e., the size of the input in the usual complexity-theoretic sense. The ratio m/n is called the *clause density* of F .

An *assignment* is a mapping from a set of variables to $\{\text{true}, \text{false}\}$. We identify an assignment with a set A of literals: if a variable x is mapped to **true** then $x \in A$; if x is mapped to **false** then $\neg x \in A$. Given a formula F and an assignment A , we write $F[A]$ to denote the result of substitution of the truth values assigned by A . Namely, $F[A]$ is a formula obtained from F as follows:

- all clauses that contain literals belonging to A are removed from F ;
- all literals that are complementary to the literals in A are deleted from the remaining clauses.

For example, for $F = \{\{x, y\}, \{\neg y, z\}\}$ and $A = \{y\}$, the formula $F[A]$ is $\{z\}$. If C is a clause, we write $F[-C]$ to denote $F[A]$ where A consists of the literals complementary to the literals in C .

An assignment A *satisfies* a formula F if $F[A] = \emptyset$. If a formula has a satisfying assignment, it is called *satisfiable*.

SAT denotes the language of all satisfiable CNF formulas (we sometimes refer to this language as *General SAT* to distinguish it from its restricted versions), *k-SAT* is its subset consisting of k -CNF formulas, *SAT- f* is the subset of SAT containing formulas with each variable occurring at most f times, *k-SAT- f* is the intersection of the last two languages. *Unique k-SAT* denotes a promise problem: an algorithm solves the problem if it gives correct answers for k -CNF formulas that have at most one satisfying assignment (and there are no requirements on the behavior of the algorithm on other formulas).

Complexity bounds are given using the standard asymptotic notation (O , Ω , o , etc), see for example [CLRS01]. We use \log to denote the binary logarithm and \ln to denote the natural logarithm. The binary entropy function is given by

$$H(x) = -x \log x - (1 - x) \log(1 - x).$$

16.1.2. Transformation rules

We describe several simple operations that transform formulas without changing their satisfiability status (we delay more specific operations until they are needed).

Unit clauses. A clause is called *unit* if its length is 1. Clearly, a unit clause determines the truth value of its variable in a satisfying assignment (if any). Therefore, all unit clauses can be eliminated by the corresponding substitutions. This procedure (iterated until no unit clauses are left) is known as *unit clause elimination*.

Subsumption. Another simple procedure is *subsumption*: if a formula contains two clauses and one is a subset of the other, then the larger one can be dropped.

Resolution. If two clauses A and B have exactly one pair of complementary literals $a \in A$ and $\neg a \in B$, then the clause $A \cup B \setminus \{a, \neg a\}$ is called the *resolvent* of A and B (by a) and denoted by $R(A, B)$. The resolvent is a logical consequence of these clauses and can be added to the formula without changing its satisfiability. The important cases of adding resolvents are:

- *Resolution with subsumption.* If F contains two clauses C and D such that their resolvent $R(C, D)$ is a subset of D , replace F by $(F \setminus \{D\}) \cup \{R(C, D)\}$.
- *Elimination of a variable by resolution.* Given a formula F and a literal a , the formula denoted $DP_a(F)$ is constructed from F by adding all resolvents by a and then removing all clauses that contain a or $\neg a$ (this transformation was used in [DP60]). A typical use of this rule is as follows: if the number of clauses (resp. the number of literal occurrences) in $DP_a(F)$ is smaller than in F , replace F by $DP_a(F)$.
- *Bounded resolution.* Add all resolvents of size bounded by some function of the formula parameters.

16.2. Tractable and intractable classes

Consider the satisfiability problem for a certain class of formulas. Depending on the class, either this restriction is in \mathbf{P} (2-SAT for example) or no polynomial-time algorithm for the restricted problem is known (3-SAT). Are there any criteria that would allow us to distinguish between tractable and intractable classes? A remarkable result in this direction was obtained by Schaefer in 1978 [Sch78]. He considered a generalized version of the satisfiability problem, namely he considered Boolean constraint satisfaction problems $\text{SAT}(\mathcal{C})$ where \mathcal{C} is a set of constraints, see precise definitions below. Each set \mathcal{C} determines a class of formulas such as 2-CNF, 3-CNF, Horn formulas, etc. Loosely speaking, Schaefer's dichotomy theorem states that there are only two possible cases: $\text{SAT}(\mathcal{C})$ is either in \mathbf{P} or \mathbf{NP} -complete. The problem is in \mathbf{P} if and only if the class determined by \mathcal{C} has at least one of the following properties:

1. Every formula in the class is satisfied by assigning true to all variables;
2. Every formula in the class is satisfied by assigning false to all variables;
3. Every formula in the class is a Horn formula;
4. Every formula in the class is a dual-Horn formula;
5. Every formula in the class is in 2-CNF;
6. Every formula in the class is affine.

We describe classes with these properties in the next section. Schaefer's theorem and some relevant results are given in Section 16.2.2.

16.2.1. "Easy" classes

Trivially satisfiable formulas. A CNF formula F is satisfied by assigning true (resp. false) to all variables if and only if every clause in F has at least one positive (resp. negative) literal. The satisfiability problem for such formulas is trivial: all formulas are satisfiable.

Horn and dual-Horn formulas. A CNF formula is called *Horn* if every clause in this formula has at most one positive literal. Satisfiability of a Horn formula F can be tested as follows. If F has unit clauses then we apply unit clause elimination until all unit clauses are eliminated. If the resulting formula F' contains the empty clause, we conclude that F is unsatisfiable. Otherwise, every clause in F' contains at least two literals and at least one of them is negative. Therefore, F' is trivially satisfiable by assigning false to all variables, which means that F is satisfiable too. It is obvious that this method takes polynomial time. Using data flow techniques, satisfiability of Horn formulas can be tested in linear time [DG84].

A CNF formula is called *dual-Horn* if every clause in it has at most one negative literal. The satisfiability problem for dual-Horn formulas can be solved similarly to the case of Horn formulas.

2-CNF formulas. A linear-time algorithm for 2-SAT was given in [APT79]. This algorithm represents an input formula F by a labeled directed graph G as follows. The set of vertices of G consists of $2n$ vertices corresponding to all variables occurring in F and their negations. Each clause $a \vee b$ in F can be viewed as two implications $\neg a \rightarrow b$ and $\neg b \rightarrow a$. These two implications produce two edges in the graph: $(\neg a, b)$ and $(\neg b, a)$. It is easy to prove that F is unsatisfiable if and only if there is a variable x such that G has a cycle containing both x and $\neg x$. Since strongly connected components can be computed in linear time, 2-SAT can be solved in linear time too.

There are also other methods of solving 2-SAT in polynomial time, for example, random walks [Pap94] or resolution (note that the resolution rule applied to 2-clauses produces a 2-clause, so the number of all possible resolvents does not exceed $O(n^2)$).

Affine formulas. A *linear equation over the two-element field* is an expression of the form $x_1 \oplus \dots \oplus x_k = \delta$ where \oplus denotes the sum modulo 2 and δ stands for 0 or 1. Such an equation can be expressed as a CNF formula consisting of 2^{k-1} clauses of length k . An *affine formula* is a conjunction of linear equations over the two-element field. Using Gaussian elimination, we can test satisfiability of affine formulas in polynomial time.

16.2.2. Schaefer's dichotomy theorem

Definition 16.2.1. A function $\phi: \{\text{true}, \text{false}\}^k \rightarrow \{\text{true}, \text{false}\}$ is called a *Boolean constraint* of arity k .

Definition 16.2.2. Let ϕ be a constraint of arity k and x_1, \dots, x_k be a sequence of Boolean variables (possibly with repetitions). The pair $\langle \phi, (x_1, \dots, x_k) \rangle$ is called a *constraint application*. Such a pair is typically written as $\phi(x_1, \dots, x_k)$.

Definition 16.2.3. Let $\phi(x_1, \dots, x_k)$ be a constraint application and A be a truth assignment to x_1, \dots, x_k . We say that A *satisfies* $\phi(x_1, \dots, x_k)$ if ϕ evaluates to true on the truth values assigned by A .

Definition 16.2.4. Let $\Phi = \{C_1, \dots, C_m\}$ be a set of constraint applications and A be a truth assignment to all variables occurring in Φ . We say that A is a *satisfying assignment* for Φ if A satisfies every constraint application in Φ .

Definition 16.2.5. Let \mathcal{C} be a set of Boolean constraints. We define $\text{SAT}(\mathcal{C})$ to be the following decision problem: given a finite set Φ of applications of constraints from \mathcal{C} , is there a satisfying assignment for Φ ?

Example. Let \mathcal{C} consist of four Boolean constraints $\phi_1, \phi_2, \phi_3, \phi_4$ defined as follows:

$$\begin{aligned}\phi_1(x, y) &= x \vee y; \\ \phi_2(x, y) &= x \vee \neg y; \\ \phi_3(x, y) &= \neg x \vee \neg y; \\ \phi_4(x, y) &= \text{false}.\end{aligned}$$

Then $\text{SAT}(\mathcal{C})$ is 2-SAT.

Theorem 16.2.1 (Schaefer’s dichotomy theorem [Sch78]). *Let \mathcal{C} be a set of Boolean constraints. If \mathcal{C} satisfies at least one of the conditions (1)–(6) below then $\text{SAT}(\mathcal{C})$ is in \mathbf{P} . Otherwise $\text{SAT}(\mathcal{C})$ is \mathbf{NP} -complete.*

1. Every constraint in \mathcal{C} evaluates to true if all arguments are true.
2. Every constraint in \mathcal{C} evaluates to true if all arguments are false.
3. Every constraint in \mathcal{C} can be expressed as a Horn formula.
4. Every constraint in \mathcal{C} can be expressed as a dual-Horn formula.
5. Every constraint in \mathcal{C} can be expressed as a 2-CNF formula.
6. Every constraint in \mathcal{C} can be expressed as an affine formula.

The main part of this theorem is to prove that $\text{SAT}(\mathcal{C})$ is \mathbf{NP} -hard if none of the conditions (1)–(6) holds for \mathcal{C} . The proof is based on a classification of the sets of constraints that are closed under certain operations (conjunction, substitution of constants, existential quantification). Any such set either satisfies one of the conditions (3)–(6) or coincides with the set of all constraints.

Schaefer’s theorem was extended and refined in many directions, for example a complexity classification of the polynomial-time solvable case (with respect to \mathbf{AC}^0 reducibility) is given in [ABI⁺05]. Likewise, classification theorems similar to Schaefer’s one were proved for many variants of SAT, including the counting satisfiability problem #SAT, the quantified satisfiability problem QSAT, the maximum satisfiability problem MAX SAT (see Part 4 of this book for the definitions of these extensions of SAT), and others, see a survey in [CKS01].

A natural question arises: given a set \mathcal{C} of constraints, how difficult is it to recognize whether $\text{SAT}(\mathcal{C})$ is “easy” or “hard”? That is, we are interested in the complexity of the following “meta-problem”: Given \mathcal{C} , is $\text{SAT}(\mathcal{C})$ in \mathbf{P} ? As shown in [CKS01], the complexity of the meta-problem depends on how the constraints are specified:

- If each constraint in \mathcal{C} is specified by its set of satisfying assignments then the meta-problem is in \mathbf{P} .
- If each constraint in \mathcal{C} is specified by a CNF formula then the meta-problem is **co-NP**-hard.

- If each constraint in \mathcal{C} is specified by a DNF formula then the meta-problem is **co-NP-hard**.

16.3. Upper bounds for k -SAT

SAT can be trivially solved in 2^n polynomial-time steps by trying all possible assignments. The design of better exponential-time algorithms started with papers [MS79, Dan81, Luc84, MS85] exploiting a simple divide-and-conquer approach¹ for k -SAT. Indeed, if a formula contains a 3-clause $\{x_1, x_2, x_3\}$, then deciding its satisfiability is equivalent to deciding the satisfiability of three simpler formulas $F[x_1]$, $F[\neg x_1, x_2]$, and $F[\neg x_1, \neg x_2, x_3]$, and the recurrent inequality on the number of leaves in such a computation tree already gives a $|F|^{O(1)} \cdot 1.84^n$ -time algorithm for 3-SAT, see Part 1, Chapter 8 for a survey of techniques for estimating the running time of such algorithms.

Later development brought more complicated algorithms based on this approach both for k -SAT [Kul99] and SAT [KL97, Hir00], see also Section 16.4.2. However, modern randomized algorithms and their derandomized versions appeared to give better bounds for k -SAT. In what follows we survey these new approaches: *critical clauses* (Section 16.3.1), *multistart random walks* (Section 16.3.2), and *cube covering* proposed in an attempt to derandomize the random-walk technique (Section 16.3.3). Finally, we go briefly through recent improvements for particular cases (Section 16.3.4).

16.3.1. Critical clauses

To give the idea of the next algorithm, let us switch for a moment to a particular case of k -SAT where a formula has at most one satisfying assignment (Unique k -SAT). The restriction of this case ensures that every variable v must occur in a v -critical clause that is satisfied only by the literal corresponding to v (otherwise one could change its value to obtain a different satisfying assignment); we call v the *principal* variable of this clause. This observation remains also valid for general k -SAT if we consider an *isolated* satisfying assignment that becomes unsatisfying if we flip the value of exactly one variable. More generally, we call a satisfying assignment j -isolated if this happens for exactly j variables (while for any other of the remaining $n - j$ variables, a flip of its value yields another satisfying assignment). Clearly, each of these j variables has its critical clause, i.e., a clause where it is the principal variable.

Now start picking variables one by one at random and assigning random values to them eliminating unit clauses after each step. Clearly, each critical clause of length k has a chance of $1/k$ of being “properly” ordered: its principal variable is chosen after all other variables in the clause and thus will be assigned “for free” during the unit clause elimination provided the values of other variables are chosen correctly. Thus the expected number of values we get “for free” is j/k ; the probability to guess correctly the values of other variables is $2^{-(n - \lfloor j/k \rfloor)}$.

¹Such SAT algorithms are usually called *DPLL algorithms* since the approach originates from [DP60, DLL62].

While this probability of success is the largest for 1-isolated satisfying assignments, j -isolated assignments for larger j come in larger “bunches”. The overall probability of success is

$$\sum_j 2^{-(n-\lfloor j/k \rfloor)} \cdot (\text{number of } j\text{-isolated assignments}),$$

which can be shown to be $\Omega(2^{-n(1-1/k)})$ [PPZ97]. The probability that the number of “complimentary” values is close to its expectation adds an inverse polynomial factor. Repeating the procedure in order to get a constant probability of error yields an $|F|^{O(1)} \cdot 2^{n(1-1/k)}$ -time algorithm, which can be derandomized for some penalty in time.

The above approach based on critical clauses was proposed in [PPZ97]. A follow-up [PPSZ98] (journal version: [PPSZ05]) gives an improvement of the $2^{n(1-1/k)}$ bound by using a preprocessing step that augments the formula by all resolvents of size bounded by a slowly growing function. Adding the resolvents formalizes the intuition that a critical clause may become “properly ordered” not only in the original formula, but also during the process of substituting the values.

Algorithm 16.3.1 (The PPSZ algorithm, [PPSZ05]).

Input: k -CNF formula F .

Output: yes, if F is satisfiable, no otherwise.²

1. Augment F using bounded resolution up to the length bounded by any slowly growing function such that $s(n) = o(\log n)$ and s tends to infinity as n tends to infinity.
2. Repeat $2^{n(1-\frac{\mu_k}{k-1}+o(1))}$ times, where $\mu_k = \sum_{j=1}^{\infty} \frac{1}{j(j+\frac{1}{k-1})}$:
 - (a) Apply unit clause elimination to F .
 - (b) Pick randomly a literal a still occurring in F and replace F by $F[a]$.³

Theorem 16.3.1 ([PPSZ05]). *The PPSZ algorithm solves k -SAT in time*

$$|F|^{O(1)} \cdot 2^{n(1-\frac{\mu_k}{k-1}+o(1))}$$

with error probability $o(1)$, where μ_k is an increasing sequence with $\mu_3 \approx 1.227$ and $\lim_{k \rightarrow \infty} \mu_k = \pi^2/6$.

16.3.2. Multistart random walks

A typical local-search algorithm for SAT starts with an initial assignment and modifies it step by step, trying to come closer to a satisfying assignment (if any). Methods of modifying may vary. For example, greedy algorithms choose a variable and flip its value so as to increase some function of the assignment, say,

²This algorithm and the other randomized algorithms described below may incorrectly say “no” on satisfiable formulas.

³Contrary to [PPSZ05], we choose a literal not out of all $2n$ possibilities (for n variables still remaining in the formula) but from a possibly smaller set. However, this only excludes a chance to assign the wrong value to a pure literal.

the number of satisfied clauses. Another method was used in Papadimitriou's algorithm for 2-SAT [Pap91]: flip the value of a variable chosen at random from an unsatisfied clause. Algorithms based on this method are referred to as *random-walk* algorithms.

Algorithm 16.3.2 (The multistart random-walk algorithm).

Input: k -CNF formula F .

Output: satisfying assignment A if F is satisfiable, no otherwise.

Parameters: integers t and w .

1. Repeat t times:
 - (a) Choose an assignment A uniformly at random.
 - (b) If A satisfies F , return A and halt. Otherwise repeat the following instructions w times:
 - Pick any unsatisfied clause C in F .
 - Choose a variable x uniformly at random from the variables occurring in C .
 - Modify A by flipping the value of x in A .
 - If the updated assignment A satisfies F , return A and halt.
2. Return no and halt.

This multistart random-walk algorithm with $t = 1$ and $w = 2n^2$ is Papadimitriou's polynomial-time algorithm for 2-SAT [Pap91]. The algorithm with $t = (2 - 2/k)^n$ and $w = 3n$ is known as Schöning's algorithm for k -SAT where $k \geq 3$ [Sch99].

Random-walk algorithms can be analyzed using one-dimensional random walks. Consider one random walk. Suppose that the input formula F has a satisfying assignment S that differs from the current assignment A in the values of exactly j variables. At each step of the walk, A becomes closer to S with probability at least $1/k$ because any unsatisfied clause contains at least one variable whose values in A and in S are different. Thus, the performance of the algorithm can be described in terms of a particle walking on the integer interval $[0..n]$. The position 0 corresponds to the satisfying assignment S . At each step, if the particle's position is j , where $0 < j < n$, it moves to $j - 1$ with probability at least $1/k$ and moves to $j + 1$ with probability at most $1 - 1/k$.

Let p be the probability that a random walk that starts from a random assignment finds a fixed satisfying assignment S in at most $3n$ steps. Using the "Ballot theorem", Schöning shows in [Sch99] that $p \geq (2 - 2/k)^{-n}$ up to a polynomial factor. An alternative analysis by Welzl reduces the polynomial factor to a constant: $p \geq (2/3) \cdot (2 - 2/k)^{-n}$, see Appendix to [Sch02]. Therefore, Schöning's algorithm solves k -SAT with the following upper bound:

Theorem 16.3.2 ([Sch02]). *Schöning's algorithm solves k -SAT in time*

$$|F|^{O(1)} \cdot (2 - 2/k)^n$$

with error probability $o(1)$.

$$\underbrace{\left\{ \begin{array}{c} \text{word}_1 \\ \text{word}_2 \\ \dots \\ \text{word}_N \end{array} \right\} \cdot \left\{ \begin{array}{c} \text{word}_1 \\ \text{word}_2 \\ \dots \\ \text{word}_N \end{array} \right\} \cdot \left\{ \begin{array}{c} \text{word}_1 \\ \text{word}_2 \\ \dots \\ \text{word}_N \end{array} \right\} \dots \left\{ \begin{array}{c} \text{word}_1 \\ \text{word}_2 \\ \dots \\ \text{word}_N \end{array} \right\}}_t$$

Figure 16.1. A block code C^t for code $C = \{\text{word}_1, \dots, \text{word}_N\}$.

16.3.3. Cube covering

Schöning’s algorithm solves k -SAT using an exponential number of relatively “short” random walks that start from random assignments. Is it possible to derandomize this approach? A derandomized version of multistart random walks is given in [DGH⁺02].

The idea behind the derandomization can be described in terms of a covering of the Boolean cube with Hamming balls. We can view truth assignments to n variables as points in the Boolean cube $\{0, 1\}^n$. For any two points $u, v \in \{0, 1\}^n$, the *Hamming distance* between u and v is denoted by $\delta(u, v)$ and defined to be the number of coordinates in which these points are different. The *Hamming ball* of radius R with center w is defined to be

$$\{u \in \{0, 1\}^n \mid \delta(u, w) \leq R\}.$$

Let \mathcal{C} be a collection of Hamming balls of radius R with centers w_1, \dots, w_t . This collection is called a *covering* of the cube if each point in the cube belongs to at least one ball from \mathcal{C} . When thinking of the centers w_1, \dots, w_t as *codewords*, we identify the covering \mathcal{C} with a *covering code* [CHLL97].

The derandomization of Schöning’s algorithm for k -SAT is based on the following approach. First, we cover the Boolean cube with Hamming balls of some fixed radius R (two methods of covering are described below). This covering should contain as few balls as possible. Then we consider every ball and search for a satisfying assignment inside it (see the procedure *Search* below). The time of searching inside a ball depends on the radius R : the smaller R we use, the less time is needed. However, if the radius is small, many balls are required to cover the cube. It is shown in [DGH⁺02] that for the particular procedure *Search* the overall running time is minimum when $R = n/(k + 1)$.

Covering of the Boolean cube with Hamming balls. How many Hamming balls of a given radius R are required to cover the cube? Since the volume of a Hamming ball of radius R is at most $2^{nH(R/n)}$ where H is the binary entropy function, the smallest possible number of balls is at least $2^{n(1-H(R/n))}$. This trivial lower bound is known as *sphere covering bound* [CHLL97]. Our task is to construct a covering code whose size is close to the sphere covering bound. To do it, we partition n bits into d blocks with n/d bits in each block. Then we construct a covering code of radius R/d for each block and, finally, we define a covering code for the n bits to be the direct sum of the covering codes for blocks (see Fig. 16.1). More exactly, the cube-covering-based algorithm in [DGH⁺02] uses the following two methods of covering.

- *Method A: Constant number of blocks of linear size.* We partition n bits into d blocks where d is a constant. Then we use a greedy algorithm for the Set Cover problem to construct a covering code for a block with n/d bits. The resulting covering code for n bits is optimal: its size achieves the sphere covering bound up to a polynomial factor. However, this method has a disadvantage: construction of a covering code for a block requires exponential space.
- *Method B: Linear number of blocks of constant size.* We partition n bits into n/b blocks of size b each, where b is a constant. A covering code for each block is constructed using a brute-force method. The resulting covering code is constructed within polynomial space, however this code is only “almost” optimal: its size achieves the sphere covering bound up to a factor of $2^{\varepsilon n}$ for arbitrary $\varepsilon > 0$.

Search inside a ball. After constructing a covering of the cube with balls, we search for a satisfying assignment inside every ball. To do this, we build a tree using the local search paradigm: if the current assignment A does not satisfy the input formula, choose any unsatisfied clause $\{l_1, \dots, l_k\}$ and consider assignments A_1, \dots, A_k where A_i is obtained from A by flipping the literal l_i (note that while a traditional randomized local search considers just *one* of these assignments, a deterministic procedure must consider *all* these assignments). More exactly, we use the following recursive procedure $Search(F, A, R)$. It takes as input a k -CNF formula F , an assignment A (center of the ball), and a number R (radius of the ball). If F has a satisfying assignment inside the ball, the procedure outputs yes (for simplicity, we describe a decision version); otherwise, the answer is no.

1. If F is true under A , return yes.
2. If $R \leq 0$, return no.
3. If F contains the empty clause, return no.
4. Choose any clause that is false under A . For each literal l in C , run $Search(F[l], A, R - 1)$. Return yes if at least one of these calls returns yes. Otherwise return no.

The procedure builds a tree in which

- each degree is at most k ;
- the height is at most R (the height is the distance from the center of the ball).

Therefore, $Search(F, A, R)$ runs in time k^R up to a polynomial factor.

Algorithm 16.3.3 (The cube-covering-based algorithm, [DGH⁺02]).

Input: k -CNF formula F .

Output: yes if F is satisfiable, no otherwise.

Parameter: $\varepsilon > 0$ (the parameter is needed only if Method B is used).

1. Cover the Boolean cube with Hamming balls of radius $R = n/(k+1)$ using either Method A or Method B.
2. For each ball, run $Search(F, A, R)$ where A is the center of the ball. Return yes if at least one of these calls returns yes. Otherwise, return false.

Theorem 16.3.3 ([DGH⁺02]). *The cube-covering-based algorithm solves k -SAT in time*

$$|F|^{O(1)} \cdot (2 - 2/(k+1))^n$$

and within exponential space if Method A is used, or in time

$$|F|^{O(1)} \cdot (2 - 2/(k+1) + \varepsilon)^n$$

and within polynomial space if Method B is used.

In the next section we refer to a weakened version of these bounds:

Proposition 16.3.4. *The cube-covering-based algorithm solves k -SAT in time*

$$|F|^{O(1)} \cdot 2^{n(1-1/k)}.$$

16.3.4. Improvements for restricted versions of k -SAT

3-SAT. Like the general case of k -SAT, the currently best bounds for randomized 3-SAT algorithms are better than those for deterministic 3-SAT algorithms.

- *Randomized algorithms.* Schöning's algorithm solves 3-SAT formulas in time $O(1.334^n)$. It was shown in [IT04] that this bound can be improved by combining Schöning's algorithm with the PPSZ algorithm. The currently best bound obtained using such a combination is $O(1.323^n)$ [Rol06].
- *Deterministic algorithms.* The cube-covering-based algorithm solves 3-SAT in time $O(1.5^n)$. This bound can be improved using a pruning technique for search inside a ball [DGH⁺02]. The currently best bound based on this method is $O(1.473^n)$ [BK04].

Unique k -SAT. The currently best bounds for Unique k -SAT are obtained using the approach based on critical clauses.

- *Randomized algorithms.* For $k > 4$, the best known bound for Unique k -SAT is the bound given by the PPSZ algorithm (Theorem 16.3.1). For Unique 3-SAT and Unique 4-SAT, the PPSZ bounds can be improved: $O(1.308^n)$ and $O(1.470^n)$ respectively [PPSZ05].
- *Deterministic algorithms.* The PPSZ algorithms can be derandomized for Unique k -SAT using the technique of limited independence [Rol05]. This derandomization yields bounds that can be made arbitrarily close to the bounds for the randomized case (see above) by taking appropriate values for the parameters of the derandomized version.

16.4. Upper bounds for General SAT

Algorithms with the currently best upper bounds for General SAT are based on the following two approaches:

- **Clause shortening** (Section 16.4.1). This method gives the currently best bound of the form $|F|^{O(1)} \cdot 2^{\alpha n}$ where α depends on n and m .
- **Branching** (Section 16.4.2, see also Part 1, Chapter 8). Algorithms based on branching have the currently best upper bounds of the form $|F|^{O(1)} \cdot 2^{\beta m}$ and $|F|^{O(1)} \cdot 2^{\gamma l}$, where β and γ are constants.

16.4.1. Algorithms based on clause shortening

The first nontrivial upper bound for SAT was given by Pudlak in [Pud98]. His randomized algorithm used the critical clauses method [PPZ97] to solve SAT with the $|F|^{O(1)} \cdot 2^{\alpha n}$ bound where $\alpha = 1 - 1/(2\sqrt{n})$. A slightly worse bound was obtained using a deterministic algorithm based on the cube-covering technique [DHW04].

Further better bounds were obtained using the *clause-shortening* approach proposed by Schuler in [Sch05]. This approach is based on the following dichotomy: *For any “long” clause (longer than some $k = k(n, m)$), either we can shorten this clause by choosing any k literals in the clause and dropping the other literals, or we can substitute false for these k literals in the entire formula.*

In other words, if a formula F contains a “long” clause C then F is equivalent to $F' \vee F''$ where F' is obtained from F by shortening C to a subclause D of length k and F'' is obtained from F by assigning false to all literals in D . This dichotomy is used to shorten all “long” clauses in the input formula F and apply a k -SAT algorithm afterwards.

The clause-shortening approach was described in [Sch05] as a randomized algorithm. Its derandomized version was given in [DHW06].

Algorithm 16.4.1 (The clause-shortening algorithm).

Input: CNF formula F consisting of clauses C_1, \dots, C_m .

Output: yes if F is satisfiable, no otherwise.

Parameter: integer k .

1. Change each clause C_i to a clause D_i as follows: If $|C_i| > k$ then choose any k literals in C_i and drop the other literals; otherwise leave C_i as is. Let F' denote the resulting formula $D_1 \vee \dots \vee D_m$.
2. Test satisfiability of F' using the cube-covering-based algorithm (Section 16.3).
3. If F' is satisfiable, output yes and halt. Otherwise, for each i , do the following:
 - (a) Convert F to F_i as follows:
 - i. Replace C_j by D_j for all $j < i$;
 - ii. Assign false to all literals in D_i .
 - (b) Recursively invoke this algorithm on F_i .
4. Return no.

What value of k is optimal? If k is small then each k -SAT instance can be solved fast, however we have a large number of k -SAT instances. If k is large then the k -SAT subroutine takes much time. Schuler’s bound and further better bounds for the clause-shortening approach were improved by Calabro, Impagliazzo, and Paturi in [CIP06]. Using this approach, they reduce a SAT instance to an exponential number of k -SAT instances and prove the following “conditional” bound:

Theorem 16.4.1 ([CIP06]). *If k -SAT can be solved in time $|F|^{O(1)} \cdot 2^{\alpha n}$ then SAT can be solved in time*

$$|F|^{O(1)} \cdot 2^{\alpha n + \frac{4m}{2^{\alpha k}}}$$

for any n, m and k such that $m \geq n/k$.

Although this theorem is not used in [CIP06] to give an improved bound for SAT explicitly, such a bound can be easily derived as follows. Since there is an algorithm that solves k -SAT with the $2^{n(1-1/k)}$ bound (Corollary 16.3.4), we can take $\alpha = 1 - 1/k$. Now we would like to choose k such as to minimize the exponent

$$\alpha n + \frac{4m}{2^{\alpha k}}$$

in the bound given by Theorem 16.4.1 above. Assuming that $m > n$, we take $k = 2 \log(m/n) + c$ where c is a constant that will be chosen later. Then

$$\begin{aligned} \alpha n + \frac{4m}{2^{\alpha k}} &= n \left(1 - \frac{1}{k}\right) + \frac{4m}{2^{k-1}} \\ &= n \left(1 - \frac{1}{2 \log(m/n) + c} + \frac{1}{(m/n) 2^{c-3}}\right) \end{aligned}$$

The constant c can be chosen so that

$$2 \log(m/n) + c < (m/n) 2^{c-3}$$

for all $m > n$. Therefore, the exponent is bounded by $n(1 - 1/O(k))$, which gives us the currently best upper bound for SAT:

Proposition 16.4.2. *SAT can be solved (for example, by Algorithm 16.4.1) in time*

$$|F|^{O(1)} \cdot 2^{n(1 - \frac{1}{O(\log(m/n))})}$$

where $m > n$.

16.4.2. Branching-based algorithms

Branching heuristics (aka DPLL algorithms) gave the first nontrivial upper bounds for k -SAT in the form $|F|^{O(1)} \cdot 2^{\alpha n}$ where α depends on k (Section 16.3). This approach was also used to obtain the first nontrivial upper bounds for SAT as functions of other parameters on input formulas: Monien and Speckenmeyer proved the $|F|^{O(1)} \cdot 2^{m/3}$ bound [MS80]; Kullmann and Luckhardt proved the $|F|^{O(1)} \cdot 2^{l/9}$ bound [KL97]. Both these bounds are improved by Hirsch in [Hir00]:

Theorem 16.4.3 ([Hir00]). *SAT can be solved in time*

1. $|F|^{O(1)} \cdot 2^{0.30897 m}$;
2. $|F|^{O(1)} \cdot 2^{0.10299 l}$.

To prove these bounds, two branching-based algorithms are built. They split the input formula F into either two formulas $F[x], F[\neg x]$ or four formulas $F[x, y], F[x, \neg y], F[\neg x, y], F[\neg x, \neg y]$. Then the following transformation rules are used (Section 16.1.2):

- *Elimination of unit clauses.*

- *Subsumption.*
- *Resolution with subsumption.*
- *Elimination of variables by resolution.* The rule is being applied as long as it does not increase m (resp., l).
- *Elimination of blocked clauses.* Given a formula F , a clause C , and a literal a in C , we say that C is *blocked* [Kul99] for a with respect to F if the literal $\neg a$ occurs only in those clauses of F that contain the negation of at least one of the literals occurring in $C \setminus \{a\}$. In other words, C is blocked for a if there are no resolvents by a of the clause C and any other clause in F . Given F and a , we define the assignment $I(a, F)$ to be consisting of the literal a plus all other literals b of F such that
 - b is different from a and $\neg a$;
 - the clause $\{ \neg a, b \}$ is blocked for $\neg a$ with respect to F .
 The following two facts about blocked clauses are proved by Kullmann in [Kul99]:
 - If C is blocked for a with respect to F , then F and $F \setminus \{C\}$ are equisatisfiable.
 - For any literal a , the formula F is satisfiable iff at least one of the formulas $F[\neg a]$ and $F[I(a, F)]$ is satisfiable.
 The rule is based on the first statement: if C is blocked for a with respect to F , replace F by $F \setminus \{C\}$.
- *Black and white literals.* This rule [Hir00] generalizes the obvious fact that if all clauses in F contain the same literal then F is satisfiable. Let P be a binary relation between literals and formulas such that for a variable v and a formula F , at most one of $P(v, F)$ and $P(\neg v, F)$ holds. Suppose that each clause in F that contains a “white” literal w satisfying $P(w, F)$ also contains a “black” literal b satisfying $P(\neg b, F)$. Then, for any literal a such that $P(\neg a, F)$, the formula F can be replaced by $F[a]$.

Remark. The second bound is improved to $2^{0.0926l}$ using another branching-based algorithm [Wah05].

Formulas with constant clause density. Satisfiability of formulas with constant clause density ($m/n \leq \text{const}$) can be solved in time $O(2^{\alpha n})$ where $\alpha < 1$ and α depends on the clause density [AS03, Wah05]. This fact also follows from Theorem 16.4.3 for $m \leq n$ and from Corollary 16.4.2 for $m > n$. The latter also shows how α grows as m/n increases:

$$\alpha = 1 - \frac{1}{O(\log(m/n))}.$$

16.5. How large is the exponent?

Given a number of $2^{\alpha n}$ -time algorithms for various variants of SAT, it is natural to ask how the exponents αn are related to each other (and how they are related to exponents for other combinatorial problems of similar complexity). Another natural question is whether α can be made arbitrarily small.

Recall that a language in **NP** can be identified with a polynomially balanced relation $R(x, y)$ that checks that y is indeed a solution to the instance x . (We

refer the reader to [Pap94] or some other handbook for complexity theory notions such as polynomially balanced relation or oracle computation.)

Definition 16.5.1. *Parameterized NP problem* (L, q) consists of a language $L \in \mathbf{NP}$ (defined by a polynomially-time computable and polynomially balanced relation R such that $x \in L \iff \exists y R(x, y)$) and a complexity parameter q , which is a polynomial-time computable⁴ integer function that bounds the size of the shortest solution to R : $x \in L \iff \exists y (|y| \leq q(x) \wedge R(x, y))$.

For $L = \text{SAT}$ or $k\text{-SAT}$, natural complexity parameters studied in the literature are the number n of variables, the number m of clauses, and the total number l of literal occurrences. We will be interested whether these problems can be solved in time bounded by a *subexponential* function of the parameter according to the following definition.

Definition 16.5.2 ([IPZ01]). A parameterized problem $(L, q) \in \mathbf{SE}$ if for every positive integer k there is a deterministic Turing machine deciding the membership problem $x \in L$ in time $|x|^{O(1)} \cdot 2^{q(x)/k}$.

Our ultimate goal is then to figure out which versions of the satisfiability problem belong to \mathbf{SE} . An *Exponential Time Hypothesis (ETH)* for a problem (L, q) says that $(L, q) \notin \mathbf{SE}$. A natural conjecture saying that the search space for $k\text{-SAT}$ must be necessarily exponential in the number of variables is $(3\text{-SAT}, n) \notin \mathbf{SE}$.

It turns out, however, that the only thing we can hope for is a kind of completeness result relating the complexity of SAT to the complexity of other combinatorial problems. The completeness result needs the notion of a reduction. However, usual polynomial-time reductions are not tight enough for this. Even linear-time reductions are not always sufficient. Moreover, it is by far not straightforward even that ETH for $(k\text{-SAT}, n)$ is equivalent to ETH for $(k\text{-SAT}, m)$, see Section 16.5.1 for a detailed treatment of these questions.

Even if one assumes ETH for 3-SAT to be true, it is not clear how the exponents for different versions of $k\text{-SAT}$ are related to each other, see Section 16.5.2.

16.5.1. SERF-completeness

The first attempt to investigate systematically ETH for $k\text{-SAT}$ has been made by Impagliazzo, Paturi, and Zane [IPZ01] who introduced reductions that preserve the fact that the complexity of the parameterized problem is subexponential.

Definition 16.5.3 ([IPZ01]). A series $\{T_k\}_{k \in \mathbb{N}}$ of oracle Turing machines forms a *subexponential reduction family (SERF)* reducing parameterized problem (A, p) to problem (B, q) if T_k^B solves the problem $F \in A$ in time $|F|^{O(1)} \cdot 2^{p(F)/k}$ and queries its oracle for instances $I \in B$ with $q(I) = O(p(F))$ and $|I| = |F|^{O(1)}$. (The constants in $O(\cdot)$ do not depend on k .)

⁴Note that the definition is different from the one being used in the parameterized complexity theory (Chapter 17).

It is easy to see that SERF reductions are transitive and preserve subexponential time. In particular, once a SERF-complete problem for a class of parameterized problems is established, the existence of subexponential-time algorithms for the complete problem is equivalent to the existence of subexponential time algorithms for every problem in the class. It turns out that the class **SNP** defined by Kolaitis and Vardi [KV87] (cf. [PY91]) indeed has SERF-complete problems.

Definition 16.5.4 (parameterized version of **SNP** from [IPZ01]). A parameterized problem $(L, q) \in \mathbf{SNP}$ if L can be defined by a series of second-order existential quantifiers followed by a series of first-order universal quantifiers followed by a quantifier-free first-order formula in the language of the quantified variables and the quantified relations f_1, \dots, f_s and input relations h_1, \dots, h_u (given by tables of their values on a specific universum of size n):

$$(h_1, \dots, h_u) \in L \iff \exists f_1, \dots, f_s \forall p_1, \dots, p_t \Phi(p_1, \dots, p_t),$$

where Φ uses f_i 's and h_i 's. The parameter q is defined as the number of bits needed to describe all relations f_i 's, i.e., $\sum_i n^{\alpha_i}$, where α_i is the arity of f_i .

Theorem 16.5.1 ([IPZ01]). $(3\text{-SAT}, m)$ and $(3\text{-SAT}, n)$ are SERF-complete for **SNP**.

SERF-completeness of SAT with the parameter n follows straightforwardly from the definitions (actually, the reduction queries only k -SAT instances with k depending on the problem to reduce). In order to reduce $(k\text{-SAT}, n)$ to $(k\text{-SAT}, m)$, one needs a *sparsification procedure* which is interesting in its own right. Then the final reduction of $(k\text{-SAT}, m)$ to $(3\text{-SAT}, m)$ is straightforward.

Algorithm 16.5.5 (The sparsification procedure [CIP06]).

Input: k -CNF formula F .

Output: sequence of k -CNF formulas that contains a satisfiable formula if and only if F is satisfiable.

Parameters: integers θ_i for $i \geq 0$.

1. For $c = 1, \dots, n$, for $h = c, \dots, 1$, search F for $t \geq \theta_{c-h}$ clauses $C_1, C_2, \dots, C_t \in F$ of length c such that $|\bigcap_{i=1}^t C_i| = h$. Stop after the first such set of clauses is found and let $H = \bigcap_{i=1}^t C_i$. If nothing is found, output F and exit.
2. Make a recursive call for $F \setminus \{C_1, \dots, C_t\} \cup \{H\}$.
3. Make a recursive call for $F[\neg H]$.

Calabro, Impagliazzo, and Paturi [CIP06] show that, given k and sufficiently small ε , for

$$\theta_i = O\left(\left(\frac{k^2}{\varepsilon} \log \frac{k}{\varepsilon}\right)^{i+1}\right)$$

this algorithm outputs at most $2^{\varepsilon n}$ formulas such that

- for every generated formula, every variable occurs in it at most $(k/\varepsilon)^{3k}$ times;

- F is satisfiable if and only if at least one of the generated formulas is satisfiable.

Since the number of clauses in the generated formulas is bounded by a linear function of the number of variables in F , Algorithm 16.5.5 defines a SERF reduction from $(k\text{-SAT}, n)$ to $(k\text{-SAT}, m)$.

16.5.2. Relations between the exponents

The fact of SERF-completeness, though an important advance in theory, does not give per se the exact relation between the exponents for different versions of $k\text{-SAT}$ if one assumes ETH for these problems. Let us denote the exponents for the most studied versions of $k\text{-SAT}$ (here $\mathbf{RTime}[t(n)]$ denotes the class of problems solvable in time $O(t(n))$ by a randomized one-sided bounded error algorithm):

$$\begin{aligned}
 s_k &= \inf\{\delta \geq 0 \mid k\text{-SAT} \in \mathbf{RTime}[2^{\delta n}]\}, \\
 s_k^{\text{freq.}f} &= \inf\{\delta \geq 0 \mid k\text{-SAT-}f \in \mathbf{RTime}[2^{\delta n}]\}, \\
 s_k^{\text{dens.}d} &= \inf\{\delta \geq 0 \mid k\text{-SAT with at most } dn \text{ clauses} \in \mathbf{RTime}[2^{\delta n}]\}, \\
 s_k^{\text{freq.}f} &= \inf\{\delta \geq 0 \mid \text{SAT-}f \in \mathbf{RTime}[2^{\delta n}]\}, \\
 s_k^{\text{dens.}d} &= \inf\{\delta \geq 0 \mid \text{SAT with at most } dn \text{ clauses} \in \mathbf{RTime}[2^{\delta n}]\}, \\
 \sigma_k &= \inf\{\delta \geq 0 \mid \text{Unique } k\text{-SAT} \in \mathbf{RTime}[2^{\delta n}]\}, \\
 s_\infty &= \lim_{k \rightarrow \infty} s_k, \\
 s^{\text{freq.}\infty} &= \lim_{f \rightarrow \infty} s^{\text{freq.}f}, \\
 s^{\text{dens.}\infty} &= \lim_{d \rightarrow \infty} s^{\text{dens.}d}, \\
 \sigma_\infty &= \lim_{k \rightarrow \infty} \sigma_k.
 \end{aligned}$$

In the remaining part of this section we survey the dependencies between these numbers. Note that we are interested here in randomized (as opposed to deterministic) algorithms, because some of our reductions are randomized.

$k\text{-SAT}$ vs Unique $k\text{-SAT}$

Valiant and Vazirani [VV86] presented a randomized polynomial-time reduction of SAT to its instances having at most one satisfying assignment (Unique SAT). The reduction, however, neither preserves the maximum length of a clause nor is capable to preserve subexponential complexity.

As a partial progress in the above problem, it is shown in [CIKP03] that $s_\infty = \sigma_\infty$.

Lemma 16.5.2 ([CIKP03]). $\forall k \forall \varepsilon \in (0, \frac{1}{4}) s_k \leq \sigma_{k'} + O(H(\varepsilon))$, where $k' = \max\{k, \frac{1}{\varepsilon} \ln \frac{2}{\varepsilon}\}$.

Proposition 16.5.3 ([CIKP03]). $s_k \leq \sigma_k + O(\frac{\ln^2 k}{k})$. Thus $s_\infty = \sigma_\infty$.

In order to prove Lemma 16.5.2 [CIKP03] employs an *isolation procedure*, which is a replacement for the result of [VV86]. The procedure starts with *concentrating* the satisfying assignments of the input formula in a Hamming ball of small radius εn . This is done by adding a bunch of “size k' ” random hyperplanes $\bigoplus_{i \in R} a_i x_i = b$ (encoded in CNF by listing the $2^{k'-1}$ k' -clauses that are implied by this equality), where the subset R of size k' and bits a_i, b are chosen at random, to the formula. For $k' = \max\{k, \frac{1}{\varepsilon} \ln \frac{2}{\varepsilon}\}$ and a linear number of hyperplanes, this yields a “concentrated” k' -CNF formula with substantial probability of success.

Once the assignments are concentrated, it remains to isolate a random one. To do that, the procedure guesses a random set of variables in order to approximate (from the above) the set of variables having different values in different satisfying assignments. Then the procedure guesses a correct assignment for the chosen set. Both things are relatively easy to guess, because the set is small.

k -SAT for different values of k

Is the sequence s_3, s_4, \dots of the k -SAT complexities an increasing sequence (as one may expect from the definition)? Impagliazzo and Paturi prove in [IP01] that the sequence s_k is strictly increasing infinitely often. More exactly, if there exists $k_0 \geq 3$ such that ETH is true for k_0 -SAT, then for every k there is $k' > k$ such that $s_k < s_{k'}$. This result follows from the theorem below, which can be proved using both critical clauses and sparsification techniques.

Theorem 16.5.4 ([IP01]). $s_k \leq (1 - \Omega(k^{-1}))s_\infty$.

Note that [IP01] gives an explicit constant in $\Omega(k^{-1})$.

k -SAT vs SAT- f

The sparsification procedure gives immediately

$$s_k \leq s_k^{\text{freq.}((k/\varepsilon)^{3k})} + \varepsilon \leq s_k^{\text{dens.}((k/\varepsilon)^{3k})} + \varepsilon.$$

In particular, for $\varepsilon = k^{-O(1)}$ this means that k -SAT could be only slightly harder than (k) -SAT of exponential density, and $s_\infty \leq s^{\text{freq.}\infty} \leq s^{\text{dens.}\infty}$.

The opposite inequality is shown using the clause-shortening algorithm: substituting an $O(2^{s_k + \varepsilon n})$ -time k -SAT algorithm and $m \leq dn$ into Theorem 16.4.1 we get (after taking the limit as $\varepsilon \rightarrow 0$)

$$s_k^{\text{dens.}d} \leq s_k + \frac{4d}{2^{ks_k}}. \quad (16.1)$$

Choosing k as a function of d so that the last summand is smaller than the difference between s_k and s_∞ , [CIP06] shows that taking (16.1) to the limit gives $s^{\text{dens.}\infty} \leq s_\infty$, i.e.,

$$s_\infty = s^{\text{freq.}\infty} = s^{\text{dens.}\infty}.$$

16.6. Summary table

The table below summarizes the currently best upper bounds for 3-SAT, k -SAT for $k > 3$, and SAT with no restriction on clause length (the bounds are given up

to polynomial factors). Other “record” bounds are mentioned in previous sections, for example bounds for Unique k -SAT (Section 16.3.4), bounds as functions in m or l (Section 16.4.2), etc.

	randomized algorithms	deterministic algorithms
3-SAT	1.323^n [Rol06]	1.473^n [BK04]
k -SAT	$2^{n(1 - \frac{\mu k}{k-1} + o(1))}$ [PPSZ98]	$(2 - 2/(k+1))^n$ [DGH ⁺ 02]
SAT	$2^{n(1 - \frac{1}{\sigma(\log(m/n))})}$ [CIP06] ⁵	$2^{n(1 - \frac{1}{\sigma(\log(m/n))})}$ [CIP06] ⁵

16.7. Addendum for the 2nd Edition: Connections to Circuit Complexity

To prove an upper bound for a computational problem Π , it suffices to design a *single* algorithm that solves Π using resources (like time or space) that do not exceed this bound. To prove a lower bound for Π , one needs to show that *every* algorithm for solving Π requires a certain amount of resources. Ryan Williams showed in [Wil10, Wil11] that there is a nontrivial connection between these somewhat opposing tasks: a slight improvement over exhaustive search for Boolean satisfiability implies a nontrivial lower bound for circuit complexity.

In circuit complexity, the basic model of computation is a family $\{C_n\}_{n \in \mathbb{N}}$ where C_n is a circuit with n input bits. Such a family *decides* a language $L \subseteq \{0, 1\}^*$ if for every n -bit string x , the circuit C_n outputs 1 on x if and only if $x \in L$. Since there may be no single algorithm producing every circuit C_n , complexity classes defined in terms of circuits are commonly referred to as “non-uniform” classes in contrast to “uniform” complexity classes, like \mathbf{P} or \mathbf{NP} , defined in terms of algorithms.

The most natural example of a non-uniform class is $\mathbf{P/poly}$ that consists of all languages decidable by families $\{C_n\}_{n \in \mathbb{N}}$ where the size of C_n is polynomial in n . It is clear that each polynomial-time algorithm can be simulated using a family of polynomial-size circuits and, therefore, \mathbf{P} is a subset of $\mathbf{P/poly}$. What about nondeterministic polynomial-time algorithms, can they be simulated by non-uniform families of polynomial-size circuits? It is commonly believed that $\mathbf{NP} \not\subseteq \mathbf{P/poly}$ but the current state of complexity theory is far from proving this (such a proof would imply $\mathbf{P} \neq \mathbf{NP}$). Moreover, it is open whether much larger classes such as \mathbf{NEXP} or $\mathbf{E}^{\mathbf{NP}}$ are contained in $\mathbf{P/poly}$; the current best lower bound is $\mathbf{MAEXP} \not\subseteq \mathbf{P/poly}$ [BFT98].

A possible approach to proving lower bounds for non-uniform computations would be to restrict types of circuits. For example, \mathbf{ACC} denotes the class of languages decidable by constant-depth polynomial-size circuits with the following gates: NOT gates, AND gates and OR gates of unbounded fan-in, MOD- m gates of unbounded fan-in (such a gate outputs 0 if the number of ones in the input is divisible by m and outputs 1 otherwise). The question of strong lower bounds for \mathbf{ACC} was open until 2011 when Williams proved the bound $\mathbf{NEXP} \not\subseteq \mathbf{ACC}$

⁵This bound can be derived from Lemma 5 in [CIP06], see Corollary 16.4.2 above.

building on connections between upper bounds and lower bounds [Wil10, Wil11]. These exciting results can be summarized as follows.

Let \mathcal{C} be a class of circuits. For example, \mathcal{C} can consist of all polynomial-size circuits over AND, OR, NOT, or \mathcal{C} can be a class of circuits used in the definition of **ACC** above. Let \mathcal{C} -SAT denote the satisfiability problem for circuits of \mathcal{C} : given a circuit $C \in \mathcal{C}$, determine whether there is an input on which C outputs 1.

Theorem 16.7.1 ([Wil10, Wil11]). *Suppose there is a $c > 0$ such that \mathcal{C} -SAT can be solved on circuits with n inputs and n^k size in $O(2^n/n^c)$ time for every k . Then **NEXP** contains a language that cannot be decided by a family of polynomial-size circuits from the class \mathcal{C} .*

This theorem is proved by contradiction, assuming that \mathcal{C} -SAT can be solved by a $O(2^n/n^c)$ algorithm and **NEXP** has polynomial-size circuits from \mathcal{C} . These two assumptions together imply an algorithm that is “too good to exist”: this algorithm could be used to simulate every nondeterministic algorithm running in $O(2^n)$ time by a nondeterministic algorithm running in $o(2^n)$ time, which contradicts the nondeterministic hierarchy theorem [SFM78].

Theorem 16.7.2 ([Wil11]). *Let \mathcal{C} be the class of circuits with NOT gates and unbounded fan-in AND, OR, MOD- m gates (such circuits are used in the definition of the class **ACC**). For every integer $d > 0$, there is an $\epsilon \in (0, 1)$ and there is an algorithm that solves \mathcal{C} -SAT on circuits with n inputs of depth d and size at most 2^{n^ϵ} in 2^{n-n^ϵ} time.*

The proof of this theorem relies on simulating **ACC** circuits by low degree polynomials [Yao90, BT91].

Proposition 16.7.3 ([Wil11]). **NEXP** $\not\subseteq$ **ACC**.

There is also a bunch of results relating modest upper bounds for satisfiability to modest lower bounds for non-uniform classes. Here are two examples of such results.

Theorem 16.7.4 ([Wil10], Theorem 6.1). *If the Exponential Time Hypothesis is false, then **E^{NP}** does not have linear size circuits.*

Theorem 16.7.5 ([JMV18], Corollary 7). *If 3-SAT is in time c^n for any $c < 2^{1/7} = 1.10\dots$, then there exists a (non-Boolean) function $f: \{0, 1\}^n \rightarrow \{0, 1\}^2$ in **E^{NP}** such that any circuit over the full basis computing it requires at least $3n$ (non-input) gates.*

Chapter 17

Fixed-Parameter Tractability

Marko Samer[†] and Stefan Szeider

17.1. Introduction

The propositional satisfiability problem (SAT) is famous for being the first problem shown to be NP-complete—we cannot expect to find a polynomial-time algorithm for SAT. However, over the last two decades, SAT-solvers have become amazingly successful in solving formulas with thousands of variables that encode problems arising from various application areas. Theoretical performance guarantees, however, are far from explaining this empirically observed efficiency. Theorists believe that the trivial 2^n time bound for solving SAT instances with n variables cannot be significantly improved, say to $2^{o(n)}$ (see the end of Section 17.2.1). This enormous discrepancy between theoretical performance guarantees and the empirically observed performance of SAT solvers can be explained by the presence of a certain “hidden structure” in instances that come from applications. This hidden structure greatly facilitates the propagation and simplification mechanisms of SAT solvers. Thus, for deriving theoretical performance guarantees that are closer to the actual performance of solvers, one needs to take this hidden structure of instances into account. The literature contains several suggestions for making the vague term of a hidden structure explicit. For example, the hidden structure can be considered as the “tree-likeness” or “Horn-likeness” of the instance (below we will discuss how these notions can be made precise). All such concepts have in common that one associates with a CNF formula F a non-negative integer $k = \pi(F)$; the smaller the integer, the more structured the instance from a certain perspective. We call such a mapping π a *satisfiability parameter* or a *parameterization* of the satisfiability problem. We will also write $\pi(F) = \infty$ to express that ϕ is not defined for F . Consider a satisfiability parameter π . For each integer k one can consider the class \mathcal{C}_k^π of formulas F such that $\pi(F) \leq k$. This gives rise to an infinite hierarchy $\mathcal{C}_0^\pi \subseteq \mathcal{C}_1^\pi \subseteq \mathcal{C}_2^\pi \subseteq \dots \subseteq \mathcal{C}_\infty^\pi$ of classes. Every CNF formula F belongs to some \mathcal{C}_k^π for k sufficiently large (namely, $k = \pi(F)$).

We are interested in satisfiability parameters π such that satisfiability of instances in \mathcal{C}_k^π and membership in \mathcal{C}_k^π can be decided in polynomial time (the latter property can be relaxed). The larger we make k (thus, the more general the

[†]1977–2010

class \mathcal{C}_k^π), the worse we expect the performance guarantee for the polynomial-time algorithm for solving instances in \mathcal{C}_k^π —in other words, we expect an inevitable *tradeoff between generality and performance*.

Assume our SAT algorithm for \mathcal{C}_k^π runs in time $\mathcal{O}(n^k)$ on instances with n variables, then we have an example for a non-uniform polynomial-time algorithm, since the degree of the polynomial depends on k . On the other hand, a running time such as $\mathcal{O}(2^k n^3)$ establishes uniform polynomial time. For a non-uniform polynomial-time algorithm even relatively small values for k render classes \mathcal{C}_k^π practically infeasible—take the above example of time complexity $\mathcal{O}(n^k)$ and consider an instance $F \in \mathcal{C}_{10}^\pi$ with $n = 1000$ variables. On the other hand, a uniform polynomial-time algorithm with running time such as $\mathcal{O}(2^k n^3)$ makes the satisfiability problem practically feasible for classes \mathcal{C}_k^π as long as k remains small.

It is an intriguing research objective to design and study satisfiability parameters and to find out whether they admit uniform polynomial-time algorithms or not. Classical complexity theory does not provide the means and tools for this purpose, as the computational complexity of a problem is considered exclusively in terms of the *input size*; structural properties of instances are not represented. In the late 1980s, Rod Downey and Mike Fellows initiated the framework of *Parameterized Complexity* which resolves this shortcoming of classical theory. Their point of departure was the following observation: uniform polynomial-time algorithms exist for finding a vertex cover of size k in a graph, but apparently, no uniform polynomial-time algorithm exists for finding an independent set of size k (in both cases k is considered as the parameter). Downey, Fellows, and their collaborators have developed a rich theoretical framework for studying the computational complexity of parameterized problems. Over recent years, parameterized complexity has become an essential branch of algorithm design and analysis in both applied and theoretical areas of computer science; hundreds of research papers and several monographs have been published so far on the subject [DF99, FG06, Nie06, CFK⁺13, DF13]. Parameterized complexity considers problem instances in a *two-dimensional* setting: the first dimension is the usual input size n , the second dimension is a non-negative integer k , the *parameter*. An algorithm that solves an instance in time $\mathcal{O}(f(k)n^c)$ is called a *fixed-parameter algorithm*; here f denotes an arbitrary computable function and c denotes a constant that is independent of n and k . Thus fixed-parameter algorithms are algorithms with a uniform polynomial-time complexity as considered in the above discussion. A parameterized problem is *fixed-parameter tractable* if a fixed-parameter algorithm can solve it. Once a problem has been found to be fixed-parameter tractable, one can try to find better and better algorithms, making the function f to grow slower, and obtaining a smaller constant c . In many cases, one can observe a trajectory of steadily improved running times for parameterized problems [Fel03]. Therefore we will mainly focus on the classification of satisfiability parameters on whether or not they admit fixed-parameter tractable satisfiability decision, and not on concrete running times.

Parameterized complexity also offers a *completeness theory* which is similar to the theory of NP-completeness in the classical setting. This completeness theory provides strong evidence that certain parameterized problems (such as the parameterized independent set problem as mentioned above) are *not* fixed-parameter

tractable. We will briefly discuss some fundamental notions of this completeness theory in Section 17.2.1. In this survey, however, we will mainly focus on positive results, describing key concepts that lead to satisfiability parameters that admit fixed-parameter algorithms. The presented negative results (i.e., hardness results) have merely the purpose of carving out territories that are very likely to be inaccessible to fixed-parameter algorithms.

The majority of combinatorial problems studied in the framework of parameterized complexity offers a “natural parameter,” e.g., it is natural to parameterize the vertex cover problem by the size of the vertex cover. However, the satisfiability problem lacks a single obvious natural parameter—there are numerous possibilities for parameters. This variety, however, makes parameterized SAT a rich and exciting research area; one of its fundamental objectives is to identify satisfiability parameters that are as general as possible (i.e., for as many instances as possible one can expect that the parameter is small), and which are still accessible to fixed-parameter algorithms.

Although our main focus is satisfiability decision, we will come across several satisfiability parameters that even render the propositional model counting problem $\#\text{SAT}$ to be fixed-parameter tractable.

Next, in Section 17.2, we will provide some preliminaries: we will introduce basic notions of parameterized complexity, our terminology on CNF formulas and truth assignments, and graphs and hypergraphs associated with CNF formulas. In Section 17.3 we will introduce a general framework for parameterizing the satisfiability problem in terms satisfiability parameters, and will discuss parameterized optimization problems related to SAT. The next three sections are devoted to satisfiability parameters of different flavors: in Section 17.4 we will consider parameters based on backdoor sets relative to a polynomial-time base class; in Section 17.5 we will consider parameters that measure the “tree-likeness” of instances; in Section 17.6 we will consider further parameters including one that is based on graph matchings and one that is based on the community structure of formulas. We will conclude with final remarks in Section 17.7.

17.2. Preliminaries

17.2.1. Fixed-Parameter Algorithms

In this section, we provide a brief (and rather informal) review of some fundamental concepts of parameterized complexity. For an in-depth treatment of the subject, we refer the reader to other sources [DF99, FG06, Nie06, CFK⁺13, DF13].

An instance of a parameterized problem is a pair (I, k) where I is the *main part* and k is the *parameter*; the latter is usually a non-negative integer. A parameterized problem is *fixed-parameter tractable* if a fixed-parameter algorithm can solve it, i.e., if instances (I, k) can be solved in time $\mathcal{O}(f(k)\|I\|^c)$ where f is a computable function, c is a constant, and $\|I\|$ denotes the size of I with respect to some reasonable encoding. FPT denotes the class of all fixed-parameter tractable decision problems.

Let us illustrate the idea of a fixed-parameter algorithm through the *vertex cover* problem parameterized by the solution size. This is the best-studied prob-

lem in parameterized complexity with a long history of improvements [CKJ01]. Let us state the parameterized vertex cover problem:

VC

Instance: A graph $G = (V, E)$ and a non-negative integer k .

Parameter: k .

Task: Decide whether there is a subset $S \subseteq V$ of size at most k such that every edge of G has at least one of its incident vertices in S (S is a *vertex cover* of G).

Note that if we consider k not as a parameter but simply as a part of the input, then we get an NP-complete problem [GJ79]. A simple fixed-parameter algorithm for **VC** can be constructed as follows. Given an instance (G, k) of **VC**, we construct a binary search tree. The root of the tree is labeled with (G, k) . We choose an arbitrary edge uv of G and observe that every vertex cover of G must contain u or v . Hence we can branch into these two cases. That is, we add two children to the root, labeled with $(G - u, k - 1)$ and $(G - v, k - 1)$, respectively (k gets decremented as we have spent one unit for taking u or v into the vertex cover). We recursively extend this branching. We stop a branch of the tree if we reach a node labeled with (G', k') such that either $k' = 0$ (we have used up the budget k) or G' has no edges (we have found a vertex cover of size $k - k'$). Note that in the second case we can find the vertex cover of size $k - k'$ by collecting the vertices that have been removed from G along the path from the root to the leaf. It is easy to see the outlined algorithm is correct and decides **VC** in time $\mathcal{O}(2^k n)$ for graphs with n vertices. Using the \mathcal{O}^* -notation [Woe03] which suppresses polynomial factors, we can state the running time of the above algorithm by the expression $\mathcal{O}^*(2^k)$.

The above algorithm for **VC** illustrates the method of *bounded search trees* for the design of fixed-parameter algorithms. *Kernelization* is another essential technique, which shrinks the size of the given problem instance by employing (polynomial-time) data reduction rules until the size is bounded by a function of the parameter k . The reduced instance is called a *problem kernel*. Once a problem kernel is obtained for a decidable problem, we know that the problem is fixed-parameter tractable, since the running time of any brute force algorithm depends on the parameter k only. The converse is also true: whenever a parameterized problem is fixed-parameter tractable, then the problem admits a polynomial-time kernelization [CCDF97]. Consider the **VC** problem again as an example. It is easy to see that a vertex v of degree greater than k must belong to every vertex cover of size at most k ; hence if we have such a vertex v , we can reduce the instance (G, k) to $(G - v, k - 1)$. Assume that we are left with the instance (G', k') after we have applied the reduction rule as long as possible (if $k' < 0$, then we reject the instance). Observe that each vertex of G' can cover at most k edges. Hence, if G' has more than k^2 edges, we know that G has no vertex cover of size at most k . On the other hand, if G' has at most k^2 edges, we have a problem kernel that can be solved by brute force.

The current best worst-case time complexity for **VC** is due to Chen, Kanj, and Xia [CKX10]. The algorithm is based on more sophisticated kernelization rules and achieves a running time of $\mathcal{O}^*(1.2738^k)$. Further information on ker-

nelization can be found in Guo and Niedermeier's survey [GN07]. Gaspers and Szeider [GS14] gave several kernelization results that are specifically relevant for parameterized satisfiability.

Next, we turn our attention to fixed-parameter *intractability*, to problems that are believed to be not fixed-parameter tractable. Consider for example the following parameterized independent set problem.

IS

Instance: A graph $G = (VE)$ and a non-negative integer k .

Parameter: k .

Task: Decide whether there is a subset $S \subseteq V$ of size at least k such that no edge of G joins two vertices in S (S is an *independent set* of G).

No fixed-parameter algorithm for this problem is known, and there is strong evidence to believe that no such algorithm exists [DF99]. For example, fixed-parameter tractability of **IS** would imply the existence of an $\mathcal{O}^*(2^{o(n)})$ -time algorithm for the n -variable 3-SAT problem [FG06]. The assumption that the latter is not the case is known as the *Exponential Time Hypothesis (ETH)* [IPZ01]; see also Chapter 16 for more information on the ETH.

Thus, **VC** is fixed-parameter tractable, whereas **IS** is believed to be not. Note, however, that under classical polynomial-time many-to-one reductions, **VC** and **IS** are equivalent for trivial reasons: a graph with n vertices has a vertex cover of size k if and only if it has an independent set of size $k' = n - k$. Hence, to distinguish between fixed-parameter tractable and fixed-parameter intractable problems, one needs a notion of reduction that restricts the way of how parameters are mapped to each other. An *fpt-reduction* from a parameterized decision problem L to a parameterized decision problem L' is an algorithm that transforms an instance (I, k) of L into an instance $(I', g(k))$ of L' in time $\mathcal{O}(f(k) \|I\|^c)$ (f, g are arbitrary computable functions, c is an arbitrary constant), such that (I, k) is a yes-instance of L if and only if $(I', g(k))$ is a yes-instance of L' . It is easy to see that indeed, if L' is fixed-parameter tractable and there is an fpt-reduction from L to L' , then L is fixed-parameter tractable as well. Note that the reduction from **VC** to **IS** as sketched above is not an fpt-reduction since $k' = n - k$ and so k' is not a function of k alone.

The class of problems that can be reduced to **IS** under fpt-reductions is denoted by $W[1]$. A problem is called *W[1]-hard* if **IS** (and so every problem in $W[1]$) can be reduced to it by an fpt-reduction. A problem is called *W[1]-complete* if it is $W[1]$ -hard and belongs to $W[1]$. Thus, a problem is $W[1]$ -complete if and only if it is equivalent to **IS** under fpt-reductions. A similar terminology applies to other parameterized complexity classes.

Consider the following parameterized hitting set problem (it is the basis for several hardness results that we will consider in the remainder of this chapter).

HS

Instance: A family \mathcal{S} of finite sets S_1, \dots, S_m and a non-negative integer k .

Parameter: k .

Task: Decide if there is a subset $R \subseteq \bigcup_{i=1}^m S_i$ of size at most k such that $R \cap S_i \neq \emptyset$ for all $i = 1, \dots, m$ (R is a *hitting set* of \mathcal{S}).

Observe that, indeed, a search tree algorithm as outlined above for **VC** does not yield fixed-parameter tractability for **HS**: since the size of the sets S_i is unbounded, a search tree algorithm would entail an unbounded branching factor. If, however, the size of the sets S_i is bounded by some constant q , then the problem (known as q -**HS**) becomes fixed-parameter tractable. The obvious search tree algorithm has time complexity $\mathcal{O}^*(q^k)$. For $q = 3$, Wahlström [Wah17] developed a fixed-parameter algorithm with running time $\mathcal{O}^*(2.076^k)$.

HS is $W[1]$ -hard, but no fpt-reduction from **HS** to **IS** is known, and it is believed that such a reduction does not exist. In other words, **HS** appears to be harder than the problems in $W[1]$. The class of problems that can be reduced to **HS** under fpt-reductions is denoted by $W[2]$. In fact, $W[1]$ and $W[2]$ form the first two levels of an infinite chain of classes $W[1] \subseteq W[2] \subseteq W[3] \subseteq \dots \subseteq W[P]$, the so-called “weft hierarchy.” All inclusions are believed to be proper. There are several sources of theoretical evidence for assuming that the classes of the weft hierarchy are distinct from FPT: accumulating evidence [Ces06], evidence based on parameterized analogs of Cook’s Theorem [DF99], and evidence obtained by proof complexity methods [DMS11].

We say that a parameterized problem is *XP-tractable* if instances (I, k) can be solved in time $\mathcal{O}(\|I\|^{f(k)})$ for a computable function f . The class XP consists of all XP-tractable parameterized decision problems. $FPT \neq XP$ is provably true [DF99, FG06]. Together with the classes of the weft hierarchy, we have the following chain of inclusions:

$$FPT \subseteq W[1] \subseteq W[2] \subseteq \dots \subseteq W[P] \subseteq XP.$$

17.2.2. CNF Formulas and Truth Assignments

Before discussing parameterizations of SAT, let us introduce some notation and basic notions related to SAT. We consider propositional formulas in conjunctive normal form (CNF), short *CNF formulas* or just *formulas*, represented as a finite set of *clauses*. A clause is a finite set of *literals*, and a literal is a negated or un-negated propositional *variable*. For a literal ℓ we denote by $\bar{\ell}$ the literal of opposite polarity, i.e., $\bar{x} = \neg x$ and $\overline{\neg x} = x$. We also write $x^1 = x$ and $x^0 = \neg x$. Similarly, for a set L of literals, we put $\bar{L} = \{\bar{\ell} : \ell \in L\}$. We say that two clauses C, D *overlap* if $C \cap D \neq \emptyset$, and we say that C and D *clash* if C and \bar{D} overlap. For a clause C we denote by $\text{var}(C)$ the set of variables that occur (negated or un-negated) in C ; for a formula F we put $\text{var}(F) = \bigcup_{C \in F} \text{var}(C)$. We measure the *size* $\|F\|$ of a formula F by its *length* $\sum_{C \in F} |C|$.

CNF formulas F and F' are *isomorphic* if they differ only in the name of variables. That is, if $F = \{C_1, \dots, C_m\}$, $F' = \{C'_1, \dots, C'_m\}$, and there is a one-to-one mapping $f : \text{var}(F) \rightarrow \text{var}(F')$ such that $C'_i = \{(f(x))^\varepsilon : x^\varepsilon \in C_i, x \in \text{var}(F), \varepsilon \in \{0, 1\}\}$ holds for all $1 \leq i \leq m$.

CNF formulas F and F' are *renamings* of each other if there exists a set $X \subseteq \text{var}(F)$ such that F' can be obtained from F by flipping the polarity of all literals $\ell \in X \cup \bar{X}$. That is, if $F = \{C_1, \dots, C_m\}$, $F' = \{C'_1, \dots, C'_m\}$, and $C'_i = \{\ell : \ell \in C_i \setminus (X \cup \bar{X})\} \cup \{\bar{\ell} : \ell \in C_i \cap (X \cup \bar{X})\}$.

Figure 17.1. Graphs associated with the CNF formula $F = \{C_1, \dots, C_5\}$ with $C_1 = \{u, \neg v, \neg y\}$, $C_2 = \{\neg u, z\}$, $C_3 = \{v, \neg w\}$, $C_4 = \{w, \neg x\}$, $C_5 = \{x, y, \neg z\}$; the primal graph $G(F)$, the incidence graph $G^*(F)$, and the dual graph $G^d(F)$.

A *truth assignment* is a mapping $\tau : X \rightarrow \{0, 1\}$ defined on some set X of variables. If $X = \{x\}$ we denote τ simply by “ $x = 1$ ” or “ $x = 0$ ”. We extend τ to literals by setting $\tau(\neg x) = 1 - \tau(x)$ for $x \in X$. $F[\tau]$ denotes the formula obtained from F by removing all clauses that contain a literal ℓ with $\tau(\ell) = 1$ and by removing from the remaining clauses all literals ℓ' with $\tau(\ell') = 0$. $F[\tau]$ is the *restriction* of F to τ . Note that $\text{var}(F[\tau]) \cap X = \emptyset$ holds for every truth assignment $\tau : X \rightarrow \{0, 1\}$ and every formula F . A truth assignment $\tau : X \rightarrow \{0, 1\}$ *satisfies* a clause C if $\tau(\ell) = 1$ for at least one literal $\ell \in C$; τ satisfies a formula F if it satisfies all clauses of F . Note that τ satisfies F if and only if $F[\tau] = \emptyset$. A formula F is *satisfiable* if there exists a truth assignment that satisfies F ; otherwise, F is *unsatisfiable*. A truth assignment $\tau : \text{var}(F) \rightarrow \{0, 1\}$ is called *total* for the formula F . A satisfying total truth assignment of F is called a *model* of F . We denote the number of models of a formula F by $\#(F)$. Two formulas are *equisatisfiable* if either both are satisfiable or both are unsatisfiable. **SAT** is the problem of deciding whether a given formula is satisfiable. **\#SAT** is the problem of determining the number of models of a given formula.

Let $x \in \text{var}(F)$ and $\varepsilon \in \{0, 1\}$. If $\{x^\varepsilon\} \in F$, then F and $F[x = \varepsilon]$ are equisatisfiable; $F[x = \varepsilon]$ is said to be obtained from F by *unit propagation*. If some clause of F contains x^ε but none contains $x^{1-\varepsilon}$, then x^ε is called a *pure literal* of F . If x^ε is a pure literal of F , then obviously F and $F[x = \varepsilon]$ are equisatisfiable. In that case, we say that $F[x = \varepsilon]$ is obtained from F by *pure literal elimination*.

17.2.3. Graphs and Hypergraphs Associated with CNF Formulas

In this section, we will discuss several graphs and hypergraphs that can be used to represent the structure of a CNF formula.

Perhaps the most prominent graph representation of a CNF formula F is the *primal graph* $G(F)$. The vertices of $G(F)$ are the variables of F ; two variables x, y are joined by an edge if they occur in the same clause, that is, if $x, y \in \text{var}(C)$ for some $C \in F$. Another important graph is the *incidence graph* $G^*(F)$. The vertices of $G^*(F)$ are the variables and clauses of F ; a variable x and a clause C

Figure 17.2. The hypergraph $H(F)$ and the dual hypergraph $H^d(F)$ associated with the CNF formula F of Figure 17.1.

are joined by an edge if $x \in \text{var}(C)$. If we orient the edges of the incidence graph according to the polarity of the literals, then we obtain the *directed incidence graph* $D^*(F)$: an edge is directed from C to x if $x \in C$, and directed from x to C if $\neg x \in C$. In analogy to the primal graph, one can also define the *dual graph* $G^d(F)$. The vertices of $G^d(F)$ are the clauses of F ; two clauses C_1, C_2 are joined by an edge if there is a variable occurring in both of them, that is, if $x \in \text{var}(C_1) \cap \text{var}(C_2)$ for some $x \in \text{var}(F)$. We also consider the following two graphs, the *conflict graph* $G^{\ddagger}(F)$ and the *consensus graph* $G^{**}(F)$, both having as vertices the clauses of F , where in $G^{\ddagger}(F)$ two clauses C_1, C_2 are joined by an edge if they clash ($C_1 \cap C_2 \neq \emptyset$), and in $G^{**}(F)$ two clauses C_1, C_2 are joined by an edge if they do not clash ($C_1 \cap \overline{C_2} = \emptyset$).

Figure 17.1 shows the primal graph, the incidence graph, and the dual graph of a CNF formula.

Hypergraphs generalize graphs in the sense that each edge may connect more than just two vertices, i.e., the edges (called *hyperedges*) of a hypergraph are non-empty sets of vertices. We associate to each CNF formula F its *hypergraph* $H(F)$. The vertices of $H(F)$ are the variables of F and for each $C \in F$ the set $\text{var}(C)$ represents a hyperedge of $H(F)$. The *dual hypergraph* $H^d(F)$ is defined symmetrically: the vertices of $H^d(F)$ are the clauses of F ; for each variable x , the set of clauses C with $x \in \text{var}(C)$ forms a hyperedge. See Figure 17.2 for examples.

17.3. Parameterized SAT

In the first part of this section we will develop the framework for parameterized SAT decision and model counting, where the parameter represents structural information of the instances. This framework will be used throughout the remainder of this chapter. In the second part of this section we will discuss parameterized optimization problems that are related to satisfiability.

17.3.1. Satisfiability Parameters

A *satisfiability parameter* is a computable function π that assigns to every formula F a non-negative integer $\pi(F)$. We assume that $\pi(F) = \pi(F')$ if two formulas F, F' are isomorphic (see Section 17.2.2), i.e., π is invariant with respect to isomorphisms.

We are interested in satisfiability parameters that allow fixed-parameter tractability of satisfiability decision for instances F with respect to the parameter $k = \pi(F)$. Accordingly, for a satisfiability parameter π we consider the following generic parameterized problem.

SAT(π)

Instance: A formula F and a non-negative integer k .

Parameter: k .

Task: Decide whether F is satisfiable, or determine that $\pi(F) > k$.

This way of parameterizing the satisfiability problem was suggested by Szeider [Sze04b]. It avoids the requirement of exactly recognizing formulas F with $\pi(F) \leq k$ and is related to the concept of a “robust algorithm” introduced by Spinrad [Spi03]. Marx and Schlotter [MS10, MS11] used the predicate “*permissive*” to describe parameterized problems of this form, in contrast to “*strict*” problems, which entail the exact determination of the parameter value. We can, as well, formulate model counting as a permissive problem:

#SAT(π)

Instance: A formula F and a non-negative integer k .

Parameter: k .

Task: Compute $\#(F)$ or determine that $\pi(F) > k$.

If we solve a parameterized satisfiability problem in the strict sense, we have to solve the parameterized *verification problem*:

VER(π)

Instance: A formula F and a non-negative integer k .

Parameter: k .

Task: Decide whether $\pi(F) \leq k$.

We assume that an affirmative solution to the verification problem is backed up with a certain *witness* for “ $\pi(F) \leq k$ ” in form of an auxiliary structure, which can subsequently be used for deciding the satisfiability of F or counting the models of F .

In some cases, **VER**(π) is W[1]-hard or just not known to be fixed-parameter tractable, but we can still use π for fixed-parameter tractability of **SAT**(π) or **#SAT**(π) if **VER**(π) is *fixed-parameter approximable*. That is, if there is a computable function g and a fixed-parameter algorithm that, given F and k , either outputs a witness for $\pi(F) \leq g(k)$, or correctly decides that $\pi(F) > k$. We can use the witness for $\pi(F) \leq g(k)$ as an input for a parameterized algorithm that decides the satisfiability of F or computes $\#(F)$, albeit the running time is worse than if we had a witness for $\pi(F) \leq k$.

Usually it is very difficult to establish parameterized hardness results for the permissive problems **SAT**(π) and **#SAT**(π), or to provide theoretical evidence

that $\mathbf{VER}(\pi)$ is not fixed-parameter approximable. We have only very few examples for such hardness results (see, e.g., Theorems 17.4.5, 17.4.8, and 17.4.5). Although a parameterized hardness result for $\mathbf{VER}(\pi)$ does not rule out the fixed-parameter tractability of $\mathbf{SAT}(\pi)$, it still provides the valuable insight that the fixed-parameter tractability of $\mathbf{SAT}(\pi)$ in the strict sense is unlikely.

The notion of *dominance* allows us to compare two satisfiability parameters π and π' with respect to their generality. We say that π *dominates* π' if there exists a computable function f such that for every formula F we have

$$\pi(F) \leq f(\pi'(F)).$$

Furthermore, π *strictly dominates* π' if π dominates π' but not vice versa. Finally, π and π' are *domination incomparable* if neither dominates the other, and *domination equivalent* if they dominate each other. If π strictly dominates π' we also say that π is *more general* than π' . Dominance, strict dominance, and domination equivalence are transitive relations between satisfiability parameters. Furthermore, since strict dominance is antisymmetric, it gives rise to a partial ordering of satisfiability parameters. The next result follows directly from the definitions.

Lemma 17.3.1. *If π dominates π' , then there is an fpt-reduction from $\mathbf{SAT}(\pi')$ to $\mathbf{SAT}(\pi)$.*

Thus, if $\mathbf{SAT}(\pi)$ is fixed-parameter tractable and π dominates π' , then $\mathbf{SAT}(\pi')$ is also fixed-parameter tractable. It is an important goal to find satisfiability parameters π that are as general as possible and for which both problems $\mathbf{SAT}(\pi)$ and $\mathbf{VER}(\pi)$ are fixed-parameter tractable. We conclude this section with three trivial examples of satisfiability parameters.

Example 17.3.1. Let $\mathbf{n}(F)$ denote the number of variables of a formula F . The verification problem $\mathbf{VER}(\mathbf{n})$ is trivial. The obvious algorithm that considers all possible truth assignments of F runs in time $\mathcal{O}^*(2^{\mathbf{n}(F)})$ and is, therefore, a fixed-parameter algorithm with respect to \mathbf{n} . Hence $\mathbf{SAT}(\mathbf{n})$ is fixed-parameter tractable. \square

A satisfiability parameter π becomes an interesting one if every class \mathcal{C}_k^π contains formulas with an arbitrarily large number of variables; i.e., if π is more general than the satisfiability parameter \mathbf{n} considered in the example above.

Example 17.3.2. Let $\mathbf{ml}(F)$ denote the *maximum length* of clauses in a SAT instance F (with $\mathbf{ml}(F) = 0$ if $F = \emptyset$). From the NP-completeness of 3SAT it follows that $\mathbf{SAT}(\mathbf{ml})$ is not fixed-parameter tractable unless $\mathbf{P} = \mathbf{NP}$. So $\mathbf{SAT}(\mathbf{ml})$ is probably not even in XP. \square

Example 17.3.3. Let \mathcal{A} be a deterministic polynomial-time algorithm that applies polynomial-time simplification and propagation rules to a formula without changing its satisfiability. Say, the algorithm applies *unit propagation* and *pure literal elimination* as long as possible (see Section 17.2.2 above), plus possibly some further rules. For more powerful preprocessing rules see, e.g., the work of Bacchus and Winter [BW04]. Let $\mathcal{A}(I)$ denote the instance obtained from I by

applying algorithm \mathcal{A} , and let $\mathbf{n}_{\mathcal{A}}(I)$ denote the number of variables of $\mathcal{A}(I)$ (if $\mathcal{A}(I)$ depends on a particular ordering of variables and clauses, let $\mathbf{n}_{\mathcal{A}}(I)$ denote the largest number over all such orderings).

It is easy to see that the problem $\mathbf{SAT}(\mathbf{n}_{\mathcal{A}})$ is fixed-parameter tractable since after the polynomial-time preprocessing we are left with an instance $\mathcal{A}(I)$ whose number of variables is bounded in terms of the parameter k , and therefore any brute-force algorithm applied to $\mathcal{A}(I)$ is a fixed-parameter algorithm. In other words, $\mathbf{SAT}(\mathbf{n}_{\mathcal{A}})$ is fixed-parameter tractable since the preprocessing provides a kernelization. $\mathbf{VER}(\mathbf{n}_{\mathcal{A}})$ is easy, as we just need to count the number of variables left after applying the polynomial-time preprocessing algorithm \mathcal{A} . Clearly $\mathbf{n}_{\mathcal{A}}$ is more general than \mathbf{n} (Example 17.3.1) since one can easily find formulas where, say, unit propagation eliminates an arbitrarily large number of variables. \square

17.3.2. Optimization Problems

Max-SAT is the optimization version of the satisfiability problem, where, given a CNF formula F and an integer k , one asks whether there is a truth assignment that satisfies at least k clauses of F . In the classical setting, Max-SAT is NP-complete even if all clauses contain at most two literals (Max-2-SAT). What happens if we consider k as the parameter?

Under this parameterization, Max-SAT is easily seen to be fixed-parameter tractable (we roughly follow [MR99]). Let (F, k) be an instance of Max-SAT. For a truth assignment τ we write $s(\tau)$ for the number of clauses of F that are satisfied by τ . Moreover, let τ^* denote the extension of τ that includes all variable assignments obtained by (iterated and exhaustive) application of pure literal elimination. For example, if $F = \{\{w, \bar{x}\}, \{x, y, \bar{z}\}, \{\bar{y}, z\}, \{\bar{w}, \bar{z}\}\}$ and $\tau = \{(w, 1)\}$, then $\tau^* = \{(w, 1), (x, 1), (y, 0), (z, 0)\}$. We construct a binary search tree T whose nodes are truth assignments. We start with the empty assignment as the root and extend the tree downwards as follows. Consider a node τ of T . If $s(\tau^*) \geq k$ or if $s(\tau^*) < k$ and $F[\tau^*] = \{\emptyset\}$, then we do not add any children to τ ; in the first case we label τ as “success leaf,” in the second case as “failure leaf.” Otherwise, if $s(\tau^*) < k$ and $F[\tau^*] \neq \{\emptyset\}$, we pick a variable $x \in F[\tau^*]$ and we add below τ the children $\tau_0 = \tau \cup \{(x, 0)\}$ and $\tau_1 = \tau \cup \{(x, 1)\}$. Note that in this case both $s(\tau_0)$ and $s(\tau_1)$ are strictly greater than $s(\tau)$. It is easy to see that there exists a total truth assignment τ of F that satisfies at least k clauses if and only if T has a success leaf (for the only-if direction note that τ defines a path from the root of T to a success leaf). Since at each branching step the number of satisfied clauses increases, it follows that T is of depth at most k and so has at most 2^k leaves. Hence the search algorithm runs in time $\mathcal{O}^*(2^k)$ which renders Max-SAT fixed-parameter tractable for parameter k . By sophisticated case distinctions, one can make the algorithm significantly faster. The currently fastest algorithm is runs in time $\mathcal{O}^*(1.3248^k)$ [CXW17].

Note that one can always satisfy at least half of the clauses of a CNF formula (the all-true or the all-false assignment will do). Thus, a more challenging parameter for Max-SAT is the number $k - |F|/2$ (this constitutes a parameterization “above the guaranteed value” $|F|/2$). Indeed, by a result of Mahajan and Raman [MR99], Max-SAT is fixed-parameter tractable also under this more general setting. For an r -CNF input formula, where r is an arbitrary constant, one

can always satisfy at least a $1 - 2^{-r}$ fraction of its clauses, and such an assignment can be found in polynomial time using Johnson's Algorithm [Joh73]. Alon et al. [AGK⁺11] showed that Max-SAT for r -CNF formulas is fixed-parameter tractable parameterized above this bound, answering a question posed by Mahajan et al. [MRS06].

One can consider an even more challenging approach, taking the *dual parameter* $k' = |F| - k$; that is, to parameterize by the number of clauses that remain unsatisfied. It is easy to see that for every *constant* k' the problem is NP-complete in general and polynomial-time solvable for 2CNF formulas (Max-2-SAT). It follows from recent results of Razgon and O'Sullivan [RO08] that Max-2-SAT is fixed-parameter tractable for the dual parameter k' . We will return to this problem again in Section 17.4.1.

Apart from Max-SAT there are also other interesting optimization versions of satisfiability. For example, *Bounded-CNF-SAT* asks whether a CNF formula can be satisfied by setting at most k variables to true. With parameter k , Bounded-CNF-SAT is W[2]-complete; Bounded-3-CNF-SAT, however, is easily seen to be fixed-parameter tractable [DMS11]. A similar problem, *Weighted-CNF-SAT*, asks for a satisfying assignment that sets *exactly* k variables to true. Weighted-CNF-SAT is W[2]-complete; Weighted- c -CNF-SAT is W[1]-complete for every constant $c \geq 2$ [DF99].

17.4. Backdoor Sets

As outlined in the introduction, every satisfiability parameter π gives rise to the hierarchy of classes

$$\mathcal{C}_0^\pi \subseteq \mathcal{C}_1^\pi \subseteq \mathcal{C}_2^\pi \subseteq \dots$$

where class \mathcal{C}_k^π contains all CNF formulas F with $\pi(F) \leq k$. We call this hierarchy the π -*hierarchy*, and we refer to the class at the lowest level of the hierarchy as the *base class*. The following are necessary conditions for a class \mathcal{C} of CNF formulas under which it could possibly act as the base class for the π -hierarchy of some satisfiability parameter π such that both **SAT**(π) and **VER**(π) are fixed-parameter tractable:

1. \mathcal{C} is closed under isomorphism;
2. membership in \mathcal{C} can be decided in polynomial time;
3. satisfiability of elements of \mathcal{C} can be decided in polynomial time.

Some authors also require that a base class is *self-reducible*, that is, if $F \in \mathcal{C}$ then $F[x = 0], F[x = 1] \in \mathcal{C}$ for all $x \in \text{var}(F)$. Most natural base classes are self-reducible.

Next, we will see how one can define a π -hierarchy starting at an arbitrary base class \mathcal{C} utilizing the notion of “backdoor sets” which was introduced by Williams, Gomes, and Selman [WGS03] for analyzing the behavior of SAT algorithms. Actually, with different terminology and context, backdoor sets have already been studied by Crama, Elkin, and Hammer [CEH97]. Consider a CNF formula F and a set $B \subseteq \text{var}(F)$ of variables. B is called a *strong \mathcal{C} -backdoor set* of F if for every truth assignment $\tau : B \rightarrow \{0, 1\}$ the restriction $F[\tau]$ belongs

to the base class \mathcal{C} . We also introduce the notion of *weak* backdoor sets. A set $B \subseteq \text{var}(F)$ is called a *weak \mathcal{C} -backdoor set* of F if there exists truth assignment $\tau : B \rightarrow \{0, 1\}$ such that the restriction $F[\tau]$ is *satisfiable* and belongs to the base class \mathcal{C} . We denote the size of a smallest strong \mathcal{C} -backdoor set of F by $\mathbf{b}_{\mathcal{C}}(F)$ and the size of a smallest weak \mathcal{C} -backdoor set of F by $\mathbf{wb}_{\mathcal{C}}(F)$.

Example 17.4.1. Consider the base class HORN of Horn formulas (an instance is Horn if each of its clauses contains at most one un-negated variable) and consider the formula $F = \{\{u, v, w\}, \{\bar{u}, x, \bar{y}\}, \{u, \bar{v}, \bar{x}, y\}, \{v, y, \bar{z}\}, \{u, v, \bar{w}, z\}\}$. The set $B = \{u, v\}$, is a strong HORN-backdoor set since $F[\tau] \in \text{HORN}$ for all four truth assignments $\tau : B \rightarrow \{0, 1\}$. \square

Note that F is satisfiable if and only if at least one of the restrictions $F[\tau]$, $\tau : B \rightarrow \{0, 1\}$, is satisfiable. Thus, if we know a strong \mathcal{C} -backdoor set B of F , we can decide the satisfiability of F by deciding the satisfiability of at most $2^{|B|}$ polynomial-time solvable formulas that belong to \mathcal{C} (this is a $\mathcal{O}^*(2^k)$ fixed-parameter algorithm with respect to the parameter $k = |B|$). Of course we can find a \mathcal{C} -backdoor set of size at most k (or decide that it does not exist) by trying all subsets $B \subseteq \text{var}(F)$ with $|B| \leq k$, and checking whether all $F[\tau]$, $\tau : B \rightarrow \{0, 1\}$, belong to \mathcal{C} ; consequently $\mathbf{VER}(\mathbf{b}_{\mathcal{C}}) \in \text{XP}$. However, as we shall see in the following section, $\mathbf{VER}(\mathbf{b}_{\mathcal{C}})$ can or cannot be fixed-parameter tractable, depending on the base class \mathcal{C} .

For an algorithm that provides fixed-parameter tractability of $\mathbf{VER}(\mathbf{b}_{\mathcal{C}})$, we will always assume that it provides, as a witness for $\mathbf{b}_{\mathcal{C}}(C) \leq k$, a strong \mathcal{C} -backdoor set of F size of size $\leq k$. Hence the fixed-parameter tractability of $\mathbf{VER}(\mathbf{b}_{\mathcal{C}})$ implies the fixed-parameter tractability of $\mathbf{SAT}(\mathbf{b}_{\mathcal{C}})$.

As mentioned above, a strong \mathcal{C} -backdoor set of F of size k reduces the satisfiability of F to the satisfiability of at most 2^k instances in \mathcal{C} . The notions of *backdoor trees* and *backdoor DNFs* [SS08, OSS21] make this reduction explicit. This allows a refined worst-case estimation of the number of instances in \mathcal{C} that need to be checked, which can be exponentially smaller than 2^k .

17.4.1. Horn, 2CNF, and Generalizations

HORN and 2CNF are two important base classes for which the detection of strong backdoor sets is fixed-parameter tractable.

Theorem 17.4.1 ([NRS04]). *For $\mathcal{C} \in \{\text{HORN}, 2\text{CNF}\}$ the problems $\mathbf{SAT}(\mathbf{b}_{\mathcal{C}})$ and $\mathbf{VER}(\mathbf{b}_{\mathcal{C}})$ are fixed-parameter tractable.*

The algorithms of Nishimura et al. rely on the concept of *variable deletion*. For explaining this, it is convenient to consider the following variant of backdoor sets: A set $B \subseteq \text{var}(F)$ is called a *deletion \mathcal{C} -backdoor set* of F if $F - B$ belongs to \mathcal{C} . Here $F - B$ denotes the CNF formula $\{C \setminus (B \cup \bar{B}) : C \in F\}$, i.e., the formula obtained from F by removing from the clauses all literals of the form ℓ or $\bar{\ell}$ for $\ell \in B$. Let $\mathbf{db}_{\mathcal{C}}(F)$ denote the size of a smallest *deletion \mathcal{C} -backdoor set* of F . For many important base classes \mathcal{C} , deletion \mathcal{C} -backdoor sets are also strong \mathcal{C} -backdoor sets. In particular, this is the case if the base class is *clause induced*, i.e., if whenever F belongs to \mathcal{C} , all subsets of F belong to \mathcal{C} as well. If \mathcal{C} is clause induced, then $F[\tau] \subseteq F - B$ holds for every $\tau : B \rightarrow \{0, 1\}$.

Lemma 17.4.2. *Let \mathcal{C} be a clause-induced base class and let F be an arbitrary formula. Then every deletion \mathcal{C} -backdoor set of F is also a strong \mathcal{C} -backdoor set of F .*

For example, the base classes HORN and 2CNF are clause induced. For these two base classes, even the converse direction of Lemma 17.4.2 holds.

Lemma 17.4.3 ([CEH97, NRS04]). *Let $\mathcal{C} \in \{\text{HORN}, 2\text{CNF}\}$ and let F be an arbitrary formula. Then the strong \mathcal{C} -backdoor sets of F are exactly the deletion \mathcal{C} -backdoor sets of F .*

Example 17.4.2. Consider the formula F of Example 17.4.1 and the strong HORN-backdoor set $B = \{u, v\}$ of F (note that B is also a strong 2CNF-backdoor set of F). Indeed, $F - B = \{\{w\}, \{x, \bar{y}\}, \{\bar{x}, y\}, \{y, \bar{z}\}, \{\bar{w}, z\}\}$ is a Horn formula. \square

Nishimura et al. describe a fixed-parameter algorithm for the detection of strong HORN-backdoor sets. Their algorithm is based on bounded search trees similarly to the vertex cover algorithm described above. In fact, we can directly use a vertex cover algorithm. To this end, we associate with a formula F the *positive primal graph* G . The vertices of G are the variables of F , and two variables x, y are joined by an edge if and only if $x, y \in C$ for some clause C of F (negative occurrences of variables are ignored). Clearly, the positive primal graph can be constructed in time polynomial in the size of F . Now it is easy to see that for sets $B \subseteq \text{var}(F)$ the following properties are equivalent:

1. B is a strong HORN-backdoor set of F ;
2. B is a deletion HORN-backdoor set of F ;
3. B is a vertex cover of G .

Thus, any vertex cover algorithm, such as the $\mathcal{O}^*(1.2738^k)$ algorithm by Chen et al. [CKX10] mentioned above, can be used to find a strong HORN-backdoor set.

For the detection of strong 2CNF-backdoor sets one can apply a similar approach. Given a CNF formula F and a positive integer k , we want to determine whether F has a strong 2CNF-backdoor set of size at most k . Let \mathcal{S} be the set of all size-3 subsets S of $\text{var}(F)$ such that $S \subseteq \text{var}(C)$ for some clause C of F . Evidently, \mathcal{S} can be constructed in polynomial time. Observe that a set $B \subseteq \text{var}(F)$ is a hitting set of \mathcal{S} if and only if B is a deletion 2CNF-backdoor set of F . By Lemma 17.4.3, the latter is the case if and only if B is a strong 2CNF-backdoor set of F . Thus, Wahlström's algorithm for **3-HS** [Wah17] solves **VER**($\mathbf{b}_{2\text{CNF}}$) in time $\mathcal{O}^*(2.076^k)$.

A generalization of backdoor sets, in particular HORN- and 2CNF-backdoor sets, to quantified Boolean formulas has been proposed by taking the variable dependencies caused by the quantifications into account [SS09].

The classes HORN and 2CNF are two of the five classes of CNF formulas that can be identified with tractable satisfiability problems considered by Schaefer in his seminal work on generalized satisfiability problems [Sch78]. The remaining three are the classes HORN^- of *anti-Horn* formulas (each clause contains at most one negative literal), and for $\varepsilon \in \{0, 1\}$ the classes $\varepsilon\text{-VAL}$ of ε -*valid* formulas. A CNF-formula F is ε -*valid* if each nonempty clause $\emptyset \neq C \in F$ contains at

least one literal x^ε with $x \in \text{var}(C)$. The affine Boolean formulas considered by Schaefer do not correspond naturally to a class of CNF formulas; hence we do not consider them here.

For a given formula F we can compute in polynomial time a smallest deletion ε -VAL-backdoor set (which is also a smallest strong ε -VAL-backdoor set) by taking the union of $\text{var}(C)$ over all $C \in F$ with $C \subseteq \{x^{1-\varepsilon} : x \in \text{var}(C)\}$. We put

$$\text{Schaefer} = \{\text{HORN}, \text{HORN}^-, \text{2CNF}, \text{0-VAL}, \text{1-VAL}\}$$

and summarize the discussed results as follows.

Theorem 17.4.4. *The problem $\text{SAT}(\mathbf{b}_C)$ is fixed-parameter tractable for all $C \in \text{Schaefer}$.*

The detection of weak \mathcal{C} -backdoor sets, however, is $W[2]$ hard for several base classes, including the classes in Schaefer . Gaspers and Szeider gave a generic reduction [GS12b, Proposition 1] that can be instantiated for various base classes \mathcal{C} . For the classes $C \in \text{Schaefer}$ hardness results even for the permissive problems $\text{SAT}(\mathbf{wb}_C)$ are known:

Theorem 17.4.5 ([GS12b]). *$\text{SAT}(\mathbf{wb}_C)$ is $W[1]$ -hard for all $C \in \text{Schaefer}$*

A significant improvement over HORN as the base class for strong backdoor sets is the consideration of the class UP of CNF formulas that can be decided by unit propagation. That is, a CNF formula F belongs to UP if and only if after repeated application of unit propagation one is either left with the empty formula (i.e., F is satisfiable) or with a formula that contains the empty clause (i.e., F is unsatisfiable). Unfortunately, $\mathbf{VER}(\mathbf{b}_{\text{UP}})$ turns out to be complete for the class $W[P]$. This holds also true if one considers the base class PL of CNF formulas decidable by pure literal elimination, and by the base class $\text{UP} + \text{PL}$ of CNF formulas decidable by a combination of unit propagation and pure literal elimination. Thus $\text{UP} + \text{PL}$ contains exactly those formulas that can be decided by the polynomial-time “subsolver” of the basic DPLL procedure [WGS03].

The following result provides strong evidence that the detection of strong backdoor sets with respect to the base classes PL , UP , and $\text{UP} + \text{PL}$ is not fixed-parameter tractable. Let us write

$$\text{Subsolver} = \{\text{PL}, \text{UP}, \text{UP} + \text{PL}\}.$$

Theorem 17.4.6 ([Sze05]). *For $C \in \text{Subsolver}$, the problem $\mathbf{VER}(\mathbf{b}_C)$ is $W[P]$ -complete.*

Given this result, it appears to be very unlikely that one can find a size- k strong backdoor set with respect to the base class of formulas decidable by DPLL subsolvers significantly faster than by trying all sets of variables of size k . Also, the consideration of deletion backdoor sets does not offer an opportunity for overcoming this limitation: the classes UP , PL , and $\text{UP} + \text{PL}$ are not clause induced—indeed, not every deletion backdoor set is a strong backdoor set with respect to these classes.

However, the class RHORN of *renamable Horn* formulas is an interesting base class that is clause induced. A formula is renamable Horn if some renaming

of it is Horn. It is well known that recognition and satisfiability of renamable Horn formulas is feasible in polynomial time [Lew78]. A renamable Horn formula is unsatisfiable if and only if we can derive the empty clause from it by unit propagation; also, whenever we can derive from a formula the empty clause by means of unit resolution, then some unsatisfiable subset of the formula is renamable Horn [KBL99]. Thus RHORN lies in a certain sense half way between UP and HORN. Since RHORN is clause induced, both strong and deletion backdoor sets are of relevance. In contrast to HORN, not every strong RHORN-backdoor set is a deletion RHORN-backdoor set. Indeed, $\mathbf{b}_{\text{RHORN}}$ is a more general satisfiability parameter than $\mathbf{db}_{\text{RHORN}}$ as can be seen from Lemma 17.4.2 and the following example.

Example 17.4.3. For $1 \leq i \leq n$, let $F_i = \{\{x_i, y_i, z\}, \{x_i, \bar{y}_i, \bar{z}\}, \{\bar{x}_i, y_i\}, \{\bar{x}_i, \bar{y}_i\}\}$, and consider $F = \bigcup_{i=1}^n F_i$. Evidently $\{z\}$ is a strong RHORN-backdoor set of F , since each proper subset of $\{\{x_i, y_i\}, \{x_i, \bar{y}_i\}, \{\bar{x}_i, y_i\}, \{\bar{x}_i, \bar{y}_i\}\}$, $1 \leq i \leq n$, is renamable Horn. However, every deletion RHORN-backdoor set of F must contain at least one variable x_i or y_i for all $1 \leq i \leq n$. Hence $\mathbf{b}_{\text{RHORN}}(F) \leq 1$ and $\mathbf{db}_{\text{RHORN}}(F) \geq n$, which shows that $\mathbf{b}_{\text{RHORN}}$ is more general than $\mathbf{db}_{\text{RHORN}}$. \square

The detection of strong RHORN-backdoor sets is $W[1]$ -hard [GS12b], but the detection of deletion RHORN-backdoor sets is fixed-parameter tractable:

Theorem 17.4.7 ([RO08, GS12b]). *The problems $\mathbf{VER}(\mathbf{db}_{\text{RHORN}})$ and $\mathbf{SAT}(\mathbf{db}_{\text{RHORN}})$ are fixed-parameter tractable.*

Even the corresponding permissive problem is hard as well.

Theorem 17.4.8 ([GS12b]). *$\mathbf{SAT}(\mathbf{wb}_{\text{RHORN}})$ is $W[1]$ -hard.*

Boros et al. [BCH90] introduced an interesting class of CNF formulas, later called QHORN [BHS94], with favorable algorithmic properties: both recognition as well as deciding satisfiability of QHORN formulas can be performed in linear time. The class QHORN properly contains the fundamental classes RHORN and 2CNF:

$$\text{HORN} \subsetneq \text{RHORN} \subsetneq \text{QHORN} \supseteq 2\text{CNF}.$$

A CNF formula F is in QHORN if there is a certifying function $\beta : \text{var}(F) \cup \overline{\text{var}(F)} \rightarrow \{0, \frac{1}{2}, 1\}$ with $\beta(x) = 1 - \beta(\bar{x})$ for every $x \in \text{var}(F)$ such that $\sum_{l \in C} \beta(l) \leq 1$ for every clause C of F .

As QHORN generalizes RHORN, it is not surprising, that the problems $\mathbf{VER}(\mathbf{b}_{\text{QHORN}})$ and $\mathbf{VER}(\mathbf{wb}_{\text{QHORN}})$ are $W[2]$ -hard as well. However, Gaspers et al. [GOR⁺16] showed that the detection of deletion QHORN-backdoor sets is fixed-parameter approximable, which implies the fixed-parameter tractability of $\mathbf{SAT}(\mathbf{db}_{\text{QHORN}})$.

Theorem 17.4.9 ([GOR⁺16]). *The problem $\mathbf{SAT}(\mathbf{db}_{\text{QHORN}})$ is fixed-parameter tractable.*

This result was later improved by Ramanujan and Saurabh [RS17] who developed a general algorithmic framework for certain skew symmetric cut problems in graphs, and applied their method to show fixed-parameter tractability of $\mathbf{VER}(\mathbf{db}_{\text{QHORN}})$.

Table 17.1. The parameterized complexity of the detection of weak, strong, and deletion \mathcal{C} -backdoor sets, i.e., $\mathbf{VER}(\mathbf{wb}_{\mathcal{C}})$, $\mathbf{VER}(\mathbf{b}_{\mathcal{C}})$, and $\mathbf{VER}(\mathbf{db}_{\mathcal{C}})$, respectively, for various base classes \mathcal{C} .

Base Class	$\mathbf{VER}(\mathbf{wb}_{\mathcal{C}})$ weak	$\mathbf{VER}(\mathbf{b}_{\mathcal{C}})$ strong	$\mathbf{VER}(\mathbf{db}_{\mathcal{C}})$ deletion
$\mathcal{C} \in \text{Schaefer}$	W[2]-h ^[NRS04] (FPT)	FPT ^[NRS04]	FPT ^[NRS04]
$\mathcal{C} \in \text{Subsolver}$	W[P]-c ^[Sze05]	W[P]-c ^[Sze05]	n/a
FOREST	W[2]-h ^[GS12a] (FPT ^[GS12a])	? [†] (?)	FPT
RHORN	W[2]-h	W[2]-h (?)	FPT ^[RO08]
QHORN	W[2]-h ^[GOR⁺16]	W[2]-h ^[GOR⁺16] (?)	FPT ^[RS17]
CLU	W[2]-h ^[NRS07] (FPT)	W[2]-h ^[NRS07] (FPT ^[NRS07])	FPT ^[NRS07]

([∘]) It is indicated in parentheses if the complexity of the problem for 3CNF formulas is different from general CNF or unknown.

? It is open whether the problem is fixed-parameter tractable.

[†] Theorem 17.4.11 shows that the problem is fixed-parameter approximable.

^{n/a} Deletion backdoor sets are undefined for base classes that are not clause-induced.

Table 17.1, which is adapted from a survey paper [GS12b], gives an overview of parameterized complexity results of backdoor set detection problems for various base classes.

17.4.2. Heterogeneous Base Classes

One can enhance the power of a strong backdoor set B of a formula F , by allowing that for different assignments τ to B , $F[\tau]$ belongs to different base classes. This enhancement can be expressed in terms of *heterogeneous base classes* which are the union of individual base classes.

Example 17.4.4. Consider the following CNF formula $F_n = \{C, D_1, \dots, D_n\}$ where $C = \{x, \neg a_1, \dots, \neg a_n\}$ and $D_i = \{\neg x, b_i, c_i\}$. It is easy to see that any strong HORN-backdoor set needs to contain at least one of the variables b_i or c_i from each clause D_i , hence such a backdoor set must be of size $\geq n$; on the other hand, any strong 2CNF-backdoor set must contain at least $n - 2$ variables from the clause C ; However, $F_n[x = 0] \in \text{HORN}$ and $F_n[x = 1] \in \text{2CNF}$, hence the singleton $\{x\}$ is a strong $\text{HORN} \cup \text{2CNF}$ -backdoor set, where $\text{HORN} \cup \text{2CNF}$ is the heterogeneous base class consisting of all Horn and all 2CNF formulas. Note that any $F \in \text{HORN} \cup \text{2CNF}$ contains either only Horn clauses or only 2CNF clauses, not a mixture of both. \square

Weak backdoor sets with respect to heterogeneous base classes can also be considered. Identifying a base class with a class of instances that are solvable by a particular polynomial-time subsolver, one can consider a heterogeneous base class as a “portfolio subsolver,” where for each instance the best suitable subsolver from the portfolio is chosen.

The concept of heterogeneous base classes was introduced by Gaspers et al. [GMO⁺17] who studied the parameterized complexity of backdoor detection with respect to heterogeneous base classes in the context of SAT and CSP. For SAT,

they gave a full classification of the problem for heterogeneous base classes that are composed of base classes from Schaefer. For a nonempty subset $\mathcal{S} \subseteq \text{Schaefer}$, let $\mathcal{S}^\cup = \bigcup_{\mathcal{C} \in \mathcal{S}} \mathcal{C}$. It turned out that the detection of strong \mathcal{S}^\cup -backdoor sets is fixed-parameter tractable for all nonempty subsets $\mathcal{S} \subseteq \text{Schaefer}$ that do not contain any of the four pairs $\{\text{HORN}, \text{HORN}^-\}$, $\{0\text{-VAL}, 1\text{-VAL}\}$, $\{\text{HORN}, 1\text{-VAL}\}$, $\{0\text{-VAL}, \text{HORN}^-\}$, and is $W[2]$ -hard otherwise. Thus, from the 31 nonempty subsets of Schaefer, the problem is fixed-parameter tractable for 13 of them, and $W[2]$ -hard for the remaining 18. The fixed-parameter tractable cases can also be described in terms of the two maximal subsets $\{2\text{CNF}, \text{HORN}, 0\text{-VAL}\}$ and $\{2\text{CNF}, \text{HORN}^-, 1\text{-VAL}\}$:

Theorem 17.4.10 ([GMO⁺17]). *Let $\emptyset \neq \mathcal{S} \subseteq \text{Schaefer}$. If $\mathcal{S} \subseteq \{2\text{CNF}, \text{HORN}, 0\text{-VAL}\}$ or $\mathcal{S} \subseteq \{2\text{CNF}, \text{HORN}^-, 1\text{-VAL}\}$, then $\mathbf{VER}(\mathbf{b}_{\mathcal{S}^\cup})$, and consequently $\mathbf{SAT}(\mathbf{b}_{\mathcal{S}^\cup})$, are fixed-parameter tractable. Otherwise, $\mathbf{VER}(\mathbf{b}_{\mathcal{S}^\cup})$ is $W[2]$ -hard.*

Concerning the detection of weak backdoor sets, the $W[2]$ -hardness for individual base classes from Schaefer propagates to heterogeneous base classes that are composed from subsets of Schaefer [GMO⁺17].

17.4.3. Acyclic Formulas

Many NP-hard problems can be solved in polynomial time for problem instances that are in a certain sense acyclic. The satisfiability problem is no exception. There are various ways of defining a CNF formula to be acyclic. Here we consider acyclicity based on (undirected) incidence graphs (see Section 17.2.3). Let FOREST denote the class of CNF formulas whose undirected incidence graphs are forests. It is well known that the satisfiability problem can be solved in polynomial time for acyclic formulas [FMR08, SS10a]. The detection of deletion FOREST-backdoor sets is fixed-parameter tractable as one can use variants of algorithms for finding feedback vertex sets (also known as cycle cut sets) in graphs. It is not known, whether the detection of strong FOREST-backdoors is fixed-parameter tractable. However, Gaspers and Szeider [GS12a] showed that the problem is fixed-parameter approximable. They gave a fixed-parameter algorithm that either outputs a strong FOREST-backdoor set of size $\leq 2^k$, or correctly decides that the given formula has no strong FOREST-backdoor set of size $\leq k$. This result renders $\mathbf{SAT}(\mathbf{b}_{\text{FOREST}})$ fixed-parameter tractable. The detection of weak FOREST-backdoor sets is $W[2]$ -hard, but fixed-parameter tractable if the input formula is in 3CNF [GS12a].

Theorem 17.4.11 ([GS12a]). *The problem $\mathbf{SAT}(\mathbf{b}_{\text{FOREST}})$ is fixed parameter tractable.*

The class BAC of β -acyclic formulas, which was studied by Paulusma et al. [OPS13], is another possible base class defined in terms of acyclicity. A CNF formula is β -acyclic if its incidence graph $G^*(F)$ is chordal bipartite, which means that $G^*(F)$ has no induced cycle on six or more vertices (a cycle is induced if there are no edges between non-consecutive vertices). SAT-decision, as well as recognition, are polynomial-time solvable problems for BAC, which is a clause-induced

base class. The detection of strong BAC-backdoor sets is $W[2]$ -hard, but it is open whether the detection of deletion BAC-backdoor sets is fixed-parameter tractable [OPS13]. The $W[2]$ -hardness of the detection of weak BAC-backdoor sets can be established by instantiating the above mentioned generic reduction [GS12b, Proposition 1].

17.4.4. Hitting Formulas

Iwama [Iwa89] observed that one could determine the number of models of a CNF formula in polynomial time if any two clauses of the formula clash; such formulas are known as *hitting formulas* [KZ01]. Consider a hitting formula F with n variables. If a total truth assignment $\tau : \text{var}(F) \rightarrow \{0, 1\}$ does *not* satisfy a clause $C \in F$, it satisfies all other clauses of F . Hence we can count the total truth assignments that do not satisfy F by considering one clause after the other, and the number of models is therefore exactly $2^n - \sum_{C \in F} 2^{n-|C|}$. Of course, if a formula is a variable-disjoint union of hitting formulas—we call such a formula a *cluster formula*—we can still compute the number of models in polynomial time by taking the product of the number of models for each component. Since satisfiability (and obviously recognition) of cluster formulas can be established in polynomial time, the class CLU of cluster formulas is a base class. CLU is evidently clause induced.

Nishimura, Ragde, and Szeider considered the parameterized problem of detecting CLU-backdoor sets.

Theorem 17.4.12 ([NRS07]). **VER**(\mathbf{b}_{CLU}) is $W[2]$ -hard but **VER**(\mathbf{db}_{CLU}) is fixed-parameter tractable.

The hardness result is obtained by an fpt-reduction from the parameterized hitting set problem **HS**. The FPT result is achieved employing an algorithm that systematically destroys certain obstructions that consist of pairs or triples of clauses. To this end, the *obstruction graph* of a CNF formula F is considered. The vertex set of this graph is the set of variables of F ; two variables x, y are joined by an edge if and only if at least one of the following conditions hold:

1. F contains two clauses C_1, C_2 that do not clash, $x \in \text{var}(C_1 \cap C_2)$, and $y \in \text{var}(C_1 \setminus C_2)$;
2. F contains three clauses C_1, C_2, C_3 such that C_1 and C_3 do not clash, $x \in \text{var}((C_1 \setminus C_3) \cap \overline{C_2})$, and $y \in \text{var}((C_3 \setminus C_1) \cap \overline{C_2})$.

Since the vertex covers of the obstruction graph are exactly the deletion CLU-backdoor sets, we can find smallest deletion CLU-backdoor sets by using a vertex cover algorithm. Hence **VER**($\mathbf{db}_{\text{CLU}}(F)$) is fixed-parameter tractable.

Example 17.4.5. Consider formula $F = \{\{u, v\}, \{s, \bar{u}, \bar{v}\}, \{u, \bar{v}, w, \bar{r}\}, \{r, \bar{w}, x, y\}, \{\bar{x}, y, z\}, \{\bar{y}, \bar{z}\}, \{\bar{s}, \bar{t}\}, \{\bar{t}\}, \{t, w\}\}$. The obstruction graph has the edges $rw, st, tw, uw, vw; ru, rv, rx, ry, su, sv, wx, wy$. The set $B = \{r, s, w\}$ forms a vertex cover of the obstruction graph; there is no vertex cover of size two. B is a deletion CLU-backdoor set and consequently also a strong CLU-backdoor set of F . There is, however, the smaller strong CLU-backdoor set $B' = \{w, s\}$. \square

The algorithm of Nishimura et al. outlined above can be used to count the number $\#(F)$ of models of a given formula F . More generally, assume that we have a base class \mathcal{C} such that $\#(F)$ can be computed in polynomial time for every $F \in \mathcal{C}$ (which is the case for CLU). Then, if we have a strong \mathcal{C} -backdoor set B of an arbitrary CNF formula F , we can compute $\#(F)$ utilizing the identity

$$\#(F) = \sum_{\tau: B \rightarrow \{0,1\}} 2^{d(F,\tau)} \#(F[\tau])$$

where $d(F, \tau) = |\text{var}(F - B) \setminus \text{var}(F[\tau])|$ denotes the number of variables that disappear from $F[\tau]$ without being instantiated. Thus determining $\#(F)$ reduces to determining the number of models for $2^{|B|}$ formulas of the base class \mathcal{C} . In particular, the above considerations yield a fixed-parameter algorithm for model counting parameterized by the clustering-width. Note, however, that for the classes HORN and 2CNF, the model counting problem is $\#P$ -hard (even for monotone formulas) [Rot96]. Thus knowing a small strong backdoor set with respect to these classes does not help to count the number of models efficiently.

We will see two further satisfiability parameters that generalize hitting formulas in Section 17.5.2 (conflict treewidth) and Section 17.6.2 (h-modularity).

17.4.5. Empty Clause Detection

Dilkina, Gomes, and Sabharwal [DGS07] suggested strengthening the concept of strong backdoor sets by means of *empty clause detection*. Let \mathcal{E} denote the class of all CNF formulas that contain the empty clause. For a base class \mathcal{C} we put $\mathcal{C}^{\{\}} = \mathcal{C} \cup \mathcal{E}$; we call $\mathcal{C}^{\{\}}$ the base class obtained from \mathcal{C} by adding *empty clause detection*. Formulas can have much smaller strong $\mathcal{C}^{\{\}}$ -backdoor sets than strong \mathcal{C} -backdoor sets; Dilkina et al. give empirical evidence for this phenomenon considering various base classes. Note that the addition of empty clause detection makes only sense for strong backdoor sets [DGS07], not for weak or deletion backdoor sets. Dilkina et al. show that given a CNF formula F and an integer k , determining whether F has a strong $\text{HORN}^{\{\}}$ -backdoor set of size k is both NP-hard and co-NP-hard (here k is considered only as part of the input and not as a parameter). Thus, the non-parameterized complexity of the search problem for strong HORN-backdoor sets gets harder when empty clause detection is added. Also, the parameterized complexity gets harder, which can be shown using results from Fellows et al. [FSW06].

Theorem 17.4.13 ([Sze08]). *For $\mathcal{C} \in \{\text{HORN}^{\{\}}, 2\text{CNF}^{\{\}}, \text{RHORN}^{\{\}}\}$ the problem $\text{VER}(\mathbf{b}_{\mathcal{C}})$ is $W[1]$ -hard.*

17.5. Treewidth

Treewidth is an important graph invariant that measures the “tree-likeness” of a graph. Many otherwise NP-hard graph problems such as Hamiltonicity and 3-colorability are fixed-parameter tractable if parameterized by the treewidth of the input graph. It is generally believed that many practically relevant problems do have low treewidth [Bod93]. For taking the treewidth of a CNF formula, one

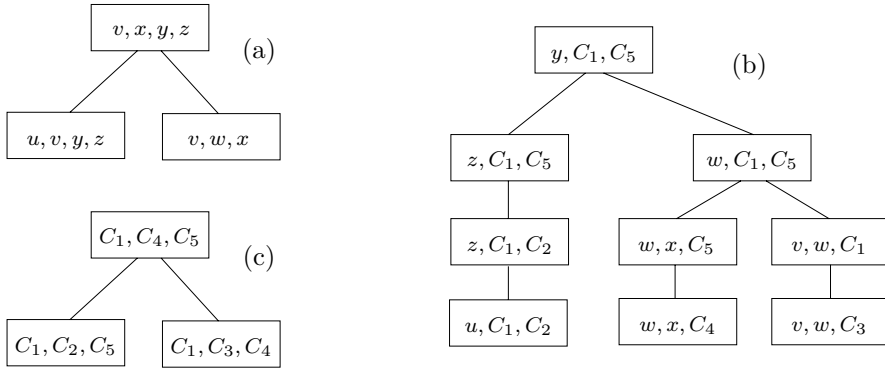

Figure 17.3. Tree decompositions of the primal graph (a), the incidence graph (b), and the dual graph (c)

needs to represent the structure of a formula as a graph. For this, we can use the graphs discussed in Section 17.2.3

Tree decompositions of graphs and the associated parameter treewidth were studied by Robertson and Seymour in their famous Graph Minors Project. A *tree decomposition* of a graph $G = (V, E)$ is a tree $T = (V', E')$ together with a labeling function $\chi : V' \rightarrow 2^V$ associating to each tree node $t \in V'$ a bag $\chi(t)$ of vertices in V such that the following three conditions hold:

1. every vertex in V occurs in some bag $\chi(t)$;
2. for every edge $xy \in E$ there is a bag $\chi(t)$ that contains both x and y ;
3. if $\chi(t_1)$ and $\chi(t_2)$ both contain x , then each bag $\chi(t_3)$ contains x if t_3 lies on the unique path from t_1 to t_2 .

The *width* of a tree decomposition is $\max_{t \in V'} |\chi(t)| - 1$. The *treewidth* of a graph is the minimum width over all its tree decompositions. The treewidth of a graph is a measure for its acyclicity, i.e., the smaller the treewidth, the less cyclic the graph. In particular, a graph is *acyclic* if and only if it has treewidth 1.

The above definition of a tree decomposition can be easily generalized to hypergraphs by requiring in item (2) that all vertices in each hyperedge occur together in some bag. Every tree decomposition of the primal graph $G(F)$ of a CNF formula F is a tree decomposition of the hypergraph $H(F)$. Thus, if the treewidth of the primal graph is k , the cardinality of each clause of F cannot be larger than $k + 1$.

For a CNF formula F , we introduce the following notions of treewidth: the (*primal*) *treewidth* \mathbf{tw} of F is the treewidth of its primal graph $G(F)$, the *incidence treewidth* \mathbf{tw}^* of F is the treewidth of its incidence graph $G^*(F)$, and the *dual treewidth* \mathbf{tw}^d of F is the treewidth of its dual graph $G^d(F)$. Tree decompositions of the three graphs associated with formula F in Figure 17.1 are shown in Figure 17.3. Since there are no tree decompositions of these graphs of smaller width, we know that $\mathbf{tw}(F) = 3$ and $\mathbf{tw}^*(F) = \mathbf{tw}^d(F) = 2$.

Kolaitis and Vardi [KV00] have shown that always $\mathbf{tw}^*(F) \leq \mathbf{tw}(F) + 1$ and $\mathbf{tw}^*(F) \leq \mathbf{tw}^d(F) + 1$. In other words, the incidence treewidth dominates

the primal treewidth and the dual treewidth. On the other hand, there exist families of CNF formulas with incidence treewidth one and arbitrarily large primal treewidth and dual treewidth, i.e., this domination is strict.

Example 17.5.1. Consider the two families $F_n = \{\{x_1, x_2, \dots, x_n\}\}$ and $G_n = \{\{x_1, y\}, \{x_2, y\}, \dots, \{x_n, y\}\}$ of CNF formulas. Then $\mathbf{tw}^*(F_n) = \mathbf{tw}^*(G_n) = 1$ while $\mathbf{tw}(F_n) = \mathbf{tw}^d(G_n) = n - 1$. \square

The intuitive idea of tree decompositions is to partition a graph into clusters of vertices that can be organized as a tree. The smaller the width of a tree decomposition, the more efficiently we can decide satisfiability of the corresponding CNF formula by a bottom-up dynamic programming approach on the tree decomposition. Thus, we aim to construct a tree decomposition of width as small as possible; in the optimal case, the width of the tree decomposition equals the treewidth of the graph.

In general, computing the treewidth of a graph is NP-hard [ACP87]. However, since tree decompositions with large width do not help us in deciding satisfiability efficiently, we are more interested in graphs with small treewidth. Bodlaender [Bod96] has shown that it can be decided in linear time whether the treewidth of a graph is at most k if k is a constant. This immediately implies fixed-parameter tractability of the problems $\mathbf{VER}(\mathbf{tw})$, $\mathbf{VER}(\mathbf{tw}^*)$, and $\mathbf{VER}(\mathbf{tw}^d)$. In Section 17.5.4 we will review algorithms for constructing tree decompositions.

17.5.1. Deciding Satisfiability

As mentioned above, if a tree decomposition of the primal graph, the incidence graph, or the dual graph is given, we can decide satisfiability of the corresponding CNF formula by a bottom-up dynamic programming approach on the tree decomposition. The smaller the width of the given tree decomposition, the more efficiently we can decide satisfiability. In particular, from Yannakakis's algorithm [Yan81] we obtain the following result as already observed by Gottlob et al. [GSS02].

Theorem 17.5.1. *The problem $\mathbf{SAT}(\mathbf{tw})$ is fixed-parameter tractable.*

To see this, consider a tree decomposition of the primal graph of a given CNF formula F and let k be the width of this tree decomposition. Note that the number of nodes of the tree can be bounded by the length $n = \|F\|$. Now, we associate with each node t of the tree a table M_t with $|\chi(t)|$ columns and at most $2^{|\chi(t)|}$ rows. Each row contains Boolean values encoding a truth assignment to the variables in $\chi(t)$ that does not falsify any clause of F . The size of each table is therefore bounded by $2^{k+1}(k+1)$ and all such tables can be computed in time $\mathcal{O}(2^k kn^2)$. In this way we can transform our SAT problem into an equivalent constraint satisfaction problem by a fixed-parameter algorithm with parameter treewidth. This constraint satisfaction problem can now be solved by Yannakakis's algorithm in time $\mathcal{O}(4^k kn)$. Yannakakis's algorithm works as follows: for each node t of the tree it is checked whether to each truth assignment in table $M_{t'}$ associated with t 's parent t' there exists a consistent truth assignment in table M_t . We remove truth assignments in table $M_{t'}$ to which no such consistent truth assignment

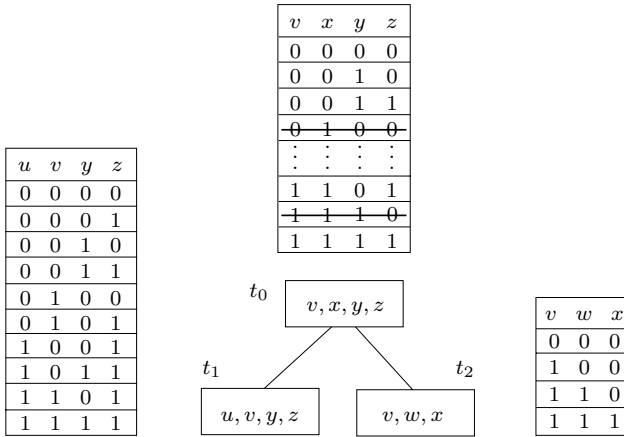

Figure 17.4. A fixed-parameter algorithm for $\text{SAT}(\text{tw})$

in table M_t exists. The whole procedure works in a bottom-up manner, i.e., a node is processed if all of its children have already been processed. The CNF formula F is satisfiable if and only if some truth assignments are left in the table associated with the root after termination of this procedure. Thus, in summary, we can decide $\text{SAT}(\text{tw})$ in time $\mathcal{O}^*(4^k)$. By using an improved algorithm, we can decide $\text{SAT}(\text{tw})$ in time $\mathcal{O}^*(2^k)$ [SS10a].

Example 17.5.2. Consider the primal graph of the CNF formula F in Figure 17.1 and its tree decomposition in Figure 17.3(a). The tables associated with each tree node are shown in Figure 17.4: there are 14 truth assignments in table M_{t_0} associated with the root t_0 , 10 in table M_{t_1} associated with the left child t_1 , and 4 in table M_{t_2} associated with the right child t_2 . Now let us start with the left child t_1 and remove the rows 1010 and 1110 from table M_{t_0} since there are no consistent truth assignments in table M_{t_1} . Then we consider the right child t_2 and remove the rows 0100, 0101, 0110, and 0111 from table M_{t_0} since there are no consistent truth assignments in table M_{t_2} . Since there are no further nodes to be processed, we are finished and know that F is satisfiable. \square

Since tw^* strictly generalizes tw , the following result is stronger than Theorem 17.5.1.

Theorem 17.5.2. *The problem $\text{SAT}(\text{tw}^*)$ is fixed-parameter tractable.*

Since incidence treewidth strictly dominates primal treewidth and dual treewidth as already mentioned above, this result implies both Theorem 17.5.1 and fixed-parameter tractability of $\text{SAT}(\text{tw}^d)$. The situation is different for “generalized satisfiability” also known as “Boolean constraint satisfaction” where Boolean relations replace clauses. Generalized satisfiability is fixed-parameter tractable for the parameter primal treewidth but $W[1]$ -hard for the parameter incidence treewidth [SS10b].

In the following, we will discuss three approaches to establishing Theorem 17.5.2.

Proof via a Logic Meta Theorem Courcelle has shown that every graph property that can be expressed in a certain formalism (monadic second-order logic, MSO) can be decided in linear time for graphs of bounded treewidth [Cou88]. This theorem applies to many NP-hard graph properties such as 3-colorability and yields fixed-parameter tractability for these problems with respect to parameter treewidth. Thus MSO theory provides a very general and convenient tool for classifying problems parameterized by treewidth as fixed-parameter tractable. Using the general methods of MSO theory, one can easily establish fixed-parameter tractability of $\mathbf{SAT}(\mathbf{tw}^*)$ [CMR01, GS08, Sze04b]. However, the algorithms obtained via the generic constructions are impractical.

Proof via Clause Splitting It is well known (see, e.g., [GJ79, p. 48]) that a CNF formula F can be transformed in polynomial time into an equisatisfiable 3CNF formula F_3 , by repeatedly splitting a clause $(\ell_1 \vee \ell_2 \vee \ell_3 \vee \dots \vee \ell_r)$ with $r \geq 4$ into two clauses $(\ell_1 \vee \ell_2 \vee x)$ and $(\neg x \vee \ell_3 \vee \dots \vee \ell_r)$ where x is a new variable. Samer and Szeider [SS10b, Remark, pp. 111] have shown that in general this procedure can increase the incidence treewidth arbitrarily, but if applied properly (respecting an ordering of clauses and variables that is inferred from a tree decomposition of the incidence graph), the incidence treewidth stays bounded.

Lemma 17.5.3 (Splitting Lemma [SS10b]). *Given a CNF formula F together with a tree decomposition of width k of the incidence graph of F . By splitting clauses we can obtain in polynomial time an equisatisfiable 3CNF formula with incidence treewidth at most $k + 1$ and primal treewidth at most $3(k + 1)$.*

Thus, there is an fpt-reduction from $\mathbf{SAT}(\mathbf{tw}^*)$ to $\mathbf{SAT}(\mathbf{tw})$, and hence Theorem 17.5.1 implies Theorem 17.5.2.

Proof via Dynamic Programming For more practical algorithms, however, one needs to use more closely the combinatorial structure of the particular problem at hand. Fischer et al. [FMR08] and Samer and Szeider [SS10a] presented practical fixed-parameter algorithms for the more general problem $\#\mathbf{SAT}(\mathbf{tw}^*)$ of counting the number of models. This trivially implies Theorem 17.5.2, since a CNF formula is satisfiable if and only if it has at least one model. In the following we present the algorithm introduced by Samer and Szeider. The algorithm is based on “nice” tree decompositions, which are a special kind of tree decompositions. It is well known that one can transform any tree decomposition of width k in linear time into a nice tree decomposition of width at most k [BK96, Klo94].

For each node t , we write X_t and F_t to denote the set of all variables and clauses occurring in $\chi(t')$, respectively, for some node t' in the subtree rooted at t . Moreover, we use the shorthands $\chi_v(t) = \chi(t) \cap X_t$ and $\chi_c(t) = \chi(t) \cap F_t$ for the set of variables and the set of clauses in $\chi(t)$ respectively. For each truth assignment $\alpha : \chi_v(t) \rightarrow \{0, 1\}$ and subset $A \subseteq \chi_c(t)$, we define $N(t, \alpha, A)$ as the set of truth assignments $\tau : X_t \rightarrow \{0, 1\}$ for which the following two conditions hold:

1. $\tau(x) = \alpha(x)$ for all variables $x \in \chi_v(t)$ and
2. A is exactly the set of clauses of F_t that are not satisfied by τ .

Now, we associate with each node t of the tree a table M_t with $|\chi(t)| + 1$ columns and $2^{|\chi(t)|}$ rows. The first $|\chi(t)|$ columns contain Boolean values encod-

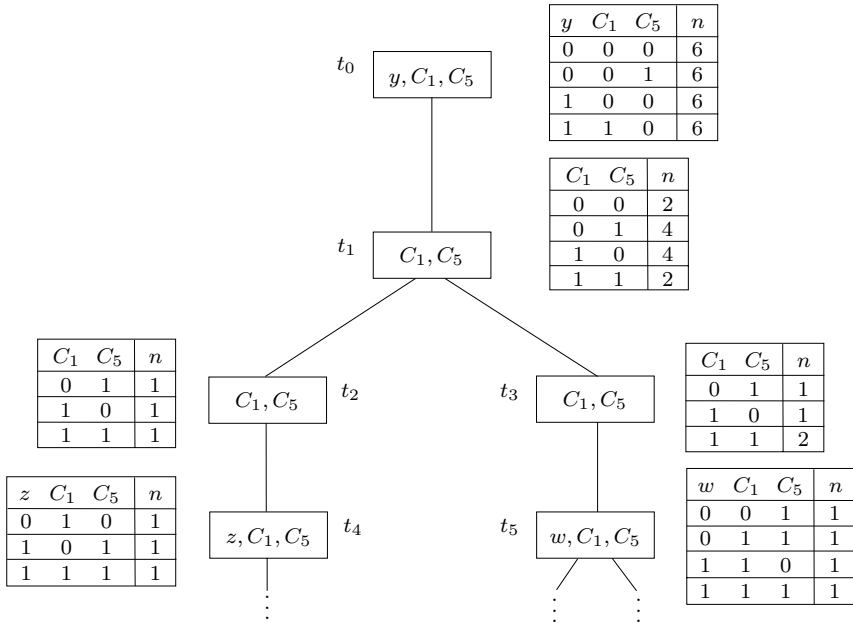

Figure 17.5. A fixed-parameter algorithm for $\#\text{SAT}(\text{tw}^*)$

ing $\alpha(x)$ for variables $x \in \chi_v(t)$, and membership of C in A for clauses $C \in \chi_c(t)$. The last column contains the integer $n(t, \alpha, A) = |N(t, \alpha, A)|$. Given the tables of the children of some node t , the table M_t can be computed in time $\mathcal{O}(4^k kl)$, where l is the cardinality of the largest clause. All the tables associated with tree nodes can be computed in a bottom-up manner. The number of models of the corresponding CNF formula F is then given by $\sum_{\alpha: \chi_v(r) \rightarrow \{0,1\}} n(r, \alpha, \emptyset)$, where r is the root of the tree. Thus, we can decide $\#\text{SAT}(\text{tw}^*)$ in time $\mathcal{O}^*(4^k)$. Based on an observation by Björklund [Bjö18], Slivovsky and Szeider [SS20] improved the running time for $\#\text{SAT}(\text{tw}^*)$ to $\mathcal{O}^*(2^k)$ through efficiently computing *covering products* [BHKK07].

Example 17.5.3. Consider the incidence graph of the CNF formula F in Figure 17.1 and its tree decomposition in Figure 17.3(b). A fragment of the corresponding nice tree decomposition and the tables associated with each tree node are shown in Figure 17.5. Note that we omit for simplicity those rows from the tables where $n = 0$. We assume that the tables M_{t_4} and M_{t_5} associated with the nodes t_4 and t_5 respectively have already been computed in a bottom-up manner starting from the leaves. For example, the entries in table M_{t_4} mean that (i) there exists exactly one truth assignment $\tau : X_{t_4} \rightarrow \{0, 1\}$ such that $\tau(z) = 0$ and τ satisfies all clauses in F_{t_4} except C_1 , (ii) there exists exactly one truth assignment $\tau : X_{t_4} \rightarrow \{0, 1\}$ such that $\tau(z) = 1$ and τ satisfies all clauses in F_{t_4} except C_5 , and (iii) there exists exactly one truth assignment $\tau : X_{t_4} \rightarrow \{0, 1\}$ such that $\tau(z) = 1$ and τ satisfies all clauses in F_{t_4} except C_1 and C_5 . The next step is to compute the tables M_{t_2} and M_{t_3} from tables M_{t_4} and M_{t_5} respectively.

Since t_2 and t_3 are forget nodes (the variable z has been forgotten in t_2 and the variable w has been forgotten in t_3), this can be done according to the rule for forget nodes as given in [SS10a]. Now we compute table M_{t_1} from tables M_{t_2} and M_{t_3} according to the rule for join nodes. Finally, we compute table M_{t_0} from table M_{t_1} according to the rule for introduce nodes. From table M_{t_0} we can now see that there are exactly 12 truth assignments $\tau : X_{t_0} \rightarrow \{0, 1\}$ such that τ satisfies all clauses in F_{t_0} (for 6 of these truth assignments it holds that $\tau(y) = 0$ and for 6 of them it holds that $\tau(y) = 1$), where $X_{t_0} = \text{var}(F)$ and $F_{t_0} = F$. Consequently, the CNF formula F has exactly 12 models. \square

Bacchus, Dalmao, and Pitassi [BDP03] presented another fixed-parameter algorithm for computing the number of models of a CNF formula F . The parameter in their algorithm is the *branchwidth* of the hypergraph $H(F)$. Similar to tree decompositions, branch decompositions and the corresponding branchwidth were introduced by Robertson and Seymour in their Graph Minors Project. It is well known that a graph with treewidth k has branchwidth at most $k + 1$ and that a graph with branchwidth k has treewidth at most $3k/2$ [RS91]. Thus, primal treewidth and branchwidth are domination equivalent satisfiability parameters. Bacchus et al. define a static ordering of the variables of F based on the branch decomposition of $H(F)$ and run a DPLL procedure with caching on this ordering. In particular, they decompose the input formula and intermediate formulas into disjoint components; these components are cached when they are solved the first time, which allows truncating the search-tree of the DPLL procedure. The resulting algorithm runs in time $2^{\mathcal{O}(k)}n^c$, where k is the branchwidth, n is the number of variables, and c is a constant.

17.5.2. Consensus Treewidth and Conflict Treewidth

Recall from above the definitions of the consensus graph $G^{\text{cs}}(F)$ and the conflict graph $G^{\text{c}}(F)$, associated with a CNF formula F . We define the *consensus treewidth* $\text{tw}^{\text{cs}}(F) = \text{tw}(G^{\text{cs}}(F))$ and the *conflict treewidth* $\text{tw}^{\text{c}}(F) = \text{tw}(G^{\text{c}}(F))$. Ganian and Szeider [GS17] introduced these two satisfiability parameters and studied their parameterized complexity. The consensus treewidth turned out to be an interesting parameter which is not dominated by any known satisfiability parameter and admits fixed-parameter tractability.

Theorem 17.5.4 ([GS17]). *The problem $\#\text{SAT}(\text{tw}^{\text{cs}})$ is fixed-parameter tractable.*

On the other hand, conflict treewidth seems to be not that useful:

Theorem 17.5.5 ([GS17]). *The problem $\text{SAT}(\text{tw}^{\text{c}})$ is W[1]-hard.*

W[1]-hardness is avoided by bounding the size of clauses and eliminating pure literals. For such formulas, however, conflict treewidth is dominated by incidence treewidth.

17.5.3. Expression Treewidth

Before discussing algorithms for computing tree decompositions, let us briefly mention a very general approach to applying treewidth to CNF formulas (or rather

Boolean functions in general), that was suggested by Jha and Suciú [JS12]. They define the *expression treewidth* of a Boolean function f as the smallest treewidth of any Boolean circuit representing the function. The circuit is considered as a directed acyclic graph D , and its treewidth is taken from the undirected graph \underline{D} obtained from D by ignoring the orientation of edges. By letting f_F denote the Boolean function represented by a CNF formula F , we can define the satisfiability parameter expression treewidth $\mathbf{xtw}(F)$ as the expression treewidth of f_F . Expression treewidth strictly dominates incidence treewidth [JS12]. Courcelle's meta-theorem [Cou88] can be used to show that $\mathbf{SAT}(\mathbf{xtw})$ is fixed-parameter tractable if the circuit D with minimal treewidth is provided as the input. Bova and Szeider [BS17] have shown that $\mathbf{VER}(\mathbf{xtw})$ is at least decidable, using a meta-theorem by Seese [See91]. It would be interesting to know more efficient algorithms for this problem.

17.5.4. Tree Decomposition Algorithms

As for most algorithms, also in the case of computing tree decompositions, there has to be a tradeoff made between runtime, space requirement, and simplicity. In the following, we use n to denote the number of vertices of the given graph. The current fastest exact tree decomposition algorithm runs in time $\mathcal{O}^*(1.8899^n)$ and is due to Fomin, Kratsch, and Todinca [FKT04] and Villanger [Vil06]. This algorithm is based on the computation of potential maximal cliques. Bodlaender et al. [BFK⁺06] developed a simpler algorithm based on a recursive divide-and-conquer technique that requires polynomial space and runs in time $\mathcal{O}^*(4^n)$. For special classes of graphs, however, there exist exact tree decomposition algorithms that run in polynomial (or even linear) time [Bod93].

Polynomial-time algorithms also exist in the case of bounded treewidth. These algorithms are fixed-parameter algorithms: Reed's algorithm [Bod93, Ree92] decides in time $\mathcal{O}(n \log n)$ whether the treewidth of a graph is at most k and, if so, computes a tree decomposition of width at most $3k + 2$. Bodlaender and Kloks [BK96] developed an algorithm with the same asymptotic runtime as Reed's algorithm that decides whether the treewidth of a graph is at most k and, if so, computes a tree decomposition of width at most k . Bodlaender [Bod96] improved this result to a linear-time algorithm. The hidden constant factors in the runtime of the latter two algorithms, however, are very large so that they are only practical for very small k (e.g., up to $k = 5$) [BK96, Bod05].

Algorithms that approximate treewidth by finding tree decompositions of *nearly* minimal width give a guarantee on the quality of the output. Bodlaender et al. [BDD⁺16] gave a single exponential algorithm that runs in $2^{\mathcal{O}(k)}n$ time, and either outputs a tree decomposition of the given graph G of width at most $5k + 4$, or determines that $\text{tw}(G) > k$.

In practice, it often suffices to obtain tree decompositions of small width without any guarantees. There exist several powerful tree decomposition heuristics for this purpose. In the worst case, the width of tree decompositions obtained by such heuristics can be far from treewidth; however, their width is often small in practically relevant cases. An important class of tree decomposition heuristics is based on finding an appropriate linear ordering of the vertices from which

a tree decomposition can be constructed [Bod05]. *Minimum degree* and *minimum fill-in* [Bod05], *lexicographic breadth-first search* [RTL76], and *maximum cardinality search* [TY84] are well-known examples of such ordering heuristics. Koster, Bodlaender, and van Hoesele [KBvH01a, KBvH01b] compared several tree decomposition heuristics by empirical evaluation.

We refer the interested reader to Bodlaender's excellent survey papers [Bod93, Bod05] for a more extensive overview of tree decomposition algorithms.

One can also use SAT solvers to determine the treewidth of graphs. Samer and Veith [SV09] gave a first SAT encoding, that, given a graph G and an integer k , produces a CNF formula $F(G, k)$ which is satisfiable if and only if $\text{tw}(G) \leq k$. This approach was further improved [BJ14, BBE17], as well as used to improve a heuristically computed tree decomposition locally [FLS17].

17.5.5. Beyond Treewidth

Beside treewidth, other decomposition-based measures for the tractability of certain computation problems with graph and hypergraph representations have been proposed in the literature. One of the most prominent examples is *clique-width* [CER93]. Intuitively, the clique-width $\text{cwd}(G)$ of a graph G is the smallest number of colors required to construct the graph by means of certain operations that do not distinguish between vertices of the same color. Clique-width is defined for undirected graphs and directed graphs. Let \underline{D} be the undirected graph obtained from a directed graph D by ignoring the orientation of edges. Then $\text{cwd}(\underline{D}) \leq \text{cwd}(D)$.

Bounding the clique-width of primal graphs does not help with deciding satisfiability: one can easily make the primal graph a clique as follows: Let F be a CNF formula and x a new variable not occurring in F . Now consider the CNF formula F^* obtained from F by adding the two clauses $C = \text{var}(F) \cup \{x\}$ and $C' = \{\bar{x}\}$. Clearly F and F^* are equisatisfiable and even share the same number of models. Now the primal graph of F^* is a clique and so it has clique-width 2. For the incidence graph, however, bounding the clique-width helps, as we shall see below.

We distinguish between $\mathbf{cwd}^*(F) = \text{cwd}(G^*(F))$ and $\mathbf{dcwd}^*(F) = \text{cwd}(D^*(F))$. From results by Courcelle and Olariu [CO00] it follows that \mathbf{cwd}^* strictly dominates \mathbf{dcwd}^* , and \mathbf{dcwd}^* strictly dominates \mathbf{tw}^* . The problems $\mathbf{VER}(\mathbf{cwd}^*)$ and $\mathbf{VER}(\mathbf{dcwd}^*)$ are not known to be fixed-parameter tractable, but fixed-parameter approximable [Oum05, FMR08].

Theorem 17.5.6 ([OPS13]). *The problem $\mathbf{SAT}(\mathbf{cwd}^*)$ is $W[1]$ -hard.*

This hardness even holds if the corresponding decomposition is provided with the input.

Theorem 17.5.7 ([SS13]). *$\#\mathbf{SAT}(\mathbf{cwd}^*)$ is XP-tractable.*

This result is obtained by a dynamic programming algorithm in which certain projections of truth assignments play an important role. Such projections have already been used previously for showing XP-tractability of $\#\mathbf{SAT}$ for the satisfiability parameter *modular treewidth* [PSS16] which is the treewidth of the

incidence graph, taken after the contraction of modules (i.e., of vertices with the same neighbors). Modular treewidth strictly dominates treewidth and is, in turn, strictly dominated by clique-width. Sæther et al. [STV15] generalized the algorithm underlying Theorem 17.5.7 to be applicable to larger classes of formulas, however, requiring the corresponding decomposition to be provided with the input.

Theorem 17.5.8 ([CMR01, FMR08]). $\#\text{SAT}(\text{dcwd}^*)$ is fixed-parameter tractable.

The fixed-parameter tractability of $\#\text{SAT}(\text{dcwd}^*)$ follows from meta-theorem of monadic second-order logic [CMR01] similarly as in the case of treewidth. Also a direct dynamic programming algorithm is known [FMR08]. For computing clique-width decompositions of (directed) incidence graphs one can use SAT-encodings [HS15, Par16].

Rank-width [RS86] is a graph invariant that is similar to clique-width and can also be defined for directed and undirected incidence graphs. The corresponding satisfiability parameters are domination equivalent with directed and undirected clique-width, respectively. For satisfiability checking and model counting, directed rank-width has an advantage over dcwd^* since the corresponding verification problem is known to be fixed-parameter tractable and so one saves the approximation error. Moreover, even if optimal clique-width or rank-width decompositions are provided, the rank-width based algorithm can be exponentially faster than the clique-width based algorithm [GHO13].

Generalizations of treewidth like hypertree-width [GLS02], spread-cut width [CJG08], and fractional hypertree-width [GM06] are defined for hypergraphs in the context of constraint satisfaction and conjunctive database queries. According to the current status of knowledge, they have no relevance for the satisfiability problem of CNF formulas [SS10a]. This can be seen, using the simple construction we considered at the beginning of Section 17.5.5: the hypergraph $H(F^*)$ is acyclic [GLS02], and so hypertree-width, spread-cut width, and fractional hypertree-width of $H(F^*)$ are 1. A similar construction can be made with respect to the dual hypergraph $H^d(F)$ [SS10a].

17.6. Further Satisfiability Parameters

In this section, we will discuss further satisfiability parameters that are (i) based on a combination of backdoor sets and treewidth, (ii) based on a community structure in the formula, and (iii) based on matchings in the incidence graph of the formula.

17.6.1. Hybrid Satisfiability Parameters

The general approaches to satisfiability parameters as discussed in the previous two sections (based on backdoors and decompositions, respectively) are complementary. Take, for instances \mathbf{b}_{HORN} (size of a smallest strong HORN-backdoor) and tw^* (treewidth of the incidence graph). The two satisfiability parameters are incomparable, as one can construct Horn formulas of arbitrarily large incidence

treewidth (i.e., \mathbf{b}_{HORN} is 0 and \mathbf{tw} is unbounded), and formulas of arbitrarily large \mathbf{b}_{HORN} and bounded primal treewidth.

Several ways for combining the strengths of the two approaches have been considered which we will briefly discuss.

Strong Backdoors into Bounded Incidence Treewidth Gaspers and Szeider [GS13] considered strong $\mathcal{W}_{\leq t}$ -backdoor sets where $\mathcal{W}_{\leq t}$ consists of all CNF formulas F with $\mathbf{tw}^*(F) \leq t$, where $t > 0$ is a fixed constant. $\mathcal{W}_{\leq t}$ is suitable as a base class (Theorem 17.5.2), even $\#\text{SAT}$ is polynomial-time tractable for $\mathcal{W}_{\leq t}$. For $t = 1$ we obtain the base class **FOREST** discussed above. It is crucial to consider strong backdoor sets, not just deletion backdoor sets, as $\mathbf{db}_{\mathcal{W}_{\leq t}}$ is easily seen to be dominated by \mathbf{tw}^* , whereas $\mathbf{b}_{\mathcal{W}_{\leq t}}$ strictly dominates \mathbf{tw}^* [GS13]. When we know a strong $\mathcal{W}_{\leq t}$ -backdoor set of size k of a formula F , we can compute $\#(F)$ in $\mathcal{O}^*(2^k)$ time. The main problem is finding such a backdoor set, i.e., $\mathbf{VER}(\mathbf{b}_{\mathcal{W}_{\leq t}})$. Gaspers and Szeider [GS13] showed that this problem is fixed-parameter approximable, which implies the following result.

Theorem 17.6.1 ([GS13]). *For every $t \geq 1$, $\#\text{SAT}(\mathbf{b}_{\mathcal{W}_{\leq t}})$ is fixed-parameter tractable.*

By adjusting t and backdoor set size, one can fine-tune the algorithm behind Theorem 17.6.1 to a particular class of input formulas. Fomin et al. [FLM⁺15] considered the problems $\mathbf{SAT}(\mathbf{wb}_{\mathcal{W}_{\leq t}})$ and $\mathbf{SAT}(\mathbf{b}_{\mathcal{W}_{\leq t}})$ for the special case where the input is an r -CNF formula for an arbitrary constant r . They showed that the corresponding permissive problems are fixed-parameter tractable. Their algorithms avoid the computation of a fixed-parameter approximation and achieves a single exponential running time.

Backdoor Treewidth Next we consider an approach due to Ganian et al. [GRS17b, GRS17a], where one considers not the size of a smallest strong \mathcal{C} -backdoor set of a given CNF formula F as the parameter, but the treewidth of a strong \mathcal{C} -backdoor set of smallest treewidth. The treewidth of a strong \mathcal{C} -backdoor set B is taken in terms of a *torso graph* G_F^B . The vertices of G_F^B are the variables in B , and an edge connects two variables $x, y \in B$ if and only if the incidence graph $G^*(F)$ contains a path between x and y that does not traverse any vertex in X (except x and y). Thus, the torso graph is obtained by “collapsing” (possibly large parts of) the incidence graph to single edges. The *\mathcal{C} -backdoor treewidth* of F , denoted $\mathbf{tw}_{\mathcal{C}}(F)$, is the smallest $\mathbf{tw}(G_F^B)$ over all strong \mathcal{C} -backdoor sets B of F . Figure 17.6 shows an example for this construction. We note that, in general, a strong \mathcal{C} -backdoor set B of F with smallest $\mathbf{tw}(G_F^B)$ might not be among the smallest strong \mathcal{C} -backdoor sets of F . In the following we focus on base classes $\mathcal{C} \in \{\text{HORN}, \text{HORN}^{-1}, 2\text{CNF}\}$.

If we know a strong \mathcal{C} -backdoor set B with $\mathbf{tw}(G_F^B) = k$, we can compile connected components of $G^*(F) - B$ into constraints, and so represent F by an equisatisfiable Boolean CSP instance over the variables B , whose primal treewidth is k . Solving this CSP instance is fixed-parameter tractable parameterized by k [GSS02]. Hence again, the challenging task is to find the set B , which was shown by Ganian et al. [GRS17a] to be fixed-parameter tractable:

Figure 17.6. Top: an example of a formula F , drawn by its incidence graph, where positive occurrences of variables are indicated with bold edges. $B = \{v, w, x, y, z\}$ forms a strong HORN-backdoor set of F . Bottom: the torso graph G_F^B , which is a path and has, therefore, treewidth 1. Consequently, the HORN-backdoor treewidth is $\mathbf{b}_{\text{HORN}}(F) = 1$.

Theorem 17.6.2 ([GRS17a]). *For $\mathcal{C} \in \{\text{HORN}, \text{HORN}^-, 2\text{CNF}\}$, the problems $\text{VER}(\text{tw}_{\mathcal{C}})$ and $\text{SAT}(\text{tw}_{\mathcal{C}})$ are fixed-parameter tractable.*

17.6.2. Modularity

Networks that arise from real-world applications frequently exhibit a certain *community structure*, where nodes form strongly interconnected communities which are sparsely connected with each other. With the notion of *modularity* [New03, New06, NG04, ZPWL13] one can measure to what extent a network exhibits such a structure. It was empirically observed, that the performance of SAT solvers shows some correlation with the modularity of the input formulas [ABGL14, NGF⁺14]. However, the presence of a community structure is not a guarantee for a formula to be tractable. In fact, it is not difficult to show that SAT remains NP-hard for highly modular instances [GS15, MFS16]. Based on this observation, Ganian and Szeider proposed the satisfiability parameter *h-modularity* which is inspired by the general concept of modularity, but in contrast to the existing notion does provide performance guarantees for SAT decision and even model counting. This satisfiability parameter is based on the splitting of the clauses of a given formula into classes, called *h-communities*, where each class is a hitting formula (see Section 17.4.4), and therefore strongly interconnected. The *h-communities* are only sparsely connected with each other, as the graph representing their interconnection (the *community graph*) as small treewidth.

More specifically, we call a subset H of a formula F to be a *hitting community* (or *h-community* in brief) in F if H is a hitting formula. The *degree* $\deg(H)$ of an *h-community* H is the number of edges in the dual graph of F between a clause in H and a clause outside of H . A *hitting community structure* (or *h-structure* in brief) \mathcal{P} is a partitioning of F into *h-communities*, and the degree $\deg(\mathcal{P})$ of \mathcal{P} is $\max\{\deg(H) : H \in \mathcal{P}\}$.

To measure the treewidth of an *h-structure* \mathcal{P} , we construct a *community graph* $G(\mathcal{P})$ as follows. The vertices of $G(\mathcal{P})$ are the *h-communities* in \mathcal{P} , and two vertices A, B in $G(\mathcal{P})$ are joined by an edge if and only if there exist clauses $C \in A$ and $D \in B$ which are adjacent.

Figure 17.7. The dual graph (left) and community graph (right) of the formula F and the h-structure \mathcal{P} .

We define the *h-modularity* of an h-structure \mathcal{P} as the maximum over $\deg(\mathcal{P})$ and $\text{tw}(G(\mathcal{P}))$. The h-modularity $\mathbf{h-mod}(F)$ of a formula F is then defined as the minimum $\mathbf{h-mod}(\mathcal{P})$ over all h-structures \mathcal{P} of F .

Example 17.6.1. Consider the formula F which can be split into h-communities $H_1 = \{\{x, y, \neg a\}, \{\neg x, y, a\}, \{x, \neg y\}, \{\neg x, \neg y\}\}$, $H_2 = \{\{a, b, c\}, \{\neg b\}\}$, $H_3 = \{\{c, \neg d, e, f\}, \{d, \neg e\}\}$, $H_4 = \{\{f, \neg g, \neg h\}, \{h, \neg i\}\}$, $H_5 = \{\{i, \neg j\}, \{j, k, l, \neg m, \neg n\}\}$, and $H_6 = \{\{u, \neg v, g, \neg k, l, m, \neg n\}, \{u, v, \neg l, \neg u, v\}\}$. Figure 17.7 (left) shows the dual graph of F with the h-communities indicated. Figure 17.7 (right) shows the corresponding community graph, which is of treewidth 2. The h-communities H_1 and H_3 have degree 2, and all other h-communities have degree 3. Therefore the h-modularity of F is at most $\max(3, 2) = 3$. \square

Once we know a community structure \mathcal{P} of a CNF formula F , then we can solve **SAT** and **#SAT** by a fixed-parameter algorithm for parameter $\mathbf{h-mod}(\mathcal{P})$ by compiling it into an instance of the Sum-of-Products problems (the counting version of CSP), and solve it using known results [BDP09, GKSS18]. For actually finding a community structure \mathcal{P} of small h-modularity, we know a fixed-parameter approximation algorithm [GS15].

Theorem 17.6.3 ([GS15]). *The problem $\mathbf{\#SAT}(\mathbf{h-mod})$ is fixed-parameter tractable.*

17.6.3. Matchings

A *matching* in a graph is a set of edges such that every vertex is incident with at most one edge of the matching. A CNF formula is called *matched* if its incidence graph has a matching such that all clauses are incident with an edge of the matching. Matched formulas are always satisfiable since one can satisfy each clause independently by choosing the right truth value for the variable that is associated with it via the matching.

Example 17.6.2. Consider the CNF formula $F = \{C_1, \dots, C_4\}$ with $C_1 = \{v, y, z\}$, $C_2 = \{\bar{y}, \bar{x}\}$, $C_3 = \{\bar{v}, \bar{z}, w\}$, $C_4 = \{y, x, \bar{w}\}$. The set $M = \{vC_1, yC_2, zC_3, xC_4\}$ is a matching in the incidence graph of F that covers all clauses. Hence F is a matched formula and it is indeed satisfiable: we put $\tau(v) = 1$ to satisfy C_1 , $\tau(y) = 0$ to satisfy C_2 , $\tau(z) = 0$ to satisfy C_3 , and $\tau(x) = 1$ to satisfy C_4 . \square

The notion of *maximum deficiency* (first used by Franco and Van Gelder [FV03] in the context of CNF formulas) allows to gradually extend the nice properties from matched formulas to more general classes of formulas. The maximum deficiency of a formula F , denoted by $\mathbf{md}(F)$, is the number of clauses remaining uncovered by a largest matching of the incidence graph of F . The parameters \mathbf{md} and \mathbf{tw}^* are domination incomparable [Sze04b]. The term “maximum deficiency” is motivated by the equality

$$\mathbf{md}(F) = \max_{F' \subseteq F} \mathbf{d}(F')$$

which follows from Hall’s Theorem. Here $\mathbf{d}(F')$ denotes the *deficiency* of F' , the difference $|F'| - |\text{var}(F')|$ between the number of clauses and the number of variables. The problem $\mathbf{VER}(\mathbf{md})$ can be solved in polynomial time, since a largest matching in a bipartite graph can be found in polynomial time through Hopcroft and Karp’s algorithm [HK73, LP86] (and the number of uncovered clauses remains the same whatever largest matching one considers).

Deficiency and maximum deficiency have been studied in the context of *minimal unsatisfiable formulas*, i.e., unsatisfiable formulas that become satisfiable by removing any clause. Let \mathbf{MU} denote the recognition problem for minimal unsatisfiable formulas. By a classic result of Papadimitriou and Wolfe [PW88], the problem \mathbf{MU} is DP-complete; DP is the class of problems that can be considered as the difference of two problems in NP and corresponds to the second level of the Boolean Hierarchy [Joh90]. Kleine Büning [Kle00] initiated the study of \mathbf{MU} parameterized by the deficiency \mathbf{d} . Since $\mathbf{d}(F) = \mathbf{md}(F) \geq 1$ holds for minimal unsatisfiable formulas F [AL86], algorithms for $\mathbf{SAT}(\mathbf{md})$ are of relevance. Fleischer et al. [FKS02] have shown that one can decide the satisfiability of formulas with maximum deficiency bounded by a constant in polynomial time.

As a consequence, minimal unsatisfiable formulas with deficiency bounded by a constant can be recognized in polynomial time. The order of the polynomial that bounds the running time of Fleischer et al.’s algorithm depends on k ; hence, it only establishes that $\mathbf{SAT}(\mathbf{md})$ and $\mathbf{MU}(\mathbf{d})$ are in XP. Szeider [Sze04a] developed an algorithm that decides satisfiability and minimal unsatisfiability of formulas with maximum deficiency k in time $\mathcal{O}^*(2^k)$, thus establishing the following result.

Theorem 17.6.4 ([Sze04a]). *The problems $\mathbf{SAT}(\mathbf{md})$ and $\mathbf{MU}(\mathbf{d})$ are fixed-parameter tractable.*

Key for Szeider’s algorithm is a polynomial-time procedure that either decides the satisfiability of a given formula F or reduces F to an equisatisfiable formula F^* with $\mathbf{md}(F^*) \leq \mathbf{md}(F)$, such that

$$\mathbf{md}(F^*[x = 0]) < \mathbf{md}(F^*) \text{ and } \mathbf{md}(F^*[x = 1]) < \mathbf{md}(F^*) \text{ for all } x \in \text{var}(F^*);$$

a formula F^* with this property is called *\mathbf{md} -critical*. In particular, a formula is \mathbf{md} -critical if every literal of F^* occurs in at least two clauses and for every non-empty set X of variables of F^* there are at least $|X| + 2$ clauses C of F^* such that $\text{var}(C) \cap X \neq \emptyset$. The above reduction is applied at every node of a (DPLL-type) binary search tree. Since at every step from a node to one of its

children the maximum deficiency of the formula gets reduced, it follows that the height of the search tree is bounded in terms of the maximum deficiency of the given formula, yielding the fixed-parameter tractability of **SAT**(**md**).

Let r be a positive integer and let \mathcal{M}_r denote the class of formulas F with $\mathbf{md}(F) \leq r$. Since both recognition and satisfiability of formulas in \mathcal{M}_r can be solved in polynomial time and, since \mathcal{M}_r is clause induced, it makes sense to consider \mathcal{M}_r as the base class for strong and deletion backdoor sets. However, such backdoor sets are difficult to find:

Theorem 17.6.5 ([Sze08]). *The problems $\mathbf{VER}(\mathbf{b}_{\mathcal{M}_r})$ and $\mathbf{VER}(\mathbf{db}_{\mathcal{M}_r})$ are $W[2]$ -hard for every $r \geq 1$.*

17.7. Concluding Remarks

We close this chapter by briefly mentioning further research on the parameterized complexity of problems related to propositional satisfiability.

For example, Fellows, Szeider and Wrightson [FSW06] have studied the problem of finding in a given CNF formula F a *small unsatisfiable subset* S parameterized by the number of clauses of S . The problem is $W[1]$ -complete, but fixed-parameter tractable for several classes of CNF formulas, including formulas with planar incidence graphs and formulas with both clause size and occurrence of variables bounded. $W[1]$ -hardness prevails if the input formula is Horn [dHKS17]. This is in stark contrast to the case where the input is a 2CNF formula; then the problem can be solved even in polynomial time [BM07].

Propositional proof complexity is a further area of research that is related to satisfiability and admits parameterizations. In particular, one can study proofs that establish that a given CNF formula cannot be satisfied by setting at most k variables to true; k is considered as the parameter. Dantchev, Martin, and Szeider [DMS11] have studied the proof complexity of resolution for such “parameterized contradictions,” with very interesting follow-up work [ABdR⁺18, BGLR12].

Another promising line of research that connects parameterized complexity with SAT solving is the exploration of *fixed-parameter tractable reductions to SAT*. The idea is to solve problems that are believed to be harder than NP (e.g., problems from the second level of the Polynomial Hierarchy) by a fixed-parameter algorithm that can call a SAT solver as an auxiliary device. Such algorithms were developed for disjunctive answer-set programming and propositional abduction problems [PRS13, FS15]. De Haan and Szeider [dHS17, dHS19] developed a parameterized hardness theory for such problems which lies the grounds for classifying problems that admit such fixed-parameter tractable reductions to SAT, and those that don’t.

We hope that this survey provides a stimulating starting point for further research on satisfiability and related topics that fruitfully utilizes concepts of parameterized complexity theory.

Chapter 18

Bounded Model Checking

Armin Biere

Besides Equivalence Checking [KK97, KPKG02] the most important industrial application of SAT is currently Bounded Model Checking (BMC) [BCCZ99]. Both techniques are used for *formal* hardware verification in the context of electronic design automation (EDA), but have successfully been applied to many other domains as well. In this chapter, we focus on BMC.

In practice, BMC is mainly used for falsification resp. testing, which is concerned with violations of temporal properties. However, the original paper on BMC [BCCZ99] already discussed extensions that can prove properties. A considerable part of this chapter discusses these complete extensions, which are often called “unbounded” model checking techniques, even though they are build upon the same principles as plain BMC.

Two further related applications, in which BMC becomes more and more important, are automatic test case generation for closing coverage holes, and disproving redundancy in designs. Most of the techniques discussed in this chapter transfer to this more general setting as well, even though our focus is on property verification resp. falsification.

The basic idea of BMC is to represent a counterexample-trace of bounded length symbolically and check the resulting propositional formula with a SAT solver. If the formula is satisfiable and thus the path feasible, a satisfying assignment returned by the SAT solver can be translated into a concrete counterexample trace that shows that the property is violated. Otherwise, the bound is increased and the process repeated. Complete extensions to BMC allow to stop this process at one point, with the conclusion that the property cannot be violated, hopefully before the available resources are exhausted.

18.1. Model Checking

The origins of model checking go back to the seminal papers [CE82] and [QS82]. Clarke, Emerson and Sifakis won the 2007 Turing Award for their pioneering work on model checking. A workshop affiliated to the Federated Conference on Logic in Computer Science (FLOC’06) celebrated the 25th anniversary of model checking. The proceedings [VG08] of this workshop and *the* model checking book

[CGP99] are good starting points to learn about model checking. A more recent survey [PBG05] adds a perspective on SAT-based model checking.

In this chapter, we focus on SAT-based symbolic model checking [McM93], which originally relied on binary decision diagrams (BDDs) [Bry86] to symbolically represent systems. Operations on system states can then be mapped to BDD operations. In practice, BDDs can handle circuits with hundreds of latches, but often blow up in space.

BMC [BCCZ99] was an attempt to replace BDDs with SAT in symbolic model checking. However, SAT lacks the possibility to eliminate variables, which is a key operation in BDD-based model checking. The solution in BMC is to focus on falsification and, at least in a first approximation, drop completeness. This paradigm shift was hard to convey originally, but was accepted at the end, since SAT-based model checking, at least for falsification, scales much better [Kur08].

Another important direction in model checking is explicit state model checking. The SPIN model checker [Hol04] is the most prominent explicit state model checker and is mainly used for checking protocols. It draws its main power from partial order reduction techniques such as [Pel94]. Related techniques exist in BMC as well, see for instance [Hel01, JHN03]. However, for the rest of this chapter we focus on symbolic techniques for synchronous systems, for which partial order techniques do not seem to apply.

The first decade¹ of research in model checking witnessed a heated debate on which specification formalism is more appropriate: linear time logic versus branching time logic. Commonly only computation tree logic (CTL) [CE82], a branching time logic, and linear time logic (LTL) [Pnu77] are used. Originally, LTL was called propositional temporal logic (PTL) as a special case of “full” first-order temporal logic. However, nowadays LTL without further qualification is solely used for propositional linear temporal logic. Also note that PTL is also an acronym for past time (propositional) linear temporal, see for instance [BHJ⁺06].

LTL is arguably easier to understand and use, but at least in theory, LTL is harder [SC85] to check than CTL. If the system is represented symbolically, there is actually no difference as both problems are PSPACE complete [SC85, Sav70, PBG05]. Specifications in practice are typically in the intersection [Mai00] between LTL and CTL. If we restrict ourself to properties in the intersection, the problem of choosing between LTL and CTL boils down to which model checking algorithm to use. In this respect, BDD-based model checking has a slight bias towards CTL, whereas SAT-based model checking has a bias towards LTL. Thus, we mainly focus on LTL in the rest of this chapter. Further details on temporal logic and its history can be found in [Eme90, Var08].

18.1.1. LTL

As first promoted by Pnueli [Pnu77], temporal logic is an adequate specification formalism for concurrent resp. reactive systems. The syntax of the linear temporal logic LTL contains propositional boolean variables V , temporal operators and the usual propositional operators, including negation \neg and conjunction \wedge . Typical

¹A similar discussion took place in the recent process of standardizing temporal logic in the form of System Verilog Assertions (SVA) and the Property Specification Logic (PSL).

temporal operators are the “next time” operator **X**, the “finally” operator **F**, and the “globally” operator **G**.

Examples of temporal formulas are as follows: $a \rightarrow \mathbf{X}b$ means the property b has to hold in the next time instance, unless a does not hold now. With **X** alone only properties about a finite future around the initial state can be specified. The other temporal operators allow to extend this finite view, and specify infinite behavior. The “globally” operator **G** allows to specify *safety properties* in form of invariants or assertions that need to hold in all reachable states. For instance, $\mathbf{G}\neg(a \wedge b)$ specifies mutual exclusion of a and b . The only *liveness* operator we consider, the “finally” operator, describes necessary behavior, e.g. $\mathbf{G}(a \rightarrow \mathbf{F}b)$, which requires each a to be followed by b . More verbosely, the following invariant holds: if a is true then at the same time or later b has to hold, i.e. b cannot be postponed forever, after a has been assured. This is an invariant with a (potentially) liveness condition attached.

The interpretation of propositional variables may change over time but is uniquely determined by the current state of the model. This correspondence is captured via a labelling function $L: S \rightarrow \mathbb{P}(V)$, where S is the set of states. A propositional variable p is true in a system state s iff $p \in L(s)$. Beside the set of states S , a model has a set $I \subseteq S$ of initial states, and a transition relation $T \subseteq S \times S$. Such a model is also called *Kripke structure*. Often only models isomorphic to the set of interpretations of the boolean variables V are considered: then $S = \mathbb{P}(V)$ and $L(V') = V'$ for all “states” $s = V' \subseteq V$. A typical example are models of synchronous circuits, where V is the set of latches and input signals, and optionally includes output and internal signals as well. In the following, we fix one Kripke structure $K = (S, I, T, L)$ over the variables V .

The transition relation T is assumed to be total and the set I of initial states to be nonempty. As in the previous example, the transition relation is in general represented symbolically, e.g. as a circuit or a formula. In the following we simply write $T(s, s')$ for this formula, with the interpretation that $T(s, s')$ holds iff there is a transition from s to s' , also written as $s \rightarrow s'$. Note that s is simply a vector of all variables V in the current state and s' a vector of their primed copies in the successor state. We use a similar interpretation for $I(s)$.

The semantics of LTL are defined along paths of the model. A path π is an infinite sequence of states $\pi = (s_0, s_1, s_2, \dots)$, with $s_i \rightarrow s_{i+1}$. A path π is initialized if its first state $\pi(0) = s_0$ is an initial state. In the following, we also use the same notation to refer to single states of a path, e.g. $\pi(i) = s_i$ with $i \in \mathbb{N} = \{0, 1, 2, \dots\}$. A suffix of a path is defined as $\pi^i = (s_i, s_{i+1}, \dots)$. We now give a simplified² version of the standard (unbounded) semantics, defined recursively over the formula structure. An LTL formula f holds along a path π , written $\pi \models f$, iff

$$\begin{array}{llll} \pi \models p & \text{iff } p \in L(\pi(0)) & \pi \models \neg p & \text{iff } p \notin L(\pi(0)) \\ \pi \models g \vee h & \text{iff } \pi \models g \text{ or } \pi \models h & \pi \models g \wedge h & \text{iff } \pi \models g \text{ and } \pi \models h \\ \pi \models \mathbf{F}g & \text{iff } \exists j \in \mathbb{N}: \pi^j \models g & \pi \models \mathbf{G}g & \text{iff } \forall j \in \mathbb{N}: \pi^j \models g \\ \pi \models \mathbf{X}g & \text{iff } \pi^1 \models g & & \end{array}$$

²In particular we do not treat the “until” operator to make the following encoding easier to explain. The full semantics and its encoding can be found in [BHJ+06].

Figure 18.1. A (k, l) -lasso with $k = 5, l = 2$.

Here we assume that the formula is in negation normal form (NNF), i.e. negations are pushed down to the variables, with the help of the following axioms of LTL:

$$\neg(g \wedge h) \equiv (\neg g) \vee (\neg h) \quad \neg \mathbf{F}g \equiv \mathbf{G}\neg g \quad \neg \mathbf{G}g \equiv \mathbf{F}\neg g \quad \neg \mathbf{X}g \equiv \mathbf{X}\neg g$$

Finally, a formula f holds in a Kripke structure K , written $K \models f$, iff $\pi \models f$ for all initialized paths π of K . The model checking problem is to determine whether $K \models f$ holds. Related to the model checking problem is the question of the existence of a witness: a formula f has a witness in K iff there is an initialized path π with $\pi \models f$. Clearly $K \models f$ iff $\neg f$ does not have a witness in K . Therefore, we can reduce the model checking problem to the search for witnesses using negation and translation into NNF.

18.2. Bounded Semantics

First observe that some infinite paths can be represented by a finite prefix with a loop: an infinite path π is a (k, l) -lasso, iff $\pi(k + 1 + j) = \pi(l + j)$, for all $j \in \mathbb{N}$. In this case, π can actually be represented as $\pi = \pi_{\text{stem}} \cdot (\pi_{\text{loop}})^\omega$, as shown in Fig. 18.1.

As LTL enjoys a small model property [LP85], the search for witnesses can be restricted to lassos, if K is finite. See [BCCZ99, CKOS05] for more details. Let us rephrase the unbounded semantics by fixing the path π , but working with different suffixes π^i of π .

$$\begin{aligned} \pi^i \models p & \quad \text{iff} \quad p \in L(\pi(i)) & \quad \pi^i \models \neg p & \quad \text{iff} \quad p \notin L(\pi(i)) \\ \pi^i \models g \vee h & \quad \text{iff} \quad \pi^i \models g \text{ or } \pi^i \models h & \quad \pi^i \models g \wedge h & \quad \text{iff} \quad \pi^i \models g \text{ and } \pi^i \models h \\ \pi^i \models \mathbf{F}g & \quad \text{iff} \quad \exists j \in \mathbb{N}: \pi^{i+j} \models g & \quad \pi^i \models \mathbf{G}g & \quad \text{iff} \quad \forall j \in \mathbb{N}: \pi^{i+j} \models g \\ \pi^i \models \mathbf{X}g & \quad \text{iff} \quad \pi^{i+1} \models g \end{aligned}$$

To obtain “bounded semantics” we only look at the first $k + 1$ states and let i range over $0 \dots k$. If π is a (k, l) -lasso then $\pi^{k+1+j} = \pi^{l+j}$ for all $j \in \mathbb{N}$ and we get the following “bounded semantics” for lassos:

$$\begin{aligned} \pi^i \models \mathbf{F}g & \quad \text{iff} \quad \exists j \in \{\min(i, l), \dots, k\}: \pi^j \models g \\ \pi^i \models \mathbf{G}g & \quad \text{iff} \quad \forall j \in \{\min(i, l), \dots, k\}: \pi^j \models g \\ \pi^i \models \mathbf{X}g & \quad \text{iff} \quad \begin{cases} \pi^{i+1} \models g & \text{if } i < k \\ \pi^l \models g & \text{if } i = k \end{cases} \end{aligned}$$

For $\mathbf{G}g$ to hold on π^i , the body g has to hold at the current position i and of course at all larger positions j , with $i \leq j \leq k$. However, if the current position

i is in the loop, then g also has to hold from the loop start up to i . Using the minimum over the current position i and the loop start l covers both cases, no matter whether i is in the loop or still in the stem of π . A similar argument applies to $\mathbf{F}g$.

Now assume that π is *not* a (k, l) -lasso for any l . Then the suffix π^{k+1} of π can have an arbitrary shape. Looking only at the first $k + 1$ states of π is in general not enough to determine whether a formula holds along π , e.g. the “bounded semantics” can only be an approximation. Still the following but only sufficient conditions hold:

$$\begin{aligned} \pi^i \models \mathbf{F}g & \quad \text{if } \exists j \in [i \dots k]: \pi^j \models g \\ \pi^i \models \mathbf{X}g & \quad \text{if } \pi^{i+1} \models g \text{ and } i < k \end{aligned}$$

These early termination criteria are useful for providing counterexamples for pure safety formulas or to more general specifications with a safety part. For instance, in order to falsify the safety property $\mathbf{G}p$, we need to find a witness for $\mathbf{F}\neg p$. If p does not hold in some initial state s in K , then $k = 0$ is sufficient. All paths starting from s are actually witnesses, even if none of them is a $(0, 0)$ -loop.

If π is not a (k, l) -lasso for any l and we do not want to examine the suffix beyond the bound k , then we cannot conclude anything about $\pi^k \models \mathbf{X}g$ nor $\pi^i \models \mathbf{G}g$ for any $i < k$. This conservative approximation avoids reporting spurious witnesses. In propositional encodings of potential witnesses, we have to replace such LTL formulas by \perp , where \perp (\top) represents the boolean constant *false* (*true*).

18.3. Propositional Encodings

The bounded approximations of LTL semantics discussed above consider only the first $k + 1$ states of π . This is the key to obtain a propositional encoding of the LTL witness problem into SAT.

Assume that we have a symbolic representation of K and let s_0, \dots, s_k be vectors of copies of the state variables, i.e. for each time frame i , there is one copy V_i of V . Further let p_i denote the copy of p in time frame i . All encodings of the LTL witness problem include model constraints:

$$I(s_0) \wedge T(s_0, s_1) \wedge \dots \wedge T(s_{k-1}, s_k)$$

Looping constraints for $l \in \{0, \dots, k\}$ are added:

$$\lambda_l \rightarrow T(s_k, s_l)$$

We further assume that “at most” one λ_l holds. This cardinality constraint can be encoded with a circuit linear in k , for instance via Tseitin transformation [Tse68] of a BDD for this function.³

These constraints are always assumed. In particular, if the propositional encoding is satisfiable, the satisfying assignment can be interpreted as a prefix of

³Note that cardinality constraints and particularly at most constraints as in this case are symmetric functions, for which the variable order of the BDD does not matter: all reduced ordered BDDs (ROBDDs) for a specific symmetric function are isomorphic.

an initialized path π of K . If λ_l is assigned to \top then π is a (k, l) -loop. What remains to be encoded are the semantics of LTL, in order to make sure that π extracted from a satisfying assignment is indeed a witness.

18.3.1. Original Encoding

The original encoding [BCCZ99] of the witness problem of LTL into SAT, is a straightforward encoding of the reformulations resp. the bounded semantics. It can be implemented as a recursive procedure that takes as parameters an LTL formula f , a fixed bound k , the loop start l , and the position i . The last two parameters range between 0 and k . Let us denote with ${}_i[f]_k^i$ the resulting propositional formula obtained by encoding f for these parameters. First we make sure, by enforcing the model and looping constraints, that the symbolically represented path is a (k, l) -loop:

$$\begin{aligned} {}_i[p]_k^i &\equiv p_i & {}_i[\neg p]_k^i &\equiv \neg p_i \\ {}_i[g \vee h]_k^i &\equiv {}_i[g]_k^i \vee {}_i[h]_k^i & {}_i[g \wedge h]_k^i &\equiv {}_i[g]_k^i \wedge {}_i[h]_k^i \\ {}_i[\mathbf{F}g]_k^i &\equiv \bigvee_{j=\min(l,i)}^k {}_i[g]_k^j & {}_i[\mathbf{G}g]_k^i &\equiv \bigwedge_{j=\min(l,i)}^k {}_i[g]_k^j \\ {}_i[\mathbf{X}g]_k^i &\equiv {}_i[g]_k^j \text{ with } j = i + 1 \text{ if } i < k \text{ else } j = l \end{aligned}$$

Encoding witnesses without loops is similar. Let $[f]_k^i$ denote the result of encoding a witness without assuming that it is a (k, l) -loop for some l :

$$[\mathbf{F}g]_k^i \equiv \bigvee_{j=i}^k [g]_k^j \quad [\mathbf{G}g]_k^i \equiv \perp \quad [\mathbf{X}g]_k^i \equiv \begin{cases} [g]_k^{i+1} & \text{if } i < k \\ \perp & \text{if } j = k \end{cases}$$

The other cases are identical to the looping case. The full encoding is as follows:

$$[f]_k \equiv [f]_k^0 \vee \bigvee_{l=0}^k \lambda_l \wedge {}_l[f]_k^0$$

The second part handles (k, l) -loops, while the first part makes no assumption whether such a loop exists. With an inductive argument $[f]_k^0 \Rightarrow {}_l[f]_k^0$ follows. Therefore, there is no need to guard the left part with $\bigvee_{l=0}^k \lambda_l$, as it was originally presented in [BCCZ99].

For fixed k , there are $\Omega(|f| \cdot k^2)$ possible different parameters to ${}_i[f]_k^i$. In addition, an application of an equation introduces $\Omega(k)$ connectives to combine sub-results obtained from recursive calls. Thus, the overall complexity is at least cubic in k and linear in the size of the LTL formula $|f|$. For large k , this is not acceptable.⁴

⁴If the result of the encoding is represented as a circuit, then subformulas in the original encoding can be shared after restructuring the formula. In some cases this may even lead to a linear *circuit* encoding. But for binary temporal operators, including the “until” operator, this is in general not possible anymore.

18.3.2. Linear Encoding

The original encoding of [BCCZ99] presented in the last section is only efficient for simple properties such as $\mathbf{F}p$ or $\mathbf{G}p$, where $p \in V$. More involved specifications with deeply nested temporal operators produce quite some overhead. This is even more problematic for deeply nested binary temporal operators, such as the “until” operator \mathbf{U} , which we do not discuss in this chapter.

In symbolic model checking with BDDs, LTL is usually handled by a variant of the tableau construction of [LP85]. The tableau of [LP85] can be interpreted as a generalized Büchi automaton. It is conjuncted with K and a witness becomes a fair path on which all the fairness constraints occur infinitely often. In the context of Büchi automata, a fairness constraint is a set of states, which has to be “hit” by a path infinitely often, in order to be a fair path.

The LTL formula $\mathbf{GF}p$, i.e. infinitely often p , is a generic single fairness constraint with the following optimized encoding:

$$[\mathbf{GF}p]_k \equiv \bigvee_{l=0}^k \left(\lambda_l \wedge \bigvee_{i=l}^k p_i \right)$$

The formula is quadratic in k . However, it is possible to share common subformulas between different loop starts l . The resulting circuit is linear in k . This linear encoding of fairness constraints can be extended to multiple fairness constraints easily. Our first implementation of a bounded model checker used this technique in order to handle hundreds of fairness constraints [BCCZ99].

The tableau construction has symbolic variants [BCM⁺92, CGH97] as well as explicit variants [WVS83, VW94]. An explicit construction may explode in space immediately, since the Büchi automaton can be exponentially large in the size of the original LTL formula. This is rather unfortunate for BMC, but see [CKOS05] for a discussion on advantages and disadvantages of using an explicit automaton construction for BMC.

However, also symbolic tableau constructions – even with the presented optimized fairness encoding – require witnesses to be (k, l) -loops. This may prohibit early termination and requires larger bounds than necessary.

An improved but still quadratic encoding can be found in [FSW02]. A simpler and linear encoding was presented in [LBHJ04], which we explain next. A survey on the problem of encoding LTL (including past time LTL) can be found in [BHJ⁺06]. Another advanced encoding for weak alternating Büchi automata was presented in [HJK⁺06]. This encoding allows to handle all ω -regular properties which is a super set of LTL. All these symbolic encodings avoid the exponential blow-up of an explicit tableau construction and also allow to terminate earlier.

Before we explain the linear encoding, we first give an example why a simple recursive formulation is incorrect. Assume we have a single variable p and the following symbolic representation of a Kripke structure:

$$I(s) \equiv \bar{p} \qquad T(s, s') \equiv (s' = s)$$

The state space is $S = \{\perp, \top\}$, e.g. consists of all the valuations of p , see also Fig. 18.2. Only one state is reachable in K on which p does not hold. The

Figure 18.2. Kripke structure for counterexample to naive recursive encoding.

LTL formula $\mathbf{F}p$ can be characterized using the following least fixpoint equation: $\mathbf{F}p \equiv p \vee \mathbf{X}\mathbf{F}p$. Therefore, it is tempting to introduce a new boolean variable to encode $\mathbf{F}p$, let us call it a , and encode this fixpoint equation for $k = 0$ as $a_0 \leftrightarrow (p_0 \vee a_0)$. Note that for $k = 0$, the only possible l , the target of the back loop, is $l = 0$ again. Model constraints, actually just the initial state constraint, together with this encoding, result in the following formula:

$$\bar{p}_0 \wedge \lambda_0 \wedge a_0 \wedge (a_0 \leftrightarrow (p_0 \vee a_0))$$

This formula seems to follow the semantics, e.g. the model constraints are enforced and the fixpoint characterization of $\mathbf{F}p$ is encoded. However, it is *satisfiable* by setting a_0 to \top . This should not be the case, since $\mathbf{F}p$ does *not* hold on the single possible path in which p never holds. The problem is that even though this recursive encoding of the LTL formula captures the intention of the fixpoint equation it ignores *least* fixpoint semantics. A similar problem occurs when handling stable models for logic programs [SNS02] or more general in the context of answer set programming (ASP) [Nie99], where the default semantics of recursive properties are defined through least fixpoints. This observation can actually be used positively, in order to succinctly encode bounded witness problem of LTL into ASP [HN03] instead into SAT.

To summarize the example, a naive encoding results in an equation system with cyclic dependencies. A solution to such a system is an arbitrary fixpoint. However, semantics of $\mathbf{F}g$ require a least fixpoint.

The basic idea of the linear encoding in [LBHJ04] is to use several iterations through the fixpoint equations of the LTL subformulas with top most \mathbf{F} operator until the values do not change anymore. As it turns out, two backward iterations are actually enough. For each iteration, the value of an LTL formula at time frame i is encoded with the help of a new boolean variable. This is actually similar to using Tseitin variables [Tse68] to encode propositional formulas of arbitrary structure into CNF.

The variables for the first (inner resp. nested) iteration are written $\langle f \rangle_k^i$, those for the second (outer) iteration $\{f\}_k^i$. The rest of the encoding relates these variables among different subformulas, iterations and time points. The full set of constraints is shown in Fig. 18.3. The correctness of this encoding is established by the following theorem, which is an instance of a more general theorem proved in [BHJ⁺06]:

Theorem 1. *Let f be an LTL formula. If $\{f\}_k^0$ is satisfiable assuming in addition model and looping constraints, then there is a path π with $\pi \models f$.*

$$\begin{aligned}
\{p\}_k^i &\equiv p_i \\
\{\neg p\}_k^i &\equiv \neg p_i \\
\{g \vee h\}_k^i &\equiv \{g\}_k^i \vee \{h\}_k^i \\
\{g \wedge h\}_k^i &\equiv \{g\}_k^i \wedge \{h\}_k^i \\
\langle \mathbf{F}g \rangle_k^i &\equiv \{g\}_k^i \vee \langle \mathbf{F}g \rangle_k^{i+1} & \{\mathbf{F}g\}_k^i &\equiv \{g\}_k^i \vee \langle \mathbf{F}g \rangle_k^{i+1} & \text{if } i < k \\
\langle \mathbf{F}g \rangle_k^i &\equiv \{g\}_k^i & \{\mathbf{F}g\}_k^i &\equiv \{g\}_k^i \vee \bigvee_{l=0}^k (\lambda_l \wedge \langle \mathbf{F}g \rangle_k^l) & \text{if } i = k \\
\langle \mathbf{G}g \rangle_k^i &\equiv \{g\}_k^i \wedge \langle \mathbf{G}g \rangle_k^{i+1} & \{\mathbf{G}g\}_k^i &\equiv \{g\}_k^i \wedge \langle \mathbf{G}g \rangle_k^{i+1} & \text{if } i < k \\
\langle \mathbf{G}g \rangle_k^i &\equiv \{g\}_k^i & \{\mathbf{G}g\}_k^i &\equiv \{g\}_k^i \wedge \bigvee_{l=0}^k (\lambda_l \wedge \langle \mathbf{G}g \rangle_k^l) & \text{if } i = k \\
\langle \mathbf{X}g \rangle_k^i &\equiv \{g\}_k^{i+1} & \{\mathbf{X}g\}_k^i &\equiv \{g\}_k^{i+1} & \text{if } i < k \\
\langle \mathbf{X}g \rangle_k^i &\equiv \bigvee_{l=0}^k (\lambda_l \wedge \{g\}_k^l) & \{\mathbf{X}g\}_k^i &\equiv \bigvee_{l=0}^k (\lambda_l \wedge \{g\}_k^l) & \text{if } i = k
\end{aligned}$$

Figure 18.3. LTL constraints for the linear encoding of LTL into SAT.

For $i < k$ and for each subformula, there are at most k connectives in the outer iteration. For $i = k$, we need $2 \cdot (k + 1)$ binary disjunctions resp. conjunctions. The inner iteration adds k more. Altogether, the encoding is linear in k and the formula size $|f|$.

The previous example shows that one iteration is incorrect, at least for $\mathbf{F}g$. It is interesting to note that encoding the fixpoint equation $\mathbf{G}g \equiv g \wedge \mathbf{X}\mathbf{G}g$ does not suffer from the same problem, due to greatest fixpoint semantics and monotonicity of the encoding. Therefore, it is possible to only use one iteration for \mathbf{G} as it is also clearly the case for the propositional operators and \mathbf{X} , for which we applied this optimization already in Fig. 18.3. More variants, extensions, proofs and experimental results can be found in [BHJ⁺06].

Also note that the “no-lasso case” is also captured by this encoding: The result is satisfiable if there is a finite prefix with $k + 1$ states, such that all infinite paths with this prefix are witnesses.

Another option is to use the “liveness to safety” translation of [BAS02, SB04] which modifies the model, but also will result in a linear encoding of certain LTL formulas and in particular in a linear encoding of fairness constraints.

18.4. Completeness

The encodings of the previous section allow to find witnesses for a particular bound k . If the resulting propositional formula turns out to be satisfiable, we are sure that we have found a witness. If the resulting formula is unsatisfiable we can increase k and search for a longer witness. If the LTL formula has a witness this process will find it. However, if it does not, when should we stop increasing k ?

In this section, we discuss techniques that allow to *terminate* the search with the conclusion that no witness can be found. We focus on the special case of simple safety properties $\mathbf{G}p$, e.g. when searching for a witness of $\mathbf{F}\neg p$.

A first answer was given in the original paper [BCCZ99]. From graph theory we can borrow the concept of diameter, which is the longest shortest path between two nodes resp. states, or more intuitively the maximum distance between connected states. It is also often called eccentricity. If a bad state is reachable, then it is reachable in a shortest path from an initial state, which has length smaller or equal than the diameter.

A number such as the diameter, which allows us to stop BMC and conclude, that no witness can be found, is called completeness threshold (CT) [CKOS04, CKOS05]. Another trivial but in practice almost useless completeness threshold is $|S|$, the number of states.

Furthermore, since a shortest witness for $\mathbf{F}\neg p$ always starts with an initial state and ends in a bad state, where p does not hold, we can also use the following distances as CT: either the largest distance of any reachable state from an initial state or if it is smaller the largest distance of any state to the set of bad states, if it can reach a bad state. The former is also referred to as radius, more specifically as forward radius, the latter as backward radius with respect to the set of bad states.

In practice, the backward radius is often quite small. For instance, if p is inductive ($p_0 \wedge T(s_0, s_1) \Rightarrow p_1$) then the backward radius is 0, because it is impossible to go from a state in which p holds to a state in which p does not hold.

Unfortunately, computing diameters directly is quite hard. It is probably as hard as solving the witness problem in the first place. But there are further weaker CTs, which still are often small enough. The first example is the reoccurrence diameter of [BCCZ99], which is the length of the longest simple path in K . A simple path is another concept borrowed from graph theory and denotes a path, on which all states are different.

The reoccurrence diameter can be arbitrarily larger than the (real) diameter. Consider as example a fully connected graph with n nodes. We can easily generate a simple path of length n without reoccurring state. Since every state is reachable from any other step in one step due to full connectivity, the diameter is 1.

Analogously to the diameter, the forward and backward reoccurrence radii with their obvious definitions are CTs as well. Typically, the forward reoccurrence radius is way too large to be of any practical value, while again there exist many examples where the backward reoccurrence radius is small enough to obtain termination.

The main reason to work with reoccurrence diameters instead of real diameters is the possibility to formulate the former in SAT, while the latter is conjectured to need QBF. A simple path constraint to ensure unique states on a path is as follows:

$$\bigwedge_{0 \leq i < j \leq k} s_i \neq s_j$$

This formulation is quadratic in k . There are multiple solutions to avoid this quadratic overhead. One proposal [KS03, CKOS05] uses hardware implementations of sorting networks, which gives an $O(n \cdot \log^2 n)$ sized encoding, but the complexity of these networks usually results in slower SAT solving times [JB07]. This last paper [JB07] also describes how QBF can be used to encode simple path constraints. Similar results are reported in [DHK05, MVS⁺07].

Figure 18.4. Example that k -induction really needs simple path constraints for completeness. The state on the left is the only reachable state, while the two states on the right are not reachable. There exists arbitrary long paths of length k , where p holds on the first k states but not on the last state. However, if these paths are assumed to be simple paths, then the induction step for k -induction becomes unsatisfiable for $k = 2$.

The currently most effective solution is given in [ES03]. The basic idea is to start without any simple path constraints, but then add those inequalities to the SAT solver, which are violated in an assignment returned by the SAT solver. Then the SAT solver is restarted. In practice, the number of incrementally added inequalities is usually very small and even large bounds with many state variables can be handled this way.

18.5. Induction

An important step towards complete BMC techniques was k -induction [SSS00], which also in practice is still quite useful. The basic idea is to strengthen the property p , for which we want to show that $\mathbf{G}p$ holds, by adding more predecessor states. The base case for k -induction is a simple bounded model checking problem:

$$I(s_0) \wedge T(s_0, s_1) \wedge \dots \wedge T(s_{k-1}, s_k) \wedge \neg p_k$$

If the base case is satisfiable, a witness has been found. Otherwise the induction step is checked:

$$p_0 \wedge T(s_0, s_1) \wedge p_1 \wedge T(s_1, s_2) \wedge \dots \wedge p_{k-1} \wedge T(s_{k-1}, s_k) \wedge \neg p_k$$

This is almost a BMC problem, except that the initial state constraint is removed and p is assumed to hold on all states except for the last state. We start with the induction step for $k = 0$, which simply checks whether $\neg p_0$ is unsatisfiable as a propositional formula without any assumptions about the state. If the formula is indeed unsatisfiable, then $\mathbf{G}p$ holds trivially.

Then we check the base case for $k = 0$. If $I(s_0) \wedge \neg p_0$ is satisfiable, then p can be already violated in an initial state. Otherwise we move on to the next induction step at $k = 1$, which is $p_0 \wedge T(s_0, s_1) \wedge \neg p_1$. If this formula is unsatisfiable, we have actually proven that p is inductive for T and again $\mathbf{G}p$ holds.

These two special cases of early termination for BMC, stateless validity and inductiveness, were also discussed in [BCRZ99], but k -induction is able to increase k further and may terminate BMC even with $k > 1$. As the example in

Fig. 18.4 shows this method is not complete. Adding simple path constraints to the induction steps makes it complete, using the argument that the reoccurrence diameter is a CT for plain BMC.

Techniques such as invariant strengthening, discussed further down in Section 18.8, can help to reduce the bound until which k -induction with simple path constraints has to be carried out.

The base case and the induction step share large parts of subformulas even when increasing k to $k + 1$.⁵ To avoid copying these parts and to reuse learned clauses another important technique in this context is the usage of incremental SAT solvers [KWS00, WKS01, ES03]. It is even possible to actively copy learned clauses between time frames as suggested by [Str01]. Variants of k -induction for more general properties are also discussed in [AS06b, HJL05].

18.6. Interpolation

Before Aaron Bradley introduced IC3 [Bra11], model checking based on interpolation [Cra57] was considered to be the most efficient and robust model checking technique, as for instance the comparison in [ADK⁺05] showed. Nowadays IC3 [Bra11] and its variant PDR [EMB11] replaced interpolation based model checking in this regard [CLP⁺14, BvdH17]. Nevertheless interpolation found many applications beside model checking and is still useful in a portfolio approach to model checking. For more information on IC3 see [BK18].

The idea to use interpolation in model checking goes back to Ken McMillan [McM03]. The key idea is to extract an interpolant from a resolution proof for a failed BMC run and use the interpolant as over-approximation for image computation. The extraction algorithm was independently discovered by McMillan, but is very similar to those described in [Kra97, Pud97]. In this section, we present this extraction algorithm and provide a simple straight-forward proof for the propositional case. Our proof is inspired by [McM05] but stripped down to the propositional case. Further usage of interpolation is discussed in Chapter 33 on SMT and in Chapter 20 on Software Verification.

Let A, B be formulas in CNF, c, d clauses, and f, g propositional formulas. With $V(h)$ we denote the set of variables occurring in a formula h . A variable is *global* if it occurs both in A and in B . Let $G = V(A) \cap V(B)$ denote the global set of variables of A and B . A variable is called *local* to A if it only occurs in A and thus is not global. According to [Cra57] a formula f is an *interpolant* for A with respect to B iff it only contains global variables and

$$(I1) \quad A \Rightarrow f \quad \text{and} \quad (I2) \quad B \wedge f \Rightarrow \perp$$

We consider as proof objects *interpolating quadruples* of the form $(A, B) \ c \ [f]$, where the clause c is called the *resolvent* and f the *preliminary interpolant*. Then an interpolating quadruple is *well formed* iff

$$(W1) \quad V(c) \subseteq V(A) \cup V(B) \quad \text{and} \quad (W2) \quad V(f) \subseteq G \cup (V(c) \cap V(A)) \subseteq V(A)$$

⁵Note that p_i can also be assumed in the base case for $i = 0 \dots k - 1$, which would actually be learned by the SAT solver from the previous unsatisfiable base case anyhow.

Thus, an interpolating quadruple is well formed iff the resolvent c is a clause made of literals over variables from A and B , and f only contains variables from A . If in addition, a variable local to A occurs in f , then it also has to occur in c . In approximation to (I1) and (I2) a well formed interpolating quadruple is *valid* iff

$$(V1) \quad A \Rightarrow f \quad \text{and} \quad (V2) \quad B \wedge f \Rightarrow c$$

Note that $A \wedge B \Rightarrow c$ follows immediately from (V1) and (V2). Thus, if a well formed and valid interpolating quadruple with the empty clause \perp as resolvent can be derived, then the preliminary interpolant f of this quadruple actually turns out to be an interpolant of A with respect to B , in particular, $A \wedge B$ is unsatisfiable.

We present tableau rules for deriving well formed and valid interpolating quadruples. This calculus can be interpreted as an annotation mechanism for resolution proofs over $A \wedge B$. It annotates clauses and resolvents with valid interpolating quadruples. Let $c \dot{\vee} l$ denote a clause made up of a subclause c and a literal l , such that $|l|$ does not occur in c , i.e. neither positively nor negatively. The variable of a literal l is written as $|l|$. The proof rules are as follows:

$$(R1) \quad \frac{}{(A, B) c [c]} c \in A \quad \frac{(A, B) c \dot{\vee} l [f] \quad (A, B) d \dot{\vee} \bar{l} [g]}{(A, B) c \vee d [f \wedge g]} |l| \in V(B) \quad (R3)$$

$$(R2) \quad \frac{}{(A, B) c [\top]} c \in B \quad \frac{(A, B) c \dot{\vee} l [f] \quad (A, B) d \dot{\vee} \bar{l} [g]}{(A, B) c \vee d [f|\bar{l} \vee g|\bar{l}]} |l| \notin V(B) \quad (R4)$$

The notation $f|\bar{l}$ denotes the *cofactor* of f with respect to \bar{l} , which is a copy of f , in which occurrences of l are replaced by \perp and occurrences of \bar{l} by \top .

This set of rules simulates the algorithm by McMillan described in [McM03] to extract an interpolant from a resolution refutation, with the exception of rule (R1), the base case for clauses from A . The original algorithm removes variables local to A from the preliminary interpolant immediately. In our first approximation to the algorithm, as given by the tableau rules, we delay the removal until variables local to A are resolved away in (R4), in order to be able to apply an inductive proof argument, i.e. (V2). If one is only interested in the final interpolant of a refutation, where the final resolvent is an empty clause, then it is obviously correct to follow the original algorithm and remove the local variables immediately, since they will be resolved away anyhow. The latter is also the approach taken in [Pud97, YM05], but does not allow to maintain (V1) and (V2).

Theorem 2. *The four rules (R1) – (R4) preserve well formedness and validity.*

Proof. The consequents of the two base case rules (R1) and (R2) are clearly well formed, i.e. (W1) and (W2), and validity, i.e. (V1) and (V2), is easily checked as well. In the inductive case, (W1) also follows immediately. Regarding rules (R3) and (R4), we can assume the antecedents to be well formed and valid.

Let us consider rule (R3) next. The formulas f and g and thus also $f \wedge g$ only contain variables from A . Any variable v of $f \wedge g$ that is local to A is different from $|l|$, since the latter is a variable from B . Therefore, v occurs in c or d and

thus in $c \vee d$, which concludes (W2). The first part (V1) of validity follows from the assumptions, i.e. $A \Rightarrow f$ and $A \Rightarrow g$ obviously imply $A \Rightarrow f \wedge g$. To show the second remaining part (V2) of validity we use soundness of resolution:

$$B \wedge (f \wedge g) \quad \Rightarrow \quad (B \wedge f) \wedge (B \wedge g) \quad \Rightarrow \quad (c \vee l) \wedge (d \vee \bar{l}) \quad \Rightarrow \quad (c \vee d)$$

Proving the consequent of rule (R4) to be well formed, i.e. (W2), is simple: The variable $|l|$ is removed both from the resolvent as well as from the preliminary interpolant of the consequent. In order to show (V1) we can assume $A \Rightarrow f$ and $A \Rightarrow g$. Any assignment σ satisfying A evaluates both formulas $A \rightarrow f$ and $A \rightarrow g$ to \top . Further assume $\sigma(A) = \sigma(l) = \top$. Then Shannon Expansion for g gives $\sigma(g) = \sigma(l \wedge g|_l \vee \bar{l} \wedge g|\bar{l}) = \sigma(g|_l) = \top$. The other case $\sigma(A) = \sigma(\bar{l}) = \top$, with a similar argument, results in $\sigma(f|\bar{l}) = \top$. Thus, $\sigma(f|\bar{l} \vee g|_l) = \top$ for any satisfying assignment σ of A , which concludes part (V1).

The last case (V2) in the proof of the validity of the consequent of rule (R4) is proven as follows. In the assumption $B \wedge f \Rightarrow c \vee l$ we can replace every occurrence of l by \perp respectively every occurrence of \bar{l} by \top without making the assumption invalid. This implies $B \wedge f|\bar{l} \Rightarrow c$, since $|l|$ does not occur in B , nor in c . With a similar argument we obtain $B \wedge g|_l \Rightarrow d$ and thus $B \wedge (f|\bar{l} \vee g|_l) \Rightarrow (c \vee d)$. This completes the proof of the validity of the consequent of rule (R4) assuming validity of its antecedents and concludes the whole proof. \square

The extended version of [YM05], which was published as a technical report [YM04] proves a variant of the algorithm given in [Pud97]. Their inductive argument is slightly more complicated than ours, i.e. (V1) and (V2). In addition, our formulation allows to derive an relation between A , B , c and its preliminary interpolant f . In particular, our preliminary interpolant f captures enough information from A , such that B together with f implies c .

The strongest interpolant of A is obtained from A by existentially quantifying over all local variables in A . Thus, interpolation can be seen as an over approximation of quantifier elimination. Consider the following example, where A contains the four clauses A_0 to A_3

$$A_0 : a \vee c \vee d \quad A_1 : \bar{a} \vee c \vee d \quad A_2 : a \vee \bar{c} \vee \bar{d} \quad A_3 : \bar{a} \vee \bar{c} \vee \bar{d}$$

and B the following four clauses B_0 to B_3 :

$$B_0 : b \vee \bar{c} \quad B_1 : \bar{b} \vee \bar{c} \quad B_2 : b \vee \bar{d} \quad B_3 : \bar{b} \vee \bar{d}$$

Variable a is local to A , while b is local to B , and the other variables c and d are global. Quantifying a from A results in $\exists a[A] \equiv c \oplus d$, where “ \oplus ” is the XOR operator, i.e. c and d have different value. Since quantifying b from B results in $\exists b[B] \equiv \bar{c} \wedge \bar{d}$, i.e. c and d both have to be \perp and are thus forced to the same

value, the CNF $A \wedge B$ is unsatisfiable. A possible refutation proof is as follows:

$Q_0 :$	(A, B)	$c \vee d$	$[c \vee d]$	resolved from A_0 and A_1
$Q_1 :$	(A, B)	\bar{c}	$[\top]$	resolved from B_0 and B_1
$Q_2 :$	(A, B)	d	$[c \vee d]$	resolved from Q_0 and Q_1
$Q_3 :$	(A, B)	\bar{d}	$[\top]$	resolved from B_2 and B_3
$Q_4 :$	(A, B)	\perp	$[c \vee d]$	resolved from Q_2 and Q_3

In brackets, we list the partial interpolants. The final interpolant of A with respect to B is $P \equiv c \vee d$, which is weaker than the strongest interpolant $\exists a[A]$, i.e. $\exists a[A] \Rightarrow P$, but it exactly captures the part of A which is required for the refutation: either c or d has to be \top .

18.7. Completeness with Interpolation

It has been shown in [McM03] that termination checks for bounded model checking do not need exact quantifier elimination algorithms as has been previously assumed [WBCG00, ABE00, AB02, MS03, McM02, PBZ03]. An over approximation as given by an interpolant extracted from a refutation of a failed bounded model checking run is enough.

The resulting method of [McM03], which we describe in this section, is originally restricted to simple safety properties. But using the “liveness to safety” translation of [BAS02, SB04] it can be applied to more general specifications, which also is reported to work reasonably well in practice.

Assume that we want to prove that p is not reachable, i.e. the property $\mathbf{G}p$ holds, or respectively there is no witness for $\mathbf{F}\neg p$. Let k be the backward radius with respect to $\neg p$. More precisely let k be the smallest number such that all states which can reach $\neg p$, can reach a state in which $\neg p$ holds in k' steps, where $k' \leq k$. The backward radius can be interpreted as the number of generations in backward breadth first search (BFS), starting with the set of bad states in which $\neg p$ holds until all states that can reach a bad state are found. In BDD-based model checking [McM93] this is the number of *preimage* computations until a fixpoint is reached, starting with the set of bad states.

If the property holds and no witness to its negation exists, then the following formula is unsatisfiable (after checking $I(s_0) \Rightarrow p_0$ separately):

$$\underbrace{I(s_0) \wedge T(s_0, s_1)}_A \wedge \underbrace{T(s_1, s_2) \wedge \dots \wedge T(s_k, s_{k+1}) \wedge \bigvee_{j=1}^{k+1} \neg p_j}_B$$

Note that we “unroll” one step further as usual. Let P_1 be the interpolant of A with respect to B . Since $P_1 \wedge B$ is unsatisfiable, all states that satisfy P_1 cannot reach a bad state in k or fewer steps. As a generalization consider the following

sequence of formulas:

$$F_i \quad : \quad \underbrace{R_i(s_0) \wedge T(s_0, s_1) \wedge T(s_1, s_2) \wedge \dots \wedge T(s_k, s_{k+1})}_{A_i} \wedge \underbrace{\bigvee_{j=1}^{k+1} \neg p_j}_{B_i}$$

These are all BMC problems with the same bound $k+1$. In the base case, let $P_0 = R_0 = I$. In order to define R_i , under the assumption that F_i is unsatisfiable, let P_{i+1} be the interpolant of A_i with respect to B_i and $R_{i+1}(s) = R_i(s) \vee P_{i+1}[s_0/s_1]$, where $P_{i+1}[s_0/s_1]$ is obtained from P_{i+1} by replacing s_1 with s_0 . If F_i becomes satisfiable, then P_j , R_j and F_j are undefined for all $j > i$.

With the same argument as in the base case, we can show that as long P_i is defined all states satisfying R_i cannot reach a bad state in k or less steps, or to phrase it differently: R_i -states are more than k steps away from bad states.

Now let us assume that there exists a smallest i for which F_i is satisfiable. Then there is a state s_0 which reaches a bad state in $k+1$ or less steps but does not reach a bad state in k or less steps. The former just immediately follows from F_i being satisfied, the latter from s_0 satisfying R_i and thus s_0 being at least $k+1$ steps away from bad states. However, this contradicts our assumption that k is the backward radius and there are no states that need more than k steps to reach a bad state. Thus, P_i , R_i and F_i are defined for all $i \in \mathbb{N}$.

In addition, since $R_i \Rightarrow R_{i+1}$, we have an increasing chain of weaker and weaker starting points, which for a finite model has to reach a fixpoint. Therefore, there is an n for which $R_n \equiv R_{n+j}$ for all $j \in \mathbb{N}$. As soon $P_{n+1} \Rightarrow R_n$, which can be checked by a SAT solver, R_n is inductive, is implied by $I(s_0)$ and is stronger than p . Therefore, we can stop and conclude $\mathbf{G}p$ to hold resp. that no witness to $\mathbf{F}\neg p$ exists. This conclusion is correct even if k is smaller than the backward radius and all F_i are defined, i.e. if there exists an n for which $P_{n+1} \Rightarrow R_n$.

However, if k is smaller than the backward radius it may happen that F_i is satisfiable for $i > 0$. In this case, we simply increase k and start a new sequence of F_j 's. In any case, if F_0 ever turns out to be satisfiable, then we have found a witness, which is a counterexample to $\mathbf{G}p$.

To implement this algorithm, a SAT solver is required which is able to generate resolution proofs. This feature is easy to implement on top of DPLL style solvers, particularly for those that use learning. The overhead to produce resolution proofs is in general acceptable [ZM03, Gel07]. However, interpolants tend to be highly redundant [McM03]. In practice, it is necessary to shrink their size with circuit optimization techniques such as SAT sweeping [Kue04] and AIG rewriting [MCB06].

The outer loop increases k until either the BMC problem becomes satisfiable or the inner loop terminates because $P_{n+1} \Rightarrow R_n$ holds. As we have shown, k is bounded by the backward radius and thus it is beneficial to strengthen p as much as possible to decrease the backward radius which in order reduces not only the number of iterations of the outer loop but also the size (at least the length) of the BMC problems.

18.8. Invariant Strengthening

If a property p is inductive ($p_0 \wedge T(s_0, s_1) \Rightarrow p_1$), then a BMC run for $k = 1$ without initial state constraints is unsatisfiable, and proves that p holds in all states, i.e. $K \models \mathbf{G}p$, unless p is violated in the initial state.

In general, it is difficult to come up with strong enough inductive invariants. However, even if p does not imply the real invariant q , which we want to prove, p 's inductiveness can still be used to strengthen q . Then we can try to prove $\mathbf{G}(p \wedge q)$ instead of $\mathbf{G}q$. The former often has a smaller backward radius, in particular the backward radius never increases after strengthening, and can help to terminate k -induction and interpolation earlier. This is particularly useful for k -induction, which suffers from an exponential gap between backward recurrence radius and real backward radius.

In the context of sequential equivalence checking, useful invariants are of course equalities between signals. If such an equality $\mathbf{G}(p = q)$ between two signals p and q is suspected, then we can try to check whether $p = q$ is inductive. This idea can be extended to multiple signal pairs, e.g. $\mathbf{G} \bigwedge_{j=1}^n (p^j = q^j)$. In this case, inductiveness is proven if the following SAT problems for $m = 1 \dots n$ are all unsatisfiable:

$$\bigwedge_{j=1}^n (p_0^j = q_0^j) \wedge T(s_0, s_1) \wedge (p_1^m \neq q_1^m)$$

This idea is described in [vE98] and has been extended to property checking [BC00, CNQ07, AS06a, BM07] and can also make use of k -induction (see Section 18.5). Related to adding invariants is target enlargement [BKA02, BBC⁺05], which increases the set of bad resp. target states by some states that provably can reach a bad state.

18.9. Related Work

In the late 90ties, the performance of SAT solvers increased considerably [MSS99, Bor97, Zha97]. At the same time progress in BDDs stalled. It became clear that BDD-based symbolic model checking cannot handle more than a couple of hundred latches, which is much smaller than what most industrial applications require. This was the main motivation behind trying to apply SAT technology to model checking. The first angle of attack was to use QBF solvers, because these allow to solve the same problem as BDD-based model checking. However, at that time, QBF solvers were lagging behind SAT solvers. The first real implementations just started to emerge [CGS98]. Therefore, a paradigm shift was necessary.

The development of BMC was influenced by SAT-based planning [KS92]. See also Chapter 19 in this handbook, which is devoted to SAT-based planning. For simple safety properties, the tasks are similar: try to find a bounded witness, e.g. a *plan*, which reaches the goal resp. the bad state. The main contribution of BMC was to show how this idea can be lifted to infinite paths and thus produce witnesses for arbitrary temporal formulas. Furthermore initial attempts were

made to prove properties. Of course, the major difficulty was to convince the formal verification community that a focus on falsification can be beneficial.

Deciding QBF plays the same role for PSPACE-hard problems as SAT does for NP hard problems. Since symbolic model checking is PSPACE complete as well [Sav70], see [PBG05] for more details, it seems natural to use QBF solvers for symbol model checking, as it was already proposed in the original BMC paper [BCCZ99]. However, even though QBF solving is improving, there are very few successful applications of QBF to symbolic model checking [DHK05, CKS07, MVS⁺07]. Most results are negative [JB07].

Often properties are local and can be proven locally. A standard technique in this context is automatic abstraction refinement. Initially, the model checker abstracts the system by removing all the model constraints on variables apart from those that directly occur in the property. This abstraction is conservative in the following sense: if the property holds in the abstracted model, then it also holds in the concrete model. If it does not hold and the abstract counterexample cannot be mapped to the concrete model the abstraction has to be refined by adding back variables and model constraints. There are various techniques that use BMC in this context. They either use proofs and unsatisfiable cores [MA03] or follow the counterexample-guided abstraction refinement (CEGAR) paradigm [CGJ⁺03]. For further details, see [PBG05] and particularly Chapter 20. We also skipped most material on circuit based techniques, including quantifier elimination [WBCG00, ABE00, AB02, McM02, PBZ03, PSD06] circuit cofactoring [GGA04] and ATPG-based techniques, which are also discussed in [PBG05].

Finally, BMC has been extended to more general models, including software as discussed in Chapter 20. BMC is used for infinite systems [dMRS03], more specifically for hybrid systems [ABCS05, FH05]. In this context, bounded semantics are typically decidable, while the general model checking problem is not. Nevertheless, complete techniques, such as k -induction and interpolation can still be useful and allow to occasionally prove properties.

18.10. Conclusion

The main reason behind the success of BMC, is the tremendous increase in reasoning power of recent SAT solvers, particularly the breakthrough realized by Chaff [MMZ⁺01] right two years after the first publication on BMC. SAT and BMC became a standard tool in the EDA industry thereafter. Their importance will be emphasized as SAT solver's capacity continues to increase.

Acknowledgements

The author would like to thank Keijo Heljanko, Viktor Schuppan and Daniel Kröning for their very valuable comments on drafts of this chapter for the first edition of the handbook.

Chapter 19

Planning and SAT

Jussi Rintanen

Planning in Artificial Intelligence is one of the earliest applications of SAT to solving generic search problems. The planning problem involves finding a sequence of actions that reaches a given goal. Such an action sequence and an associated state sequence correspond to a satisfying assignment of a propositional formula which can be easily constructed from the problem description.

19.1. Introduction

Planning in artificial intelligence is the process of finding a sequence of actions that reaches a predefined goal. The problem is usually expressed in terms of a description of an initial state, a set of actions, and a goal state. In the most basic form of planning, called classical planning, there is only one initial state and the actions are deterministic.

In their 1992 paper, Kautz and Selman suggested that the classical planning problem could be solved by translating it into a propositional formula and testing its satisfiability [KS92]. This approach was in strong contrast with earlier works on planning which viewed planning as a deductive problem or a specialized search problem. At first, this idea did not attract much interest, but in 1996 Kautz and Selman demonstrated that the best algorithms for SAT together with improved translations provided a competitive approach to classical planning [KS96].

The success of SAT in planning suggested the same approach to solving other similar problems, such as model-checking in computer-aided verification and validation. A SAT-based approach to model-checking properties expressed in the linear temporal logic LTL [Pnu77] was proposed soon after the success of planning as satisfiability became more widely known [BCCZ99].

Following the work by Kautz and Selman, similar translations of planning into many other formalisms were proposed: nonmonotonic logic programs [DNK97], mixed integer linear programming [KW99, WW99, VBLN99], and constraint satisfaction problems CSP [vBC99, DK01].

The classical planning problem is PSPACE-complete [Byl94], so there are presumably (assuming $P \neq PSPACE$) no polynomial time translations from classical planning into SAT. The formulae that represent the classical planning problem

may, in the worst case, be exponential in the size of the problem instance. However, the formula size is determined by a natural parameter which tends not to be very high in practically interesting cases: the plan length. Most classes of planning problems are solvable with plans of a polynomial length, which means that the corresponding propositional formulae have a polynomial size. So in practice it is feasible to reduce the planning problem to SAT.

The underlying idea in using SAT for planning is to encode the bounded plan existence problem, i.e. whether a plan of a given length n exists, as a formula in the classical propositional logic. The formula for a given n is satisfiable if and only if there is a plan of size n . Finding a plan reduces to testing the satisfiability of the formulae for different values of n .

The efficiency of the SAT-based approach is determined by three largely orthogonal components.

1. Efficient representations ϕ_n of the planning problem for a given plan length n . This is the topic of Sections 19.3 and 19.4.
2. Efficient algorithms for testing the satisfiability of ϕ_n .
3. Algorithms for choosing which values of n to consider to find a satisfiable ϕ_n as quickly as possible. This is the topic of Section 19.5.

Section 19.3 describes the most basic representation of planning in SAT, and the most important improvements to it to achieve efficient planning.

Section 19.4 introduces the notion of parallel plans [BF97, KS96] which is an important factor in the efficiency of planning as satisfiability. In a parallel plan there may be more than one action at each time point. The length parameter n restricts the number of time points but not directly the number of actions. Different notions of parallel plans can be defined, and for maintaining the connection to sequential plans it is required that there is a parallel plan exactly when there is a sequential plan, and moreover, mapping a given parallel plan to a sequential plan should be possible in polynomial time.

Section 19.5 presents different strategies for making the satisfiability tests for the bounded planning problem for different lengths.

Section 19.6 describes the extension of Kautz and Selman's ideas to temporal planning, in which actions have a real or rational valued duration and multiple actions can temporally each other.

Section 19.7 discusses possibilities to reduce more general planning problems, for example with nondeterminism and sensing, to SAT and its quantified extensions.

19.2. Classical Planning

We consider planning in a setting where the states of the world are represented in terms of a set X of Boolean state variables which take the value *true* or *false*. Formulae are formed from the state variables with the connectives \vee and \neg . The connectives \wedge , \rightarrow and \leftrightarrow are defined in terms of \vee and \neg . A *literal* is a formula of the form x or $\neg x$ where $x \in X$ is a state variable. We define the *complements* of literals as $\bar{x} = \neg x$ and $\overline{\bar{x}} = x$ for all $x \in X$. A *clause* is a disjunction $l_1 \vee \dots \vee l_n$ of one or more literals. We also use the constant atoms \top and \perp for denoting

true and false, respectively. Each state $s : X \rightarrow \{0, 1\}$ assigns each state variable in X a value 0 or 1.

Actions change the state of the world.

Definition 19.2.1. An *action* over a set of state variables X is a pair $\langle p, e \rangle$ where

1. p is a propositional formula over X (*the precondition*) and
2. e is a set of pairs $f \Rightarrow d$ (*the effects*) where f is a propositional formula over X and d is a set of literals over X . (In the planning literature, the case in which f is not \top is called a “conditional effect”.)

The meaning of $f \Rightarrow d$ is that the literals in d are made true if the formula f is true. For an action $a = \langle p, e \rangle$ its *active effects* in a state s are

$$[a]_s = [e]_s = \bigcup \{d \mid f \Rightarrow d \in e, s \models f\}.$$

The action is *executable* in s if $s \models p$ and $[a]_s$ is consistent (does not contain both x and $\neg x$ for any $x \in X$.) If this is the case, then we define $exec_a(s)$ as the unique state that is obtained from s by making $[a]_s$ true and retaining the values of the state variables not occurring in $[a]_s$. For sequences $a_1; a_2; \dots; a_n$ of actions we define $exec_{a_1; a_2; \dots; a_n}(s)$ as $exec_{a_n}(\dots exec_{a_2}(exec_{a_1}(s)) \dots)$. For sets S of actions and states s we define $exec_S(s)$ as the result of simultaneously executing all actions in S . We require that $exec_a(s)$ is defined for every $a \in S$ and that the set $[S]_s = \bigcup_{a \in S} [a]_s$ of active effects of all actions in S is consistent. For actions $a = \langle p, e \rangle$ and atomic effects l of the form x and $\neg x$ (for $x \in X$) define the *effect precondition* $EPC_l(a) = \bigvee \{f \mid f \Rightarrow d \in e, l \in d\}$ where the empty disjunction $\bigvee \emptyset$ is defined as \perp . This formula represents those states in which l is an active effect of a .

Lemma 19.2.1. For literals l , actions a and states s , $l \in [a]_s$ if and only if $s \models EPC_l(a)$.

Let $\pi = \langle X, I, A, G \rangle$ be a *problem instance* consisting of a set X of state variables, a state I over X (the initial state), a set A of actions over X , and a formula G over X (the goal formula).

A (sequential) *plan* for π is a sequence $\sigma = a_1; \dots; a_n$ of actions from A such that $exec_\sigma(I) \models G$. This means that executing the actions in the given order starting in the initial state is defined (the precondition of every action is true and the active effects are consistent when the action is executed) and produces a state that satisfies the goal formula. Sometimes we say that an action sequence is a plan for A and I when we simply want to say that the plan is executable starting from I without specifying the goal states.

19.3. Sequential Plans

Consider a problem instance $\langle X, I, A, G \rangle$. We define, for any $t \geq 0$, the set $X@t = \{x@t \mid x \in X\}$ of propositional variables which contains a variable $x@t$ for every state variable $x \in X$. The variable $x@t$ refers to the value of x in a state

at time t . The propositional variables refer to the values of x at different integer time points. We will later use these superscripts with formulae ϕ so that $\phi@t$ is the formula obtained from ϕ by replacing every $x \in X$ by the corresponding $x@t \in X@t$.

An action $a = \langle p, e \rangle$ can be represented as

$$\tau_a = p@0 \wedge \bigwedge_{x \in X} [(EPC_x(a)@0 \vee (x@0 \wedge \neg EPC_{\neg x}(a)@0)) \leftrightarrow x@1]. \quad (19.1)$$

This formula expresses the precondition of the action and the new value of each state variable x in terms of the values of the state variables before the action is executed: a will be true if it becomes true or it was true already and does not become false.

Lemma 19.3.1. *Let s and s' be states over X . Let $s_0 : X@0 \rightarrow \{0, 1\}$ be a state over $X@0$ such that $s_0(x) = s(x)$ for all $x \in X$. Let $s_1 : X@1 \rightarrow \{0, 1\}$ be a state over $X@1$ such that $s_1(x') = s'(x)$ for all $x \in X$. Then $s_0 \cup s_1 \models \tau_a$ if and only if $s' = \text{exec}_a(s)$.*

The formula for representing the possibility of taking any of the actions is

$$\mathcal{T}(0) = \bigvee_{a \in A} \tau_a. \quad (19.2)$$

Later we will use this formula by replacing occurrences of the propositional variables in $X@0$ and $X@1$ by propositional variables referring to different integer time points.

Lemma 19.3.2. *Let s and s' be states over X . Let $s_0 : X@0 \rightarrow \{0, 1\}$ be a state over $X@0$ such that $s_0(x) = s(x)$ for all $x \in X$. Let $s_1 : X@1 \rightarrow \{0, 1\}$ be a state over $X@1$ such that $s_1(x') = s'(x)$ for all $x \in X$. Then $s_0 \cup s_1 \models \tau_a$ if and only if $s' = \text{exec}_a(s)$. Then $s_0 \cup s_1 \models \mathcal{T}(0)$ if and only if $s' = \text{exec}_a(s)$ for some $a \in A$.*

Since the formula $\mathcal{T}(0)$ expresses the changes in the state of the world between two time points by one action, the changes caused by a sequence of actions over a sequence of states can be expressed by iterating this formula.

Theorem 19.3.3. *Let $\pi = \langle X, I, A, G \rangle$ be a problem instance. Let $\iota = \bigwedge \{x@0 | x \in X | s \models x\} \wedge \bigwedge \{\neg x@0 | x \in X, I \not\models x\}$. The formula*

$$\iota \wedge \mathcal{T}(0) \wedge \mathcal{T}(1) \wedge \cdots \wedge \mathcal{T}(t-1) \wedge G@t \quad (19.3)$$

is satisfiable if and only there is a sequence a_0, a_1, \dots, a_{t-1} of t actions such that $\text{exec}_{a_{t-1}}(\cdots \text{exec}_{a_1}(\text{exec}_{a_0}(I)) \cdots) \models G$.

A satisfying assignment represents the sequence of states that is visited when a plan is executed. The plan can be constructed by identifying actions which correspond to the changes between every pair of consecutive states.

19.3.1. Improvements

This basic representation of planning in the propositional logic can be improved many ways, and effort in implementation technologies for the underlying SAT solving can be critical for the scalability [Rin12b, Rin12a]. Next we briefly discuss two powerful ways to improve the translations of planning into the propositional logic.

19.3.1.1. Approximations of Reachability

Important for the efficiency of planning with SAT is that the search by a SAT algorithm focuses on sequences of states that are reachable from the initial state. Testing whether a state is reachable is as difficult as planning itself but there are efficient algorithms for finding approximate information about reachability, for example, in the form of dependencies between state variables. A typical dependence between some state variables x_1, \dots, x_n is that at most one of them has value 1 at a time, in any reachable state. Adding formulae $\neg x_i \vee \neg x_j$ for all $i \in \{1, \dots, n\}$ and $j \in \{1, \dots, n\}$ such that $i \neq j$ may improve the efficiency of the satisfiability tests tremendously because no states need to be considered that are later found not to be reachable from the initial state. This kind of dependencies are called *invariants*. There are algorithms for finding invariants automatically [Rin98, GS98, Bra01, Rin08]. These algorithms run in polynomial time and find a subset of the invariants that are 2-literal clauses. Invariants were first introduced to planning in the form of *mutexes* in the planning graphs of Blum and Furst [BF97].

19.3.1.2. Factoring

Input languages for planning systems represent sets of actions as an action schema together with objects by which the variables in the action schema are instantiated in order to obtain the non-schematic (ground) actions of Section 19.2. The size of the set of ground actions may be exponential in the size of the schematic representation. Sometimes it is possible to reduce the size increase by representing part of the instantiation process directly as a propositional formula. For example, an action $\text{move}(x, y, z)$ for moving an object x from location y to location z can be represented by the parameters $x \in X$, $y \in Y$ and $z \in Y$ where X is the set of all objects and Y is the set of all locations. Instead of $|X| \times |Y|^2$ propositional variables for representing the ground actions, only $|X| + 2|Y|$ propositional variables are needed for representing the possible parameter values of the move action. This has been called a factored representation [KMS96, EMW97]. Factoring may reduce the potential for parallelism (Section 19.4) in plans: in the move action above, the action should be factored only with respect to the location parameters y and z , as different objects can be moved in parallel, but any given object can be moved only from one location to another. Factoring can speed up the planning process substantially [RGPS09].

19.4. Parallel Plans

An important factor in the efficiency of SAT-based planners is the notion of parallel plans. Few plans are purely sequential in the sense that any two consecutive actions have to be in the given order. For example, the last two actions in a plan for achieving $a \wedge b$ could respectively make a and b true and be completely independent of each other. The ordering of the actions can be reversed without invalidating the plan. This kind of independence naturally leads to the notion of partially ordered plans, which was first utilized in the connection of the so-called non-linear or partial order approach to AI planning [Sac75, MR91]. Techniques utilizing partial orders and independence outside planning include partial-order reduction techniques [God91, Val91, ABH⁺97] for reachability analysis.

The highly influential GraphPlan planner [BF97] introduced a restricted notion of partial ordering which turned out to be very effective for SAT-based planning [KS96]: a plan is viewed as a sequence of sets of actions.

In this section we discuss two forms of partially ordered plans and present their translations into the propositional logic. The first definition generalizes that of Blum and Furst [BF97]. The second was proposed by Dimopoulos et al. [DNK97] and later formalized and applied to SAT-based planning [RHN06].

19.4.1. \forall -Step Plans

The first definition of parallel plans interprets parallelism as the possibility of ordering the actions to any total order.

Definition 19.4.1 (\forall -Step plans). For a set of actions A and an initial state I , a \forall -step plan for A and I is a sequence $T = \langle S_0, \dots, S_{l-1} \rangle$ of sets of actions for some $l \geq 0$ such that there is a sequence of states s_0, \dots, s_l (the execution of T) such that

1. $s_0 = I$, and
2. $exec_{a_1, \dots, a_n}(s_i)$ is defined and equals s_{i+1} for every $i \in \{0, \dots, l-1\}$ and every total ordering a_1, \dots, a_n of S_i .

When active effects are independent of the current state and preconditions are conjunctions of literals, Definition 19.4.1 exactly corresponds to a syntactic definition of independence [RHN06]. In more general cases the correspondence breaks down, and syntactically independent sets of actions are only a subclass of sets of actions which can be ordered to any total order.

Testing whether a sequence of sets of actions is a \forall -step plan is in general intractable [RHN06] which justifies syntactic rather than semantic restrictions on parallel actions [BF97, KS96].

We define positive and negative occurrences of state variables in a formula.

Definition 19.4.2 (Positive and negative occurrences). We say that a state variable a occurs positively in ϕ if $positive(a, \phi)$ is true. Similarly, a occurs negatively

in ϕ if $\text{negative}(a, \phi)$ is true.

$$\begin{aligned} \text{positive}(x, x) &= \text{true, for all } x \in X \\ \text{positive}(x, y) &= \text{false, for all } \{x, y\} \subseteq X \text{ such that } x \neq y \\ \text{positive}(x, \phi \vee \phi') &= \text{positive}(x, \phi) \text{ or } \text{positive}(x, \phi') \\ \text{positive}(x, \neg\phi) &= \text{negative}(x, \phi) \end{aligned}$$

$$\begin{aligned} \text{negative}(x, y) &= \text{false, for all } \{x, y\} \subseteq X \\ \text{negative}(x, \phi \vee \phi') &= \text{negative}(x, \phi) \text{ or } \text{negative}(x, \phi') \\ \text{negative}(x, \neg\phi) &= \text{positive}(x, \phi) \end{aligned}$$

A state variable x occurs in ϕ if it occurs positively or negatively in ϕ .

Definition 19.4.3 (Affect). Let X be a set of state variables and $a = \langle p, e \rangle$ and $a' = \langle p', e' \rangle$ actions over X . Then a affects a' if there is $x \in X$ such that

1. $x \in d$ for some $f \Rightarrow d \in c$ and x occurs in f for some $f \Rightarrow d \in c'$ or occurs negatively in p' , or
2. $\neg x \in d$ for some $f \Rightarrow d \in c$ and x occurs in f for some $f \Rightarrow d \in c'$ or occurs positively in p' .

An action a which affects another action a' may prevent its execution or change its active effects. This means that replacing $a'; a$ by $a; a'$ in a plan may make the plan invalid or change its execution.

Definition 19.4.4 (Interference). Let X be a set of state variables. Actions a and a' interfere if a affects a' or a' affects a .

If actions a and a' do not interfere, then the sequences $a; a'$ and $a'; a$ are interchangeable. Non-interference is a sufficient but not a necessary condition for interchangeability.

19.4.2. \exists -Step Plans

A more relaxed notion of parallel plans was proposed by Dimopoulos et al. [DNK97] and formalized and investigated in detail by Rintanen et al. [RHN06].

Definition 19.4.5 (\exists -Step plans). For a set A of actions and an initial state I , a \exists -step plan is $T = \langle S_0, \dots, S_{l-1} \rangle \in (2^A)^l$ together with a sequence of states s_0, \dots, s_l (the execution of T) for some $l \geq 0$ such that

1. $s_0 = I$, and
2. for every $i \in \{0, \dots, l-1\}$ there is a total ordering $a_1 < \dots < a_n$ of S_i such that $s_{i+1} = \text{exec}_{a_1; \dots; a_n}(s_i)$.

The difference to \forall -step plans is that instead of requiring that each step S_i can be ordered to any total order, it is sufficient that there is at least one order that maps state s_i to s_{i+1} . Unlike for \forall -step plans, the successor s_{i+1} of s_i is not uniquely determined solely by S_i because the successor depends on the implicit ordering of S_i . For this reason the definition has to make the execution s_0, \dots, s_l explicit.

The more relaxed definition of \exists -step plans sometimes allows much more parallelism than the definition of \forall -step plans.

Example 19.4.1. Consider a row of n Russian dolls, each slightly bigger than the preceding one. We can nest all the dolls by putting the first inside the second, then the second inside the third, and so on, until every doll except the largest one is inside another doll.

For four dolls this can be formalized as follows.

$$\begin{aligned} a_1 &= \langle \text{out1} \wedge \text{out2} \wedge \text{empty2}, \{\top \Rightarrow \text{1in2}, \top \Rightarrow \neg \text{out1}, \top \Rightarrow \neg \text{empty2}\} \rangle \\ a_2 &= \langle \text{out2} \wedge \text{out3} \wedge \text{empty3}, \{\top \Rightarrow \text{2in3}, \top \Rightarrow \neg \text{out2}, \top \Rightarrow \neg \text{empty3}\} \rangle \\ a_3 &= \langle \text{out3} \wedge \text{out4} \wedge \text{empty4}, \{\top \Rightarrow \text{3in4}, \top \Rightarrow \neg \text{out3}, \top \Rightarrow \neg \text{empty4}\} \rangle \end{aligned}$$

The shortest \forall -step plan nests the dolls in three steps: $\langle \{a_1\}, \{a_2\}, \{a_3\} \rangle$. The \exists -step plan $\langle \{a_1, a_2, a_3\} \rangle$ nests the dolls in one step.

Theorem 19.4.1. (i) Every \forall -step plan is a \exists -step plan, and (ii) for every \exists -step plan T there is a \forall -step plan whose execution leads to the same final state as that of T .

Similarly to \forall -step plans, testing the validity of \exists -step plans is intractable in the worst case [RHN06]. One way of achieving tractability uses two restrictions. All parallel actions are required to be executable in the current state (unlike for \forall -step plans this does not follow from the definition), and parallel actions are required to fulfil an ordered dependence condition based on Definition 19.4.3: actions are allowed in parallel if they can be totally ordered so that no action affects a later action. This means that the actions preceding a given action do not change its effects or prevent its execution.

Theorem 19.4.2. Let A be a set of actions, I a state, $T = \langle S_0, \dots, S_{l-1} \rangle \in (2^A)^l$, and s_0, \dots, s_l a sequence of states. If

1. $s_0 = I$,
2. for every $i \in \{0, \dots, l-1\}$ there is a total ordering $<$ of S_i such that if $a < a'$ then a does not affect a' , and
3. $s_{i+1} = \text{exec}_{S_i}(s_i)$ for every $i \in \{0, \dots, l-1\}$,

then T is a \exists -step plan for A and I .

Even though the class of \exists -step plans based on *affects* is narrower than the class sanctioned by Definition 19.4.5, much more parallelism is still possible in comparison to \forall -step plans. For instance, nesting of Russian dolls in Example 19.4.1 belongs to this class.

19.4.3. Optimality of Parallel Plans

The most commonly used measure for plan quality is the number of actions in the plan. So the problem of finding an optimal plan is the problem of finding the shortest sequential plan, or in terms of the satisfiability tests, finding an integer t such that the formula for plan length $t-1$ is unsatisfiable and the formula for plan length t is satisfiable. For parallel plans the question is more complicated. It is possible to find an optimal parallel plan for a given parallel length by using cardinality constraints on the number of actions in the plans, but it seems that

finding an optimal parallel plan in the worst case reduces to testing the existence of sequential plans [BR05]: if there is a parallel plan with t time points and n actions, the optimality test may require testing whether there is a sequential plan with $n - 1$ time points and $n - 1$ actions. Tests restricting to formulae with t time points are not sufficient.

19.4.4. Representation in SAT

In this section we present translations of parallel plans into the propositional logic. A basic assumption is that for sets S of simultaneous actions executed in state s the state $exec_S(s)$ is defined, that is, all the preconditions are true in s and the set of active effects of the actions is consistent.

19.4.4.1. The Base Translation

Planning is performed by propositional satisfiability testing by producing formulae $\phi_0, \phi_1, \phi_2, \dots$ such that ϕ_l is satisfiable iff there is a plan of length l . The translations for different forms of parallel plans differ only in the formulae that restrict the simultaneous execution of actions. Next we describe the part of the formulae that is shared by both definitions of parallel plans.

Consider the problem instance $\pi = \langle X, I, A, G \rangle$. Similarly to the state variables in X , for every action $a \in A$ we have the propositional variable a^t for expressing whether a is executed at time point $t \in \{0, \dots, l - 1\}$.

A formula $\Phi_{\pi, l}$ is generated to answer the following question. Is there an execution of a sequence of l sets of actions that reaches a state satisfying G when starting from the state I ? The formula $\Phi_{\pi, l}$ is conjunction of $\iota = \bigwedge \{x@0 \mid x \in X, s \models x\} \wedge \bigwedge \{\neg x@0 \mid x \in X, I \not\models x\}, G@l$, and the formulae described below, instantiated with all $t \in \{0, \dots, l - 1\}$.

First, for every $a = \langle p, e \rangle \in A$ there are the following formulae. The precondition p has to be true when the action is executed.

$$a@t \rightarrow p@t \tag{19.4}$$

Then we define, for every $x \in X$, the condition under which x becomes true or false at step t

$$causes(x)@t = \bigvee_{a \in A} (a@(t-1) \wedge EPC_x(a)@(t-1)) \tag{19.5}$$

$$causes(\neg x)@t = \bigvee_{a \in A} (a@(t-1) \wedge EPC_{\neg x}(a)@(t-1)) \tag{19.6}$$

These formulas are used in defining when a state variable becomes true or false at a given time point.

$$causes(x)@t \rightarrow x@t \tag{19.7}$$

$$causes(\neg x)@t \rightarrow \neg x@t \tag{19.8}$$

Second, the value of a state variable does not change if no action that changes it is executed. Hence for every state variable x we have two formulae, one expressing the conditions for the change of x from true to false,

$$(x@t \wedge \neg x@(t+1)) \rightarrow \text{causes}(\neg x)@(t+1) \quad (19.9)$$

and another from false to true,

$$(\neg x@t \wedge x@(t+1)) \rightarrow \text{causes}(x)@(t+1). \quad (19.10)$$

The formulae $\Phi_{\pi,l}$, just like the definition of $\text{exec}_S(s)$, allow sets of actions in parallel that do not correspond to any sequential plan. For example, the actions $\langle x, \{\top \Rightarrow \neg y\} \rangle$ and $\langle y, \{\top \Rightarrow \neg x\} \rangle$ may be executed simultaneously resulting in a state satisfying $\neg x \wedge \neg y$, even though this state is not reachable by the two actions sequentially. But we require that all parallel plans can be executed sequentially. Further formulae that are discussed in the next sections are needed to guarantee this property.

Theorem 19.4.3. *Let $\pi = \langle X, I, A, G \rangle$ be a transition system. Then there is $T = \langle S_0, \dots, S_{l-1} \rangle \in (2^A)^l$ so that s_0, \dots, s_l are states so that $I = s_0, s_l \models G$, and $s_{i+1} = \text{exec}_{S_i}(s_i)$ for all $i \in \{0, \dots, l-1\}$ if and only if there is a valuation satisfying the formula $\Phi_{\pi,l}$.*

Proposition 19.4.4. *The size of the formula $\Phi_{\pi,l}$ is linear in l and in the size of π .*

Theorem 19.4.3 says that a sequence of actions fulfilling certain conditions exists if and only if a given formula is satisfiable. The theorems connecting certain formulae to certain notions of plans (Theorems 19.4.5 and 19.4.6) provide an implication only in one direction: whenever the formula for a given value of parameter l is satisfiable, a plan of l time points exists. The other direction is missing because the formulae in general only approximate the respective definition of plans and there is no guarantee that the formula for a given l is satisfiable when a plan with l time points exists. However, the formula with some higher value of l is satisfiable. This follows from the fact that whenever a \forall -step or \exists -step plan $\langle S_0, \dots, S_{l-1} \rangle$ with $n = |S_0| + \dots + |S_{l-1}|$ occurrences of actions exists, there is a plan consisting of n singleton sets, and the corresponding formulae $\Phi_{\pi,n} \wedge \Phi_{A,n}^x$ are satisfiable. The formulae $\Phi_{A,n}^z$ represent the parallel semantics z for actions A .

19.4.4.2. Translation of \forall -Step Plans

The simplest representation of the interference condition in Definition 19.4.4 is by formulae

$$\neg(a_1@t \wedge a_2@t) \quad (19.11)$$

for every pair of interfering actions a_1 and a_2 . Define $\Phi_{A,l}^{\forall\text{step}}$ as the conjunction of the formulae (19.11) for all time points $t \in \{0, \dots, l-1\}$ and for all pairs of interfering actions $\{a, a'\} \subseteq A$ that could be executed simultaneously. There are $O(ln^2)$ such formulae for n actions. This can be improved to linear [RHN06].

Theorem 19.4.5. *Let $\pi = \langle X, I, A, G \rangle$ be a transition system. There is a \forall -step plan of length l for π if $\Phi_{\pi,l} \wedge \Phi_{A,l}^{\forall\text{step}}$ is satisfiable.*

19.4.4.3. Translation of \exists -Step Plans

The simplest efficient representation of \exists -step plans imposes a fixed total ordering on the actions and allows the simultaneous execution of a subset of the actions only if none of the actions affects any action later in the ordering. There are more permissive ways of guaranteeing the validity of \exists -step plans, but they seem to be difficult to implement efficiently, and furthermore, there are ways of identifying most permissive total orderings as a preprocessing step by finding strongly connected components of the graph formed by the *affects* relation on actions [RHN06].

The representation does not allow all the possible parallelism but it leads to small formulae and is efficient in practice. In the translation for \exists -step plans the set of formulae constraining parallel execution *is a subset* of those for the less permissive \forall -step plans. One therefore receives two benefits simultaneously: possibly much shorter parallel plans and formulae with a smaller size / time points ratio.

The idea is to impose beforehand an (arbitrary) ordering on the actions a_1, \dots, a_n and to allow parallel execution of two actions a_i and a_j such that a_i affects a_j only if $i \geq j$. The formula $\Phi_{A,l}^{\exists\text{step}}$ is the conjunction of

$$\neg(a_i@t \wedge a_j@t) \text{ if } a_i \text{ affects } a_j \text{ and } i < j$$

for all a_i and a_j and all time points $t \in \{0, \dots, l-1\}$. Of course, this restriction to one fixed ordering may rule out many sets of parallel actions that could be executed simultaneously according to some other ordering than the fixed one.

The formula $\Phi_{A,l}^{\exists\text{step}}$ (similar to the translation for \forall -step plans in Section 19.4.4.2) has a quadratic size because of the worst-case quadratic number of pairs of actions that may not be simultaneously executed. This can be improved to linear [RHN06].

Theorem 19.4.6. *Let $\pi = \langle X, I, A, G \rangle$ be a transition system. There is a \exists -step plan of length l for π if $\Phi_{\pi,l} \wedge \Phi_{A,l}^{\exists\text{step}}$ is satisfiable.*

19.5. Finding a Satisfiable Formula

Given a sequence ϕ_0, ϕ_1, \dots of formulae representing the bounded planning problem for different plan lengths, a satisfiability algorithm is used for locating a satisfiable formula. The satisfying assignment can be translated into a plan. In this section we describe three high-level algorithms that use the formulae ϕ_i for finding a plan. We call them Algorithms S, A and B.

Algorithm S is the obvious sequential procedure for finding a satisfiable formula: first test the satisfiability of ϕ_0 , then ϕ_1 , ϕ_2 , and so on, until a satisfiable formula is found. It has been used by virtually all works that reduce planning to the fixed-length planning problem [KS92, BF97]. This algorithm has the property that it always find a plan with the smallest number of time points. It can be used for finding plans with the minimum number of actions if used in connection with the sequential encoding of planning from Section 19.3.

Figure 19.1. SAT solver runtimes for two problem instances and different plan lengths

Figure 19.2. SAT solver runtimes for two problem instances and different plan lengths

If the objective is to find a plan with not necessarily the smallest number of actions or time points, the Algorithm S is often inefficient because the satisfiability tests for the last unsatisfiable formulae are often much more expensive than for the first satisfiable formulae. Consider the diagrams in Figures 19.1, 19.2 and Figure 19.3. Each diagram shows the cost of detecting the satisfiability or unsatisfiability of formulae that represent the existence of plans of different lengths. Grey bars depict unsatisfiable formulae and black bars satisfiable formulae. For more difficult problems the peak formed by the last unsatisfiable formulae is still much more pronounced.

Except for the rightmost diagram in Figure 19.2 and the leftmost diagram in Figure 19.3, the diagrams depict steeply growing costs of determining unsatisfiability of a sequence of formulae followed by small costs of determining satisfiability of formulae corresponding to plans.

We would like to run a satisfiability algorithm with the satisfiable formula for which the runtime of the algorithm is the lowest. Of course, we do not know which formulae are satisfiable and which has the lowest runtime. With an infinite number of processes we could find a satisfying assignment for one of the formulae in the smallest possible time: let each process $i \in \{0, 1, 2, \dots\}$ test the satisfiability of ϕ_i . However, an infinite number of processes running at the same speed cannot be simulated by any finite hardware. Algorithms A and B attempt to approximate

2:    $i := 0$ ;
3:   repeat
4:     test satisfiability of  $\phi_i$ ;
5:     if  $\phi_i$  is satisfiable then terminate;
6:      $i := i + 1$ ;
7:   until 1=0;

```

Figure 19.4. Algorithm S

this scheme by using a finite number processes. Algorithm A uses a fixed number n of processes. Algorithm B uses a finite but unbounded number of processes which are run at variable rates.

19.5.1. Algorithm S: Sequential Testing

The standard algorithm for finding plans in the satisfiability and related approaches to planning tests the satisfiability of formulae for plan lengths 0, 1, 2, and so on, until a satisfiable formula is found [BF97, KS96]. This algorithm is given in Figure 19.4.

19.5.2. Algorithm A: Multiple Processes

Algorithm A (Figure 19.5) distributes plan search to n concurrent processes and initially assigns the first n formulae to the n processes. Whenever a process finds its formula satisfiable, the computation is terminated. Whenever a process finds its formula unsatisfiable, the process is given the next unassigned formula. This strategy can avoid completing the satisfiability tests of many of the expensive unsatisfiable formulae, thereby saving a lot of computation effort.

Algorithm S is the special case with $n = 1$. The constant ϵ determines the coarseness of CPU time division. The *for each* loop in this algorithm and in the next algorithm can be implemented so that several processes are run in parallel.

```

1: procedure AlgorithmA( $n$ )
2:    $P := \{\phi_0, \dots, \phi_{n-1}\}$ ;
3:    $\text{next} := n$ ;
4:   repeat
5:      $P' := P$ ;
6:     for each  $\phi \in P'$  do
7:       continue computation with  $\phi$  for  $\epsilon$  seconds;
8:       if  $\phi$  was found satisfiable then terminate;
9:       if  $\phi$  was found unsatisfiable then
10:          $P := P \cup \{\phi_{\text{next}}\} \setminus \{\phi\}$ ;
11:          $\text{next} := \text{next} + 1$ ;
12:       end if
13:     end do
14:   until  $0=1$ 

```

Figure 19.5. Algorithm A

```

1: procedure AlgorithmB( $\gamma$ )
2:    $t := 0$ ;
3:   for each  $i \geq 0$  do  $\text{done}[i] = \text{false}$ ;
4:   for each  $i \geq 0$  do  $\text{time}[i] = 0$ ;
5:   repeat
6:      $t := t + \delta$ ;
7:     for each  $i \geq 0$  such that  $\text{done}[i] = \text{false}$  do
8:       if  $\text{time}[i] + n\epsilon \leq t\gamma^i$  for some maximal  $n \geq 1$  then
9:         continue computation for  $\phi_i$  for  $n\epsilon$  seconds;
10:        if  $\phi_i$  was found satisfiable then terminate;
11:         $\text{time}[i] := \text{time}[i] + n\epsilon$ ;
12:        if  $\phi_i$  was found unsatisfiable then  $\text{done}[i] := \text{true}$ ; end if
13:      end if
14:    end do
15:   until  $0=1$ 

```

Figure 19.6. Algorithm B

19.5.3. Algorithm B: Geometric Division of CPU Use

Algorithm B (Figure 19.6) uses an unbounded but finite number of processes. The amount of CPU given to each process depends on the index of its formula: if formula ϕ_k is given t seconds of CPU during a certain time interval, then a formula ϕ_i , $i \geq k$ is given $\gamma^{i-k}t$ seconds. This means that every formula gets only slightly less CPU than its predecessor, and the choice of the exact value of the constant $\gamma \in]0, 1[$ is less critical than the choice of n for Algorithm A.

Variable t , which is repeatedly increased by δ , characterizes the total CPU time $\frac{t}{1-\gamma}$ available so far. As the computation for ϕ_i proceeds only if it has been going on for at most $t\gamma^i - \epsilon$ seconds, CPU is actually consumed less than $\frac{t}{1-\gamma}$, and there will be at time $\frac{t}{1-\gamma}$ only a finite number $j \leq \log_\gamma \frac{\epsilon}{t}$ of formulae for which computation has commenced.

The constants n and γ respectively for Algorithms A and B are roughly related by $\gamma = 1 - \frac{1}{n}$: of the CPU capacity $\frac{1}{n} = 1 - \gamma$ is spent in testing the first unfinished formula. Algorithm S is the limit of Algorithm B when γ goes to 0.

Algorithms A and B have two very useful properties [RHN06]. First, both al-

Figure 19.7. Illustration of two runs of Algorithm B. When $\gamma = 0.5$ most CPU time is spent on the first formulae, and when the first satisfiable formula is detected also the unsatisfiability of most of the preceding unsatisfiable formulae has been detected. With $\gamma = 0.8$ more CPU is spent for the later easier satisfiable formulae, and the expensive unsatisfiability tests have not been completed before finding the first satisfying assignment.

gorithms can be arbitrarily much faster than Algorithm S. This is because testing the satisfiability of some of the unsatisfiable formulae may be arbitrarily difficult in comparison to the easiest satisfiable formulae. Second, both algorithms are at most a constant factor slower than Algorithm S. This constant is n for Algorithm A and $\frac{1}{1-\gamma}$ for Algorithm B. So even in cases in which these algorithms do not improve on Algorithm S, the efficiency loss is bounded.

19.6. Temporal Planning

The SAT modulo Theories (SMT) [WW99, ABC⁺02] framework, which supports numerical and other constraints in addition to Boolean ones, can be applied to the solution of more general planning problems.

The first application of SAT extended with numerical constraints was by Wolfman and Weld [WW99] to the classical planning problem with numerical state variables. The notion of plans and executions are the same as in classical planning. The difference is that in addition Boolean state variables, there are numerical state variables which can be assigned values expressed as arithmetic expressions.

Shin and Davis gave a systematic translation of an expressive planning language into the SMT framework [SD05]. This is a major generalization of the representations of classical planning as propositional formulas. Instead of a sequence of states, with a number of actions taking between any two consecutive states, in temporal planning there can be multiple actions temporally overlapping each other in different ways, and the execution of one action can span multiple steps of the plan. This framework can be applied to a range of modelling languages [Rin17], and as the number of steps of a plan is bounded similarly to classical planning, the same solving strategies (Section 19.5) are applicable.

Here we sketch the main ideas of the type of encodings first proposed by Shin and Davis [SD05] which have later been used for solving planning problems by using SMT solvers.

We use a simple formalization of temporal planning, with a set X of state variables and actions as triples (p, d, e) , where p is a propositional formula over X just like in classical planning, and $d > 0$ is a rational *duration* of the action, and e is a set of literals over X made true by the action. The precondition p has to be true at the time point in which the action is taken, and the effects e become true after time d .

Unlike in classical planning, timelines in temporal planning are continuous, either rational or real valued, but it is still sufficient to represent explicitly only a finite sequence of time points in which an action is taken or an effect of an action takes place, just like in classical planning.

As before, l denotes the index of the last step so that the $l + 1$ steps of a plan are indexed from 0 to l . We use the same atomic propositions $a@i$ and $x@i$ to indicate whether an action is taken or a state variable is true at a given step i . Additionally, we associate an absolute time $\tau@i$ with each step. The numeric inequalities

$$\tau@i > \tau@j \quad (19.12)$$

for all i and j such that $l \geq j > i > 0$, forces the absolute time to be monotonically increasing. Next we express the properties of actions and state variables at different steps of a plan.

We have the formula

$$a@i \rightarrow p@i \quad (19.13)$$

for the precondition p of action a , for every $i \in \{0, \dots, l - 1\}$.

For an action $a = (p, d, e)$, define $EPC_i(a) = \top$ iff $l \in e$ and otherwise $EPC_i(a) = \perp$. Like earlier, we define $causes(l)@i$ to denote the conditions under which literal l becomes true at step i . For temporal planning this can refer to multiple earlier steps, as the last step might not be the one in which an action affecting l took place.

$$causes(x)@i = \bigvee_{a \in A} \bigvee_{j=0}^{i-1} (a@j \wedge EPC_x(a)@j \wedge (\tau@i - \tau@j = d_a)) \quad (19.14)$$

we denote the disjunction of all the conditions under which x becomes true at step $i \in \{0, \dots, l\}$. These formulas refer to atomic propositions for earlier steps. Similarly $causes(\neg x)@i$ for x becoming false. Hence when $causes(l)@i$ is true, the effect l takes place.

$$causes(x)@i \rightarrow x@i \quad (19.15)$$

$$causes(\neg x)@i \rightarrow \neg x@i \quad (19.16)$$

Frame axioms allow inferring that the value of a state variable remains unchanged.

$$(x@i \wedge \neg x@(i - 1)) \rightarrow causes(x)@i \quad (19.17)$$

$$(\neg x@i \wedge x@(i - 1)) \rightarrow causes(\neg x)@i \quad (19.18)$$

When $t > 0$, to guarantee that there is a step for every effect, we need

$$a@i \rightarrow \bigvee_{j=i+1}^l (\tau@j - \tau@i = t). \quad (19.19)$$

Most temporal planning problems restrict the possibilities to overlap two actions in various ways. Assume that no overlap for actions a and a' is allowed, and these actions respectively have durations d and d' . Now, if a is taken at t , then a' cannot be started before time $t + d$, and if a' is taken at t , then a cannot be started before time $t + d'$, expressed by

$$a@i \rightarrow \bigwedge_{j=i}^l (a'@j \rightarrow (\tau@j - \tau@i \geq d)) \quad (19.20)$$

$$a'@i \rightarrow \bigwedge_{j=i}^l (a@j \rightarrow (\tau@j - \tau@i \geq d')) \quad (19.21)$$

For different limits on the concurrency of actions see the literature [SD05, Rin17].

Temporal planning can be reduced to plain SAT [RGS15], but as numerical durations are not represented, a satisfying assignment is not guaranteed to correspond to a valid plan, and multiple calls, with tighter Boolean constraints, may be required to find one. Also, minimization of the durations of plans is harder.

19.7. Contingent Planning

Classical planning and temporal planning assume the world to be completely predictable. Nondeterminism and unpredictability, as well as limited observability, complicate planning and reduce the possibilities of effective reductions to SAT.

With a polynomial bound on the number of actions in a plan, the complexity of classical planning decreases from PSPACE-complete to NP-complete. More general planning problems have a complexity far exceeding PSPACE: planning with nondeterministic actions and full observability is EXP-complete [Lit97], with no observability EXPSPACE-complete [HJ00], and with partial observability 2-EXP-complete [Rin04]. Merely bounding plans to polynomial size will not decrease the complexity to NP. There are two options: either use a formalism harder than NP, or impose further restrictions. Both options have been considered.

In planning with full or partial observability, a plan may have to handle different contingencies in order to achieve its objectives (which is why these problems are sometimes called contingent planning.) Plans can no longer be limited to sequences of actions, as different observations made during the execution may lead to alternative courses of action, represented for example as a branching plan, or a mapping from observations (and the execution state) to actions.

If both plan sizes and executions are restricted to be polynomial, the planning problem is in Σ_2^P [Rin99]. Problems belonging to this complexity class correspond to quantified Boolean formulas (QBF) [SM73] with the prefix $\exists\forall$ (Section 19.7.1).

Even stricter restrictions can reduce the complexity to NP. Chatterjee et al. [CCD16] have shown that planning with partial observability, when the state space is represented simply as a graph with states as nodes, is NP-complete, and can therefore be reduced to SAT (Section 19.7.2).

For problems with very large state spaces, the explicit representation of all states is not feasible. Geffner and Geffner [GG18] have shown that, for a relatively broad class of contingent planning problems with full observability and actions

and states represented in terms of state variables, reduction to SAT can still be a competitive solution method (Section 19.7.3).

19.7.1. Contingent Planning in Σ_2^P with QBF

In this section we discuss the use of quantified Boolean formulas for solving simple contingent planning problems with a polynomial length bound, and more expressive contingent planning problems with a size bound and other, more restrictive conditions to bring the complexity down to NP.

The complexity class Σ_2^P corresponds to QBF with the prefix $\exists\forall$. However, the most natural translation of the planning problem into QBF has the prefix $\exists\forall\exists$, corresponding to problems in Σ_3^P . This discrepancy can be interpreted as the power of QBF with prefix $\exists\forall\exists$ to handle a generalized planning problem in which the possibility of taking an action in a given state and computing the unique successor state cannot be performed in polynomial time [Tur02]. In this section we present the most obvious translation that uses the prefix $\exists\forall\exists$. Translation with prefix $\exists\forall$ is less intuitive [Rin07]. The planning problem with several initial states is similar to the problem of finding homing or reset or synchronizing sequences of transition systems [PB91].

The uncertainty about the initial state as well as the nondeterminism of actions and the environment can be represented as state variables that can assume arbitrary values and different ones at different steps of the executions. We call these state variables the *contingency variables*.

Actions cannot change the values of the contingency variables, but the actions can otherwise depend on them: contingency variables can occur in the actions' preconditions and the condition parts of the effects, thereby affecting the applicability of actions and the effects of actions.

We define a contingent planning problem as a tuple $\langle X, C, I, A, G \rangle$, where X is the set of all state variables, $C \subseteq X$ is the contingency variables, I is a formula for the initial states, A is the set of actions, and G is the formula for the goal states. Here X , A , and G are like for classical in Section 19.2. The contingency variables and the definition of I as a formula are where these definitions diverge.

Next we define a quantified Boolean formula that represents the problem of finding a sequence of actions that leads from any of the initial state to any of the goal states, under any possible combination of contingencies.

Define $P = \{a@i | a \in A, 0 \leq i \leq l\}$ for the set of atomic propositions representing the action and thereby the plan. Define $Z = \{x@i | x \in C, 0 \leq i \leq l - 1\} \cup \{x@0 | x \in X \setminus C\}$ for the values of the contingency variables at all points of the execution, and also the values of all other state variables at the first step of the execution (the initial state). Define $E = \{x@i | x \in X, 1 \leq i \leq l\}$ for the values of non-contingency state variables at all steps of the execution after the initial state. The values of these state variables are determined unique by the action variables and the values of the contingency variables on the previous steps.

Now the translation of the planning problem into QBF is as follows.

$$\exists P \forall Z \exists E (I@0 \rightarrow (\mathcal{T}(0) \wedge \cdots \wedge \mathcal{T}(l-1) \wedge G@l)) \quad (19.22)$$

The formula says that there is a plan (expressed by P) such that for all combinations of contingencies (expressed by Z), there is an execution (expressed by E) that leads to a state that satisfies the goal formula G .

This QBF evaluates to *true* if and only if such a plan exists. For a true QBF the valuation of the outermost variables P indicates what the plan is.

The above formula representing planning *without* observability: a single sequence of actions has to reach the goals independently of the contingencies. In more general cases, observations made during the execution can determine how the plan execution is continued. This corresponds to plans with branching, and the variables P above could represent such a plan, together with a more complex body for the QBF to express how such a branching plan would determine which actions are taken during the execution [Rin99].

The QBF-based representation can be generalized also in other ways. A probabilistic extension of QBF, stochastic satisfiability or SSAT, makes it possible to express transition probabilities associated with nondeterministic actions and noisy observations [ML03].

19.7.2. Planning with Partial Observability in NP

Chatterjee et al. [CCD16] observe that contingent planning with partial observability is in NP if limiting the memory available during the execution, and considering an enumerative – rather than a state variable based – representation of the state space. A graph represents all possible executions of all possible plans. A given plan selects a subset of the arcs of the graph, and the plan must be chosen so that the goals are reached on all execution of the given plan.

Despite the explicit representation of the state space as a graph, the problem is still NP-hard because the actions (outgoing arcs) for each state cannot be chosen independently of other states, and, instead, all states for which the observation (and possibly memory) are the same, must have the same action. This problem of choosing a suitable action for every observation so that goals are reached, makes the problem harder than the corresponding fully observable problem which could be solved in polynomial time.

First we formalize the planning problem.

Definition 19.7.1. A transition system $P = (S, A, O, \delta, Z, I, G)$ consists of

- S is a finite set of states,
- A is a finite set of actions,
- O is a finite set of observations,
- $\delta \subseteq S \times A \times S$ is the transition relation,
- $Z : S \rightarrow O$ is the observation function,
- $I \subseteq S$ is the set of initial states, and
- $G \subseteq S$ is the set of goal states.

The transition relation $\delta(s, a, s')$ expresses whether a transition from s to s' is possible with action a . The function Z associates an observation $Z(s) \in O$ with every state s .

Plans associate an action with every observation. Executions under a given plan include an arc from s to s' if the observation $Z(s)$ in s is associated with

the action a , and $(s, a, s') \in \delta$. A valid plan is one that guarantees that for any state reachable from an initial state, it is always possible to reach one of the goal states.

We will next describe the reduction of this problem to SAT. A core part of it is – similarly to the problem considered in Section 19.7.3 – the representation of constraints expressing the constraint that a given node is (or is not) reachable from another node. For simplicity, we only correspond the memory-free case: generalization to multiple memory states is obtained with a straightforward extension of the formulas given here [CCD16].

The encodings rely on implicitly representing all possible plans and all possible execution graphs. The choice of a plan – the choice of actions and memory updates for all observation and memory state combinations – induces one particular execution graph. A plan is determined by a truth-value assignment to variables π below, and the remaining variables represent the corresponding execution graph (through the variables Arc) and its properties.

A number of propositional variables are defined to encode contingent planning problem with bounded memory into SAT. The first two represent the functions π of bounded-memory plans.

- $\pi(o, a)$ means that action a is taken on observation o .
- $Arc(s, s')$ means that there is a transition from state s to state s' , for all $(s, s') \in Y$ where $Y = \{(s, s') \in S \times S \mid (s, a, s') \in \delta \text{ for some } a \in A\}$.
- $R^I(s)$ means that s is reachable from an initial node under the current plan.
- $R^G(s)$ means that a goal node is reachable from s under the current plan.

The arc variables determine whether a given arc (s, s') is considered to be present in the graph representing all executions of a given plan expressed by the valuation of the variables $\pi(o, a)$.

The value of $\pi(o, a)$ has to be unique for all o and a :

$$\neg(\pi(o, a_1) \wedge \pi(o, a_2)) \quad (19.23)$$

for all $o \in O, a_1 \in A, a_2 \in A$ such that $a_1 \neq a_2$.

The function π has to be defined for states that are reachable: for all $s \in S$, if s is reachable from an initial state, then at least one of the actions executable in s should be enabled in s and hence part of the plan.

$$R^I(s) \rightarrow \bigvee_{a \in X(s)} \pi(Z(s), a) \quad (19.24)$$

Here, $X(s) = \{a \in A \mid (s, a, s') \in \delta, \text{ for some } s'\}$. Whether an arc is included in the graph of possible executions is determined as follows.

$$Arc(s, s') \leftrightarrow \left(\bigvee_{a \in Y(s, s')} \pi(Z(s), a) \right) \quad (19.25)$$

Here, $Y(s, s') = \{a \in A \mid (s, a, s') \in \delta\}$. Finally, it is required that a goal state is reachable from any state that is reachable from an initial state.

$$R^I(s) \rightarrow R^G(s) \quad (19.26)$$

There are alternative ways of encoding these reachability constraints, including a set of clauses and using a specialized graph constraint for reachability or for acyclicity, and as these constraints dominate the encoding, they can have a strong impact on the scalability of the approach [PR18].

19.7.3. Planning with Full Observability in NP

Earlier works had suggested that contingent planning in general either requires a formalism that is harder than NP, or must be dramatically limited in terms of the size of the plans, the length of the executions, and the compactness of the transition system representation.

However, Geffner and Geffner [GG18] demonstrated that for a class of contingent planning problems with full observability, plans and their executions can be represented as a propositional formula even with the actions and states represented compactly in terms of state variables.

In this formula, each node of a plan is associated with atomic propositions that describe the relevant features of the state when the execution is in that node. This allows each satisfying assignment of the formula to represent both a branching plan and all of its relevant executions, thereby bringing the complexity down to NP and enabling reductions to SAT.

This approach resembles the preceding one (Section 19.7.2) in identifying executions with a graph that is represented in the satisfying assignments of the formula, and by relying on graph constraints to express the conditions for the validity of a plan.

The approach seems to be limited by the requirement that all states in a given node of the plan have to agree on the values of some of the state variables, but many practical problems are still effectively representable in this way.

Chapter 20

Software Verification

Daniel Kroening

20.1. Programs use Bit-Vectors

Ensuring correctness or quality of computer software is an increasingly difficult task due to the ever-growing size and complexity of programs. Correctness is especially important in the case of software that runs on computers embedded in our transportation and communication infrastructure. Examples of software errors that led to huge financial losses and loss of life are easy to find.

From the point of view of a computer scientist, these quality problems are not easy to explain, as reasoning about sequential programs is possibly the oldest discipline in computer science. Programs are well-understood as a set of instructions that manipulate the values of a given set of program variables. When reasoning about a program, e.g., within a program analyzer, these program variables are typically modeled as unbounded integers.

In reality, program analyzers rarely need to reason about unbounded integers. With a few exceptions, most programming languages offer basic data types that have *bit-vector semantics*, i.e., they have a bounded range defined by the number of bits allocated for them. In case of an unsigned number with n bits, this range is $0, \dots, 2^n - 1$. If this range is exceeded by an arithmetic operation, the result *wraps around*, which means that the modulo 2^n of the actual result is computed.

But it is not modular arithmetic that is needed: All commercially available processors implement bit-wise operators, such as shifting or a bit-wise logical ‘AND’. Such operators are inexpensive to implement in hardware, and the corresponding instructions are executed more efficiently than arithmetic instructions. As a consequence, many programs use such instructions, e.g., for performance-critical operations such as encodings of data streams or the like. Some bit-wise operators have reasonable arithmetic models when interpreted as operators over integers, e.g., a one-bit left-shift corresponds to a multiplication by two. However, most bit-wise operators require modeling with non-linear integer arithmetic if interpreted as functions over integers. Due to these issues, many program analysis engines are unsound with respect to the actual semantics of arithmetic over bit-vectors.

A possible solution is to model programs by closely following the hardware that is used to implement their execution environment: bit-vectors can be modeled as a set of Boolean variables, and bit-vector operators as a set of Boolean functions. Propositional SAT is therefore an accurate and efficient decision engine for decision problems that arise in program verification.

In this chapter, we describe methods for program verification using a SAT solver as decision procedure. For a broader perspective on program verification, see [DKW08]. In Section 20.2, we first describe how to automatically extract formal models of software from program source code. We use ANSI-C as programming language for the examples, but all techniques that we describe are also applicable to languages that are similar, e.g., JAVA or C++. In Section 20.3, we explain how to transform typical program expressions into propositional logic, making them suitable as input for a SAT solver. In Section 20.4, we then extend Bounded Model Checking (BMC), a hardware verification technique, to apply to software. BMC is often limited to refutation. *Predicate Abstraction* is a technique that is geared at proving control-flow dominated properties of programs. We describe a SAT-based variant of predicate abstraction in Section 20.5.

20.2. Formal Models of Software

The program that is to be analyzed is typically modeled by means of an state transition system.

Definition 1 (Transition System) *A Transition System is a triple (S, S_0, R) , where S is a set of states, $S_0 \subseteq S$ is the set of initial states, $R \subseteq S \times S$ is the transition relation.*

The transition system (the model) of the program is denoted by M . A program state $s \in S$ comprises of an encoding of the current program location and a valuation of the (global and local) program variables. We denote the finite set of program locations by \mathcal{L} , and the program location of state $s \in S$ by $s.l$. A particular program location, denoted by ℓ_0 , is designated as the entry point (main function).

We assume that there is a set of variables V over a finite domain D . The set V is possibly unbounded if dynamic allocation of objects is permitted. We use $s.v$ to denote the value of a variable $v \in V$ in state s .

Function calls are typically modeled by means of an unbounded function call stack $\Gamma : \mathbb{N} \rightarrow D \dot{\cup} \mathcal{L}$, which allows recursion. The stack can be used to save call locations (i.e., elements from \mathcal{L}) and local variables in order to preserve locality (i.e., elements from D). We write $s.\Gamma$ to denote the stack in state s . In summary, S consists of three components:

$$S = \mathcal{L} \times \underbrace{(V \rightarrow D)}_{\text{Variables}} \times \underbrace{(\mathbb{N} \rightarrow (D \dot{\cup} \mathcal{L}))}_{\text{Stack}}$$

This definition only permits one program counter, and thus, only one thread. An initial state in S_0 assigns the initial program location ℓ_0 to the program

counter. The initialization of global data is assumed to be performed as part of the program, and is not encoded in S_0 .

The instructions of the program are modeled by means of the transition relation R : given a pair of states $\langle s, s' \rangle \in S \times S$, $R(s, s')$ holds if and only if there is a transition from s to s' . This encodes both the control flow (by means of constraints on the program counters in s and s'), and the changes in data and of the call stack. Following the structure of the program, R is partitioned into separate relations R_l , one for each program location $l \in \mathcal{L}$. The appropriate R_l is chosen by means of a case-split on $s.l$, i.e.:

$$R(s, s') : \iff \bigwedge_{l \in \mathcal{L}} (s.l = l \longrightarrow R_l(s, s')) \quad (20.1)$$

The transformation of a program given in a typical sequential programming language into this form is straight-forward.

```
extern int  getch();
extern int  printf(const char *, ... );

int main( void ) {
    char x;
    x = getch();
    while (x != '\n') {
        switch(x) {
            case 'a':
            case 'b':
                printf("a_or_b");
                break;
            case 'c':
                printf("c_and_");
                /* fall-through */
            default:
                printf("d");
                break;
        }
    }
    return 0;
}
```

Figure 20.1. A fragment of a C program

Example 1 *As an example, consider the ANSI-C code fragment given in Fig. 20.1. The control flow graph is shown in Fig. 20.2. The variable `getch$1` is an auxiliary variable added as part of the translation process. It contains the return value of the `getch()` function. Similar variables are used to eliminate any side-effects from the expressions, e.g., the compound assignment operators.*

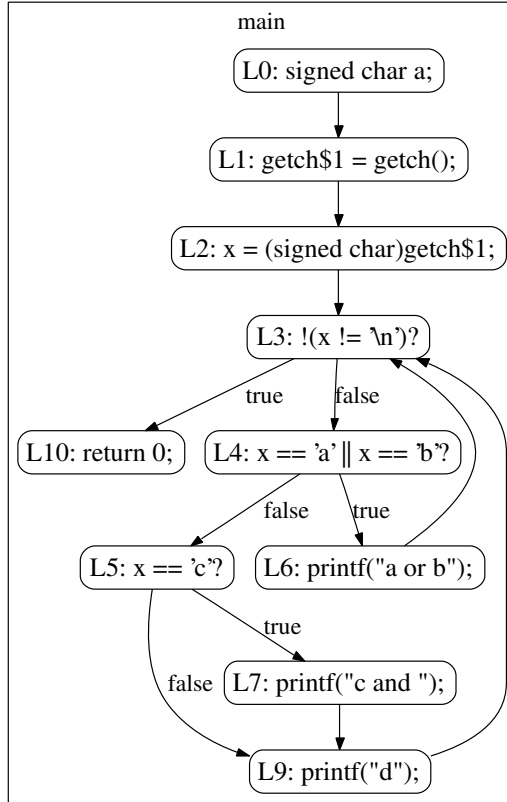

Figure 20.2. Control flow graph of the C program in Fig. 20.1: the nodes in the graph correspond to the program locations.

Each node in the graph corresponds to one program location in \mathcal{L} . Consider the assignment to x in location $L2$. The corresponding transition relation has four conjuncts:

$$\begin{aligned}
 R_{L2}(s, s') &\iff s'.l = L3 \\
 &\quad \wedge \forall v \neq x : s'.v = s.v \\
 &\quad \wedge s'.x = TC(s.\text{getch}\$1) \\
 &\quad \wedge s'.\Gamma = s.\Gamma
 \end{aligned}$$

The first conjunct corresponds to the unconditional edge from node $L2$ to $L3$. The second conjunct enforces that the values of all variables but x do not change in the transition from s to s' . The third conjunct defines the new value of x . The function TC is a mapping from the signed integers to the type `char`, which corresponds to a modulo 256 operation on most architectures. Finally, the fourth conjunct states that the stack does not change.

As an example of a branch, consider program location $L3$. If x is equal to `'\n'`, the **while** loop terminates and program proceeds to location $L10$. Otherwise, the

program continues with location $L4$. Formally, this is captured by a case-split on the value of x in state s :

$$R_{L3}(s, s') \iff s'.\ell = \begin{cases} L10 : s.x = \wedge n' \\ L4 : \textit{otherwise} \end{cases} \\ \wedge \forall v \in V. s'.v = s.v \\ \wedge s'.\Gamma = s.\Gamma$$

We write $s \longrightarrow t$ as a shorthand for $R(s, t)$, and we write $s \rightsquigarrow t$ as shorthand for $R^*(s, t)$, where R^* denotes the reflexive transitive closure of R . The main property of interest in software verification is reachability of certain 'bad' program locations, called *error locations*.¹ This is formalized by the following definition.

Definition 2 (Counterexample) We denote the set of error locations by $\mathcal{L}_E \subset \mathcal{L}$. An error state is a state $s \in S$ with $s.\ell \in \mathcal{L}_E$. A counterexample for a reachability property is a sequence of states s_0, s_1, \dots, s_n with $s_i \in S$, $s_0 \in S_0$, $s_n.\ell \in \mathcal{L}_E$, and $s_j \longrightarrow s_{j+1}$ for $0 \leq j < n$.

20.3. Turning Bit-Vector Arithmetic into CNF

Program analysis algorithms generate verification conditions, which are formulas in the combined expression and assertion logic of the programming language that is used. Let ψ denote such a verification condition.

20.3.1. Pointers

In addition to the usual arithmetic and bit-level operators, we also consider verification conditions ψ that contain operators related to pointers and (possibly unbounded) arrays. The pointer and array operators are usually removed as a pre-processing step by means of a reduction to bit-vector arithmetic. Note that reference types (as offered by JAVA or C++) are simply pointer types with different syntax and a restricted set of operators.

The transformation of pointer-typed variables is commonly done by replacing each pointer-typed variable in ψ by a pair $\langle o, i \rangle$ of bit-vectors. The first component identifies the object that the pointer points to. The second component denotes the offset within the object that the pointer points to. Note that an array is considered to be only one object, independently of how many elements it may have. Therefore, ψ can only contain a finite number of objects, and a finite-width bit-vector is sufficient to enumerate them.

The pointer dereferencing operators require some form of alias analysis. Alias analysis is performed in every modern optimizing compiler, and the algorithms implementing it are well-optimized. Such an analysis can be applied in the context of program verification as well: the output of the alias-analysis procedure is a function that maps the pointers in the program to the set of objects that the pointer may point to. We denote this map by \mathcal{V} . Using this map, the dereferencing

¹Many other properties, e.g., assertions, array-bounds, memory-safety, can be trivially rewritten as reachability problems.

operators in the formula can be replaced by a simple case-split. Let $\mathcal{V}(p)$ be $\{x_1, x_2, \dots, x_n\}$. We substitute each occurrence of $*p$ in ψ as follows:

$$*p = \begin{cases} x_1 : p.o = (\&x_1).o \\ x_2 : p.o = (\&x_2).o \\ \dots \\ x_n : \text{otherwise} \end{cases}$$

Recall that $p.o$ denotes the object that a pointer p points to. In case of an x_i of array type, the index into the array is $p.i$. The other pointer-related operators are transformed as follows:

- The address-of operator $\&x$ returns a constant that uniquely identifies the object x . The numbering can be done in an arbitrary manner, as languages such as ANSI-C do not guarantee an ordering of the objects in memory. Expressions such as $\&x[i]$ can be transformed into $\&x[0] + i$.
- The NULL pointer is a constant with a unique object number.
- The formula ψ may contain calls to procedures that allocate memory dynamically, e.g., `malloc()` in case of ANSI-C, or `new` in case of the object-oriented languages. A new variable of the appropriate type is generated for each one of these calls. The call to `malloc()` or `new` is subsequently replaced by a (constant) pointer pointing to the corresponding new variable.
- Pointer arithmetic $p + z$ and $p - z$ is simply arithmetic on the offset component of p . ANSI-C does not permit pointer arithmetic to exceed the bounds of an object.
- Equality on pointers is equality of the corresponding pairs.
- The relational operators on pointers $p < q$ are replaced by the corresponding relations on the offsets. ANSI-C does not permit relations between pointers that point to different objects.
- The difference $p - q$ of two pointers is the difference of the offsets of p and q . Again, ANSI-C does not permit computing the difference of two pointers that point to different objects.
- Casts between pointer types do not change the value of the pointer.

The alias analysis required for the pointer dereferencing operators has to be performed prior to deciding validity of the verification condition, and depends on the actual program analysis engine, two of which are described later.

20.3.2. Arrays

If of finite size, array-typed variables and the corresponding array-operators can be turned trivially into very large bit-vectors. However, this transformation is usually only efficient if the size of the array is rather small, and infeasible if the size of the array is not a constant. In case of large arrays, or arrays that have variable size, array expressions are typically removed using a reduction to *uninterpreted functions*, which in turn, can be reduced to bit-vector logic by adding equality expressions. The details of this step are described in Part 2, Chapter 33. The resulting formula only contains bit-vector-typed variables and operators over bit-vectors.

20.3.3. Deciding Bit-Vector Arithmetic

There is a large body of work on efficient solvers for bit-vector arithmetic. The earliest work is based on algorithms from the theorem proving community, and uses a canonizer and solver for the theory. The work by Cyrluk et al. [CMR97] and by Barrett et al. on the Stanford Validity Checker [BDL98] fall into this category. These approaches are very elegant, but are restricted to a subset of bit-vector arithmetic comprising concatenation, extraction, and linear equations (not inequalities) over bit-vectors. Non-linear operations, including unrestricted bit-wise operations, are typically not supported.

Bit-Blasting With the advent of efficient propositional SAT solvers such as ZChaff [MMZ⁺01], these approaches have been obsoleted. The most commonly applied approach to check satisfiability of these formulas is to replace the arithmetic operators by circuit equivalents to obtain a propositional formula. This propositional formula is then converted into CNF using a Tseitin encoding (see Part 1, Chapter 2: CNF encodings). The CNF formula is then given to the propositional SAT solver. This approach is commonly referred to as 'bit-blasting', as the word-level structure is lost. It is used by many software analysis tools, e.g., by Alloy [Jac06]. We now provide a short tutorial on this technique.

We denote the bit-vector formula we want to convert by ψ , and the result of the bit-blasting procedure (the propositional formula) by ψ_f . Let $A(\psi)$ denote the set of atoms in ψ . As a first step, each atom $a \in A(\psi)$ is replaced by a new Boolean variable, denoted by $\mu(a)$. The resulting formula is denoted by ψ_{sk} , and is called the *propositional skeleton* of ψ . The propositional skeleton is the expression that is assigned to ψ_f initially.

The algorithm then assigns a vector of new Boolean variables to each bit-vector term in ψ . We use $\mu(t)$ to denote this vector of variables for a given term t , and $\mu(t)_i$ to denote the variable for the bit with index i of the term t . The algorithm then computes a constraint for each unique term in t that is not a variable. The constraint depends on the operator in the term.

The constraint for bit-wise operators is straight-forward. As an example, consider bit-wise OR, i.e., t is $a \mid b$, and let both a and b have l bits. The constraint added to ψ_f is:

$$\bigwedge_{i=0}^{l-1} ((a_i \vee b_i) \iff \mu(t)_i) \quad (20.2)$$

The constraints for other bit-wise operators follow the same pattern. The constraint for the arithmetic operators (addition, subtraction, and so on) follows simplistic implementations of these operators as a circuit.

The Cogent procedure is an implementation of bit-blasting that takes ANSIC expressions as input [CKS05a]. Most other decision procedures use simple variants of this technique. CVC-Lite pre-processes the input formula using a normalization step followed by equality rewrites before finally bit-blasting to SAT [BGD05]. Wedler et al. have a similar approach wherein they normalize bit-vector formulas in order to simplify the generated SAT instance [WSK05]. STP [CGP⁺06], which is the engine behind the EXE program analyzer, is a successor to the CVC-Lite system; it performs several array optimizations, as well

as arithmetic and Boolean simplifications on the bit-vector formula before bit-blasting. Yices [DdM06] applies bit-blasting to all bit-vector operators except for equality. Bryant et al. present a method to solve hard instances that is based on iterative abstraction refinement [BKO⁺07].

20.4. Bounded Model Checking for Software

20.4.1. Background on BMC

Bounded model checking (BMC) is one of the most commonly applied formal verification techniques for circuitry in the semiconductor industry. The technique owes this success to the impressive capacity of propositional SAT solvers. The design under verification is unwound k times together with a correctness property to form a propositional formula, which is then passed to the SAT solver. The formula is satisfiable if and only if there is a trace of length k that refutes the property. The technique is inconclusive if the formula is unsatisfiable, as there might still be a counterexample that is longer than k steps.

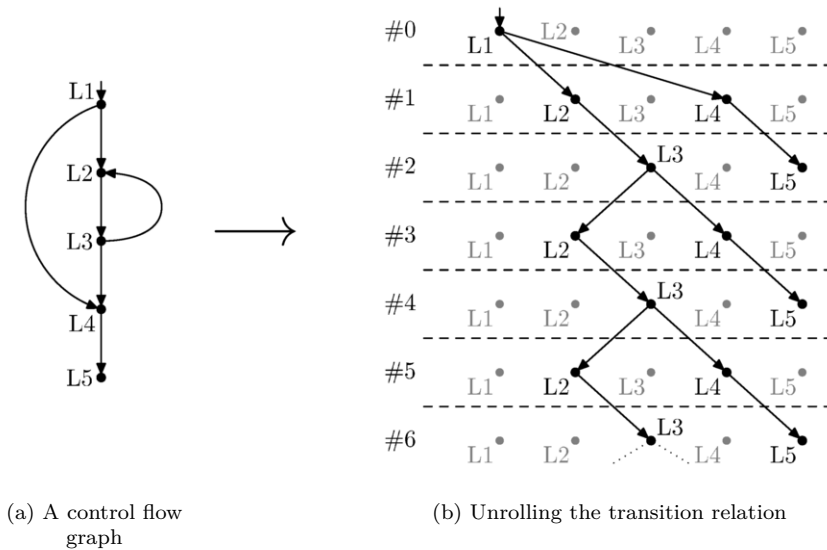

BMC encodings have been proposed for a wide range of specification logics, including LTL and CTL. The presentation that follows is restricted to reachability properties. As defined in Sec. 20.2, we use R to denote the relation that describes the set of possible steps (transitions) the design can make. The set of initial states of the system is given by S_0 , and we use the predicate p as a short-hand for the reachability property of interest. To obtain a BMC instance with k steps, the transition relation is replicated k times. The variables in each replica are renamed such that the next state of step k is used as current state of step $k + 1$. The transition relations are conjoined. In addition to that, the current state of the first step is constrained to be in S_0 , and one of the states must satisfy $\neg p$:

$$\begin{array}{ccccccc} S_0 \wedge R & \xrightarrow{\wedge} & R & \xrightarrow{\wedge} & \dots & \xrightarrow{\wedge} & R \\ \bullet & \xrightarrow{\quad} & \bullet & \xrightarrow{\quad} & \bullet & \xrightarrow{\quad} & \bullet \\ \neg p & \vee & \neg p & \vee & \neg p & \vee & \neg p \end{array}$$

Any satisfying assignment to such a formula corresponds to a path beginning in the initial state that ends in a state that violates p , and thus, is a counterexample to p . The size of this formula is linear in the size of the design and in k .

20.4.2. Unwinding the Entire Program at once

The idea of BMC is also applicable to system-level software. The most straightforward manner to implement BMC for software is to treat the entire program as one transition relation R , and thus, to ignore the partitioning given by the program location. The program counter ℓ can be represented using a bit-vector of width $\lceil \log_2 |\mathcal{L}| \rceil$ using a binary encoding, or with a one-hot encoding, which uses one bit for each program location. An additional optimization is to merge instructions that form a basic block into a single program location, which reduces the number of locations.

(a) A control flow graph

(b) Unrolling the transition relation

Figure 20.3. When unrolling the entire transition relation (a), the unreachable nodes (in grey) may be omitted (b).

We denote the state in time-frame i of the unwinding by s_i , and construct the following formula: state s_0 must be an initial state, there must be a transition between s_i and s_{i+1} for any i , and one of the s_i must reach an error state.

$$S_0(s_0) \wedge \bigwedge_{i=0}^{k-1} R(s_i, s_{i+1}) \wedge \bigvee_{i=0}^k \bigvee_{l \in \mathcal{L}_E} s_i.l = l \quad (20.3)$$

This formula can then be passed to a decision procedure, e.g., the procedure for deciding bit-vector logic described in Sec. 20.3. If it is satisfiable, the solver is also expected to provide a satisfying assignment. From this satisfying assignment, we can extract the values of s_0, \dots, s_k , which is a counterexample according to Def. 2. If Eq. 20.3 is unsatisfiable, we can conclude that no error state is reachable in k or less steps.

Optimizations The size of Eq. 20.3 is k times the size of R , i.e., the size of the program. For large programs, this is already prohibitive, and thus, several optimizations have been proposed. The first step is to perform an analysis of the control flow that is possible within the bound. Consider the small control flow graph in Fig. 20.3a. Each node corresponds to one basic block; the edges correspond to possible control flow between the blocks. Note that block L1 can only be executed in the very first step of any path. Similarly, block L2 can only be executed in step 2, 4, 6 and so on. This is illustrated in Fig. 20.3b: the nodes unreachable in the corresponding time-frames are in grey. This optimization can be seen as the equivalent of the bounded cone of influence (B-COI) reduction [BCRZ99].

Figure 20.4. A loop-based unrolling of the control flow graph in Fig. 20.3a

20.4.3. Unwinding Loops Separately

Again, consider the example in Fig. 20.3a: observe that any path through the CFG contains L4 and L5 at most once. However, note that the unwinding of the transition relation in Fig. 20.3b contains a total of three copies of L4 and L5. This motivates the idea of *loop unwinding*. Instead of unwinding the entire transition relation, each loop is unwound separately. Loop unwinding is illustrated in Fig. 20.4: the loop between L2 and L3 is unwound twice. The algorithm maintains a separate unrolling bound for each loop of the program. In case of nested loops, a separate bound can be used even for each *instance* of a specific loop.

As a consequence, the transition relation R can no longer simply be replicated k times. Instead, the control-flow of the original program is modified by unwinding the loops. Unwinding a loop k times corresponds to replicating the body of the loop k times. Each copy is guarded by an appropriate `if` statement in order to handle loops whose execution aborts before k iterations.

The example in Fig. 20.5 shows an unwinding with $k = 2$. This permits loops where the number of actual iterations depends on a non-deterministically chosen input. The last `if` statement is augmented with an `else` branch. The `else` branch corresponds to the case that k is too low for this loop, and not enough unwinding was performed. The `assume(false)` statement ensures that this does not result in spurious paths. Appropriate care must be taken to preserve the locality of variables that are declared within the loop body. Recursive function calls, and loops built by means of backward `goto` statements can be unwound in the same manner as explicit loops.

$$\begin{array}{l}
 \text{while}(x) \\
 \text{BODY;}
 \end{array}
 \longrightarrow
 \begin{array}{l}
 \text{if}(x) \{ \\
 \text{BODY;} \\
 \text{while}(x) \\
 \text{BODY;} \\
 \}
 \end{array}
 \longrightarrow
 \begin{array}{l}
 \text{if}(x) \{ \\
 \text{BODY;} \\
 \text{if}(x) \\
 \text{BODY;} \\
 \text{else} \\
 \text{assume(false);} \\
 \}
 \end{array}$$

Figure 20.5. A loop-based unrolling of a **while** loop with depth two.

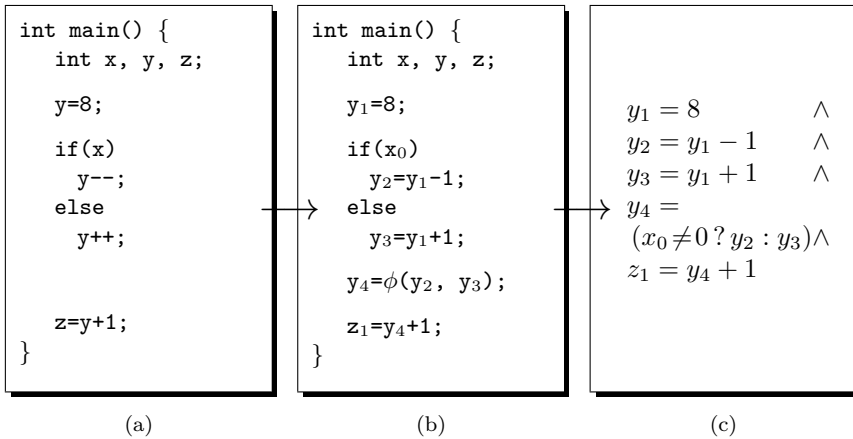

Figure 20.6. The program (a) is transformed into SSA (b). The merge-point in the control flow graph following the **if** statement is turned into a ϕ -node. The SSA is transformed into a formula (c).

The next step after unwinding is to transform the program into static single assignment (SSA) form [AWZ88]. This operation is also found in most modern optimizing compilers, and thus, it is easy to find efficient implementations. We illustrate this transformation by example: Fig. 20.6 shows a small C program and its SSA form. The SSA form is built by numbering the variables according to the number of times they have been assigned so far. At merge points within the control flow graph, the appropriate value is chosen using a ϕ -function, which is simply a case-split using the branch condition. It is straight-forward to turn the SSA-form into a formula: one simply reads the assignments as equality, and conjoins them.

There are alternatives for generating formulas from programs, e.g., a path-based exploration, which amounts to building a separate formula for each program path. Loop unwinding, as described above, is not the same as a path-based exploration: in the example, the path that corresponds to the branch from L1 to L4 merges with the path that follows the loop. As a consequence, the formula that is generated is *linear* in the number of loop unrollings and in the size of the

program, even if there is an exponential number of paths through the CFG.

Compared to unrolling the entire program, the loop-based unrolling may result in formulas that are more compact. The loop-based unrolling also requires fewer case-splits in the formula, as the program location is fixed for a particular part of the formula. A disadvantage of the loop-based unwinding is that it may require more time-frames in order to reach a given control flow location. In the example in Fig. 20.4, the unwinding of the transition relation reaches iteration three in the loop between L2 and L3, whereas the loop-based unrolling only reaches iteration two with the same number of steps.

20.4.4. A Complete BMC for Software

Bounded Model Checking, when applied as described above, is inherently incomplete, as it searches for violations of the property only up to the given bound. Bugs that are deeper than the given bound are missed. Nevertheless, BMC can be used to *prove* safety properties if applied in a slightly different way.

Intuitively, if we could perform the search *deep enough*, we can guarantee that we have already examined all the relevant behavior of the model, and that searching any deeper only exhibits states that we have explored already. A depth that provides such a guarantee is called a *completeness threshold* [KS03]. Computing the smallest such threshold is as hard as Model Checking itself, and thus, one settles for over-approximations in practice.

In the context of software, one way to obtain a depth-bound for the program is to determine a high-level worst-case execution time (WCET). This time is given in terms of a bound on the maximum number of loop-iterations. Tools that compute a WCET often perform a simplistic syntactic analysis of loop structures. If that fails, an iterative algorithm can be applied: One first guesses a bound, and then checks an assertion that is violated by paths that exceed this bound [KCY03, CKL04]. If so, the bound is increased, and the procedure starts over. Such an assertion is called an *unwinding assertion*, and is obtained by simply replacing the `assume(false)` statement as explained above by an `assert(false)` statement. This technique is applicable if the program (or at least the body of its main loop) has a runtime-bound, which is highly desirable for many embedded applications.

20.4.5. Tools that Implement BMC for Software

There are a number of implementations of BMC available for software verification. The first implementation of a depth-bounded symbolic search in software was reported in 2000 by Currie et al. [CHR00].

The CBMC tool, developed at CMU, emulates a wide range of architectures as environment for the program under test [KCY03, CKL04]. It supports both little-endian and big-endian memory models, and the header files needed for Linux, Windows, and Mac-OS X. It implements loop unrolling as described in Sec. 20.4.3. It uses bit-flattening, or bit-blasting, to decide the resulting bit-vector formula. It also has options to export the formula in a variety of word-level formats. It is the only tool that also supports C++, SpecC and SystemC. The main application of CBMC is checking consistency of system-level circuit models given in C or

SystemC with an implementation given in Verilog. IBM has developed a version of CBMC for concurrent programs [RG05].

The only tool that implements an unwinding of the entire transition system, as described in Sec. 20.4.2, is F-SOFT [ISGG05], developed at NEC Research. It also features a SAT solver that is customized to the decision problems that are generated by BMC. The benchmarks that have been reported are system-level UNIX applications such as `pppd`.

A number of variants of these implementations have been reported. Armando et al. implement a version of CBMC that generates a decision problem for an SMT solver for integer linear arithmetic [AMP06].

SATURN is a very specialized implementation of BMC: it is custom-tailored to the properties it checks [XA05]. It implements loop unwinding as described in Sec. 20.4.3. The authors have applied it to check two different properties of Linux kernel code: NULL-pointer dereferences and locking API conventions. They demonstrate that the technique is scalable enough to analyze the entire Linux kernel. Soundness is relinquished for performance; SATURN performs at most two unwindings of each loop. Bugs that are only revealed with more than two loop iterations are missed. This approach is implemented by numerous software analysis tools as well, e.g., by ESC/Java [FLL⁺02].

The EXE tool is also specialized to bug-hunting [YST⁺06]. It combines explicit execution and path-wise symbolic simulation in order to detect bugs in system-level software such as file system code. It uses a very low-level memory model, which permits checking programs that rely on specific memory layouts.

While BMC is probably the best technique for bug-hunting, other techniques are better at *proving* properties. Predicate abstraction excels at the verification of light-weight control-flow dominated properties, and is discussed next.

20.5. Predicate Abstraction using SAT

20.5.1. The Need for Abstraction

In most cases, proving correctness of the entire code is not the goal of automatic software verification. To begin with, writing a sufficiently strong specification of all program behavior is already very hard. Many properties of programs that are of interest for automatic verification are therefore very light-weight.

As an example of a light-weight property, consider the pre-conditions of a locking-API, such as offered by the PTHREAD library. The `pthread_mutex_lock(m)` function attempts to acquire a given mutex m , while the `pthread_mutex_unlock(m)` releases the lock m . Similar functions are provided by many other APIs. A program using this API must obey certain restrictions on its use:

- A process holding a lock must not attempt to acquire it again before releasing it,
- a process must not release a lock unless it holds it.

As a consequence of the two rules above, a program using the API is expected to call the lock/unlock functions in an alternating fashion. E.g., two consecutive calls to `pthread_mutex_lock(m)` with the same mutex m are erroneous.

While bugs related to concurrency can have serious consequences, it is obvious that locking and unlocking mutexes is not the main purpose of the program. The program likely contains many more instructions, which are irrelevant with respect to the lock/unlock property. The code that can influence the calls to the lock/unlock functions likely comprises only a small fraction of the total amount of code. In case of the lock/unlock property, the right order of calls is often already apparent from the control flow graph, completely disregarding any data.

The goal of *abstraction* is therefore to construct a model that only contains those parts of the program that are actually relevant to the property of interest. As this model is often much smaller than the original program, the verification becomes more efficient. The trick is to be sure that the reduction is done in a *conservative manner*, i.e., that details relevant to the property are preserved. We describe a systematic approach to construct such abstractions next.

20.5.2. Existential Abstraction

Formally, the goal of abstraction is to compute an abstract model \hat{M} from the concrete model M such that the size of the state-space is reduced while the property of interest is preserved. We denote the set of abstract states by \hat{S} . A concrete state is mapped to an abstract state by means of an *abstraction function*, which we denote by $\alpha : S \rightarrow \hat{S}$. We also extend the definition of α to sets of states: Given a set $S' \subseteq S$, we denote $\{\hat{s} \in \hat{S} \mid \exists s \in S'. \alpha(s) = \hat{s}\}$ by $\alpha(S')$. The inverse of α , called the *concretization function*, maps abstract states back to the corresponding concrete states, and is denoted by γ [CC77]:

$$\gamma(\hat{S}') := \{s \in S \mid \alpha(s) \in \hat{S}'\} \quad (20.4)$$

As mentioned above, we restrict the presentation to *safety properties*. The goal therefore is to compute an abstraction that preserves safety properties: any program location that is reachable in M must be reachable in \hat{M} . *Existential Abstraction* is a form of abstraction that preserves safety properties [CGL92].

Definition 3 (Existential Abstraction [CGL92]) *Given an abstraction function $\alpha : S \rightarrow \hat{S}$, a model $\hat{M} = (\hat{S}, \hat{S}_0, \hat{R})$ is called an Existential Abstraction of $M = (S, S_0, R)$ iff the following conditions hold:*

1. *The abstract model can make a transition from an abstract state \hat{s} to \hat{s}' iff there is a transition from s to s' in the concrete model and s is abstracted to \hat{s} and s' is abstracted to \hat{s}' :*

$$\begin{aligned} \forall \hat{s}, \hat{s}' \in (\hat{S} \times \hat{S}). \hat{R}(\hat{s}, \hat{s}') \iff \\ (\exists s, s' \in (S \times S). R(s, s') \wedge \alpha(s) = \hat{s} \wedge \alpha(s') = \hat{s}') \end{aligned} \quad (20.5)$$

2. *The set of abstract initial states \hat{S}_0 is simply the abstraction of the set of concrete initial states:*

$$\hat{S}_0 = \alpha(S_0) \quad (20.6)$$

The fact that existential abstraction is a conservative abstraction with respect to safety properties is formalized as follows:

Theorem 1 Let \hat{M} denote an existential abstraction of M , and let p denote a safety property. If p holds on \hat{M} , it also holds on M :

$$\hat{M} \models p \implies M \models p$$

Thus, for an existential abstraction \hat{M} and any program location l that is not reachable in the abstract model \hat{M} , we may safely conclude that it is also unreachable in the concrete model M . Note that the converse does not hold, i.e., there may be locations that are reachable in \hat{M} but not in M .

In program verification, the abstract transition relation \hat{R} is typically represented using a partitioning, similarly to the concrete transition relation R (see section 20.2). The abstract transition relation for program location $l \in \mathcal{L}$ is denoted by $\hat{R}_l(\hat{s}, \hat{s}')$:

$$\hat{R}(\hat{s}, \hat{s}') : \iff \bigwedge_{l \in \mathcal{L}} (s.l = l \longrightarrow \hat{R}_l(\hat{s}, \hat{s}')) \quad (20.7)$$

As the abstract program has the same control flow structure as the original program, the computation of \hat{R} follows the structure of the partitioning according to the program locations, i.e., \hat{R} is generated by computing \hat{R}_l from R_l for each location $l \in \mathcal{L}$ separately. In the following, we describe algorithms for this task.

20.5.3. Predicate Abstraction

There are various possible choices for an abstraction function α . *Predicate Abstraction* is one possible choice. It is one of the most popular and widely applied methods for systematic abstraction of programs. Predicate abstraction abstracts data by only keeping track of certain predicates on the data. The predicates are typically defined by Boolean expressions over the concrete program variables. Each predicate is then represented by a Boolean variable in the abstract program, while the original data variables are eliminated. The resulting program is called *Boolean Program*. Due to the smaller state-space of the Boolean program, Model Checking becomes feasible. A manual form of predicate abstraction was introduced by Graf and Saïdi [GS97]. An automated procedure to generate predicate abstractions was introduced by Colón and Uribe [CU98]. Predicate abstraction is promoted by the success of the SLAM project at Microsoft Research [BR00b]. The SLAM tool checks control-flow dominated properties of Windows device drivers.

The difficulty of predicate abstraction is to identify appropriate predicates, since they determine the accuracy of the abstract model. The predicates can be automatically inferred using *Counterexample-guided abstraction refinement* [Kur94, CGJ⁺00]: Abstract counterexamples that cannot be replayed in the concrete program serve as guide for refining the abstract model.

We postpone the problem of obtaining suitable predicates for now, and instead, focus on how to compute the abstract model once a set of predicates is given. We denote the set of Boolean values by $\mathbb{B} := \{\text{T}, \text{F}\}$. Let $\Pi := \{\pi_1, \dots, \pi_n\}$ denote the set of predicates. An abstract state \hat{s} consists of the program location and a valuation of the predicates, i.e., $\hat{S} = \mathcal{L} \times \mathbb{B}^n$. We denote the program location of an abstract state \hat{s} by $\hat{s}.l$, and the vector of predicates by $\hat{s}.\pi$. We

<pre> int main() { int i; ... L1: i=0; ... L2: while(even(i)) L3: i++; L4: ... return 0; } </pre>	<pre> void main() begin decl p1, p2; ... L1: p1,p2 := T,T; ... L2: while p2 do L3: p1,p2 := (p1 p2)?F:* ,!p2; od; L4: ... end </pre>
--	---

Figure 20.7. A C program and its corresponding Boolean program for the predicates $\pi_1 \iff i = 0$ and $\pi_2 \iff \text{even}(i)$. The predicate π_1 is represented by the program variable **p1**, while π_2 is represented by **p2**.

denote the value of predicate i by $\hat{s}.\pi_i$. The abstraction function $\alpha(s)$ maps a concrete state $s \in S$ to an abstract state $\hat{s} \in \hat{S}$:

$$\alpha(s) := \langle s.\ell, \pi_1(s), \dots, \pi_n(s) \rangle \quad (20.8)$$

We use Figure 20.7 as a running example to illustrate the concept of Boolean programs. It shows a small C program and its corresponding Boolean program. The syntax of Boolean programs follows that of most traditional sequential programming languages. Assume that the following set of predicates is given:

$$\begin{aligned} \pi_1 &\iff i = 0 \\ \pi_2 &\iff \text{even}(i) \end{aligned}$$

The predicate $\text{even}(i)$ holds iff i is an even number. The Boolean program uses the variables **p1** and **p2** to keep track of the value of these two predicates. The abstraction of the first assignment to the program variable **i** is straight-forward: both predicates hold after the execution of the statement. Boolean programs permit a parallel assignment to multiple variables, and thus, the pair **T, T** is assigned to the vector of the two predicates.

The Boolean program has the same control flow structure as the original program, and thus, the **while** loop is replicated. The abstraction of the condition is trivial, as the expression used as condition in the concrete program is available as predicate π_2 .

The abstraction of the **i++** statement inside the **while** loop is more complex: again, both predicates may change, and thus, a parallel assignment to **p1** and **p2** is performed. The new value of **p2** is the negated value of **p2**, as an even number becomes odd when incremented, and vice versa. The new value of **p1** depends on the current value of the predicates as follows:

- If $p1$ is \top , i is zero, we know that the new value of i is 1. Consequently, the new value of $p1$ must be F . Similarly, if $p2$ is \top , we can conclude that $i \neq -1$, the new value of i cannot be 0, and thus, the new value of $p1$ must be F .²
- If both $p1$ and $p2$ are F , we cannot make any conclusion about the new value of $p1$; the variable i may be -1, which yields \top as new value of $p1$, or a value that yields F , e.g., the value 3.

The second case above requires non-determinism in the Boolean program; i.e., the program may proceed into a state in which the new value of $p1$ is not determined. We use a ‘*’ to denote a non-deterministic value within the Boolean program.

In practice, Boolean programs are constructed algorithmically from the C program, that is, an algorithm computes \hat{R}_l given R_l and the set of predicates. \hat{R} is also called the *image* of the predicates Π over R .

Continuing our running example, consider the program statement $i++$ at $L3$ in the **while** loop, which has the most complex abstraction. Disregarding the control flow, this statement translates to the following concrete transition relation $R_l(s, s')$:

$$R_{L3}(s, s') \iff s'.i = s.i + 1$$

Again, assume that the set of predicates consists of $\pi_1 \iff i = 0$ and $\pi_2 \iff \text{even}(i)$. With $n = 2$ predicates, there are $(2^n) \cdot (2^n) = 16$ potential abstract transitions. A naïve way of computing \hat{R} is to enumerate the pairs \hat{s}, \hat{s}' and to check Eq. 20.5 for each such pair separately. As an example, the transition from $\hat{s} = \langle L3, \text{F}, \text{F} \rangle$ to $\hat{s}' = \langle L2, \text{F}, \text{F} \rangle$ corresponds to the following formula over concrete states:

$$\exists s, s'. \underbrace{\neg s.i = 0}_{\neg\pi_1} \wedge \underbrace{\neg \text{even}(s.i)}_{\neg\pi_2} \wedge \underbrace{s'.i = s.i + 1}_{R_{L3}} \wedge \underbrace{\neg s'.i = 0}_{\neg\pi'_1} \wedge \underbrace{\neg \text{even}(s'.i)}_{\neg\pi'_2} \quad (20.9)$$

Formula 20.9 can then be passed to a satisfiability checker as described in Sec. 20.3. The abstract transition is in \hat{R}_{L3} if and only if the formula is satisfiable. Continuing our example, the decision procedure will find Eq. 20.9 to be unsatisfiable, and thus, the particular abstract transition is not in \hat{R}_{L3} . Fig. 20.8 shows the abstract transitions for the program statement above, and one corresponding concrete transition (i.e., a satisfying assignment to Eq. 20.5) for each possible abstract transition.

The procedure described above results in the ‘best’ possible, i.e., the most precise abstract transition relation for the given predicates. The drawback of this approach is that the run-time of the abstraction procedure is exponential in the number of predicates. The only predicate abstraction framework implementing this approach is MAGIC [CCG⁺04].

20.5.4. Successive Approximation of \hat{R}

Most implementations of predicate abstraction approximate \hat{R} iteratively, in order to avoid the exponential number of calls to the theorem prover. This is done

²Note that the ANSI-C standard does not provide any guarantees in case of overflow of signed integers; however, we can argue that an even number does not overflow if incremented.

Abstract Transition				Concrete Transition	
$\hat{s}.\pi_1$	$\hat{s}.\pi_2$	$\hat{s}'.\pi_1$	$\hat{s}'.\pi_2$	s	s'
F	F	F	T	$s.i = 1$	$s'.i = 2$
F	F	T	T	$s.i = -1$	$s'.i = 0$
F	T	F	F	$s.i = 2$	$s'.i = 3$
T	T	F	F	$s.i = 0$	$s'.i = 1$

Figure 20.8. Example for existential abstraction: Let the concrete transition relation $R_{L3}(s, s')$ be $s'.i = s.i + 1$ and let $\pi_1 \iff i = 0$ and $\pi_2 \iff \text{even}(i)$. The table lists the transitions in \hat{R}_{L3} and an example for a corresponding concrete transition.

by computing a series of over-approximations \hat{R}' of \hat{R} , and is also called *Lazy Abstraction*. The resulting abstract model is weaker as it permits more paths than the model obtained using \hat{R} . Note that the claim in Theorem 1 still holds, as any over-approximation of \hat{R} fulfills the requirements of an existential abstraction. An example of such a procedure is the abstraction component C2BP of the SLAM Model Checker [BPR01, BMMR01].

Predicate Partitioning One technique to compute an over-approximation of \hat{R} is *Predicate Partitioning*. It was introduced in the context of predicate abstraction for Verilog designs by Jain et al. [JKSC05]. As a first step, the set of predicates is partitioned into a number of clusters.

We denote the clusters by $\mathcal{C}_1, \dots, \mathcal{C}_k$. For the purposes of this partitioning, the predicates over the current state s are distinguished from the predicates in the next state s' : Let $\Pi = \{\pi_1, \dots, \pi_n\}$ denote the set of predicates over s , and $\Pi' = \{\pi'_1, \dots, \pi'_n\}$ denote the same predicates over s' . A cluster \mathcal{C}_i is a non-empty subset of $\Pi \dot{\cup} \Pi'$. The union of the clusters is not required to be disjoint or to cover all predicates.

Given a partitioning \mathcal{P} , we denote the existential abstraction of R_l with respect to \mathcal{P} by $\hat{R}_l^{\mathcal{P}}$. It is defined by means of k separate abstract transition relations $\hat{R}_l(1), \dots, \hat{R}_l(k)$, where $\hat{R}_l(j)$ is the precise existential abstraction of R_l with respect to the predicates in the cluster \mathcal{C}_j :

$$(\hat{s}, \hat{s}') \in \hat{R}_l(j) \iff \exists s, s'. R_l(s, s') \wedge \bigwedge_{\pi_i \in \mathcal{C}_j} \hat{s}.\pi_i = \pi_i(s) \wedge \bigwedge_{\pi'_i \in \mathcal{C}_j} \hat{s}'.\pi_i = \pi_i(s') \quad (20.10)$$

The abstract transition relations $\hat{R}_l(j)$ are conjoined to form $\hat{R}_l^{\mathcal{P}}$:

$$\hat{R}_l^{\mathcal{P}} := \bigwedge_{j=1}^k \hat{R}_l(j) \quad (20.11)$$

It is easy to see that $\hat{R}_l \subseteq \hat{R}_l^{\mathcal{P}}$, i.e., $\hat{R}_l^{\mathcal{P}}$ is an over-approximation of \hat{R}_l . The abstract transition relation for each cluster can be computed by using all-SAT as suggested in [CKSY04] or by any other precise abstraction method, e.g., enumeration as described above, or by means of BDDs.

The choice of clusters is typically done by a syntactic analysis of \hat{R}_l and the predicates, e.g., by analyzing the variables that are mentioned in the predicates

and what variables are affected by a transition. A possible strategy is to put predicates that share variables into common clusters.

As a result of the over-approximation \hat{R} , we may obtain an abstract counterexample $\hat{s}_1, \dots, \hat{s}_m$ that contains abstract transitions $\langle \hat{s}_i, \hat{s}_{i+1} \rangle \in \hat{R}'$ for which no concrete counterpart exists, i.e., $\langle \hat{s}_i, \hat{s}_{i+1} \rangle \notin \hat{R}$. Such a transition is called a *spurious transition*. In such a case, \hat{R}' is strengthened by removing some of the transitions. We defer the discussion of how to refine \hat{R}' to section 20.5.7.

20.5.5. Verification of the Abstract Model

Once the Boolean program is constructed, it is passed to a model checker. The purpose of this phase is to determine if there are paths that can reach an error location. Such a path is called an *abstract counterexample*, and is formalized as follows:

Definition 4 (Abstract Counterexample) *An abstract counterexample \hat{t} is a witness for the reachability of an error state \hat{s}_n (where $\hat{s}_n.l \in \mathcal{L}_E$) in the abstract model \hat{M} . Analogously to concrete counterexamples (Def. 2), an abstract counterexample is provided by means of a finite execution trace $\hat{s}_0, \hat{s}_1, \dots, \hat{s}_n$, for which $\bigwedge_{0 \leq i < n} \hat{R}(\hat{s}_i, \hat{s}_{i+1})$ and $\hat{s}_0 \in \hat{S}_0$ holds.*

As mentioned above, the Boolean program has exactly the same control flow structure as its corresponding original program, including (possibly recursive) function calls. There is a wide range of model checking techniques available for the analysis of such abstract models, depending on the set of control flow constructs used by the program.

While the reachability problem for sequential C programs is undecidable, it is decidable for sequential Boolean programs, despite the presence of a potentially unbounded call stack [Büc64]. Since only topmost variables of the stack are visible at each program point, the successor state of a transition is exclusively determined by them and the global variables. Once the return value of a procedure call for certain input values (i.e., global variables and actual parameters) is determined, a second evaluation of the function call with the same arguments is redundant [SP81]. This can be exploited by storing input-output pairs for each procedure (such a pair is called a *summary edge* [BR00a, FWW97]). The reachable states are then computed using a fixed point computation.

All existing model checkers for Boolean programs use a symbolic representation for states: Instead of explicitly enumerating all possible states, Boolean formulas are used to represent sets of states. Binary Decision Diagrams (BDDs) are a particularly well suited representation for Boolean formulas used in fixed point computations, since the computation of the set of successor states can be performed easily [Bry86]. However, BDDs do not scale for a growing number of variables (the upper limit is typically reached with about 100 variables). The number of variables a SAT-solver can handle is several magnitudes higher, but the SAT-based approach requires Quantified Boolean formulas (QBF) for the detection of fixed points [CKS05b]. QBF is a classical PSPACE-complete problem, and is discussed in Part 2, Chapter 29. In practice, QBF-solvers are not nearly as scalable as propositional SAT-solvers. BOPPO is an implementation of a model

checker for concurrent Boolean programs that is based on propositional SAT for path checks, and on QBF for the fixed point detection [CKS07].

If no error state is reachable, then Theorem 1 guarantees that there is also no counterexample in M , and the verification algorithm terminates. In case an abstract counterexample is found, we cannot simply conclude that there is a corresponding counterexample for the original program, as the converse of Theorem 1 does not hold. The abstract counterexample has to be *simulated* on the original program. We describe this process in the next section.

20.5.6. Simulation

As explained in the previous section, not every abstract counterexample has a corresponding concrete counterpart. Therefore, the feasibility of an abstract counterexample must be verified before it is reported to the user. Infeasible counterexamples are eliminated by refining the abstraction, i.e., the approach does not report false negatives.

The easiest way to check if there is a concrete counterexample in M that corresponds to a given abstract counterexample \hat{t} is to perform *symbolic simulation* along the path given by \hat{t} . Recall that \hat{t} is a sequence $\hat{s}_0, \hat{s}_1, \dots, \hat{s}_n$ of abstract states, each of which contains a program location $\hat{s}_i.\ell$. We use $l(i) := \hat{s}_i.\ell$ as a short-hand for these program locations.

In order to check if there is a path in M that follows $l(1), \dots, l(n)$, we iteratively build a formula F_n as follows:

$$\begin{aligned} F_0(s_0) &:= \top \\ F_i(s_i) &:= F_{i-1} \wedge R_{l(i-1)}(s_{i-1}, s_i) \end{aligned} \quad (20.12)$$

The construction of F_n corresponds to the symbolic execution of the transition relation R along the program locations given by \hat{t} . It can be passed to a SAT-based decision procedure as described in Sec. 20.3. If it is found to be satisfiable, a concrete counterexample can be extracted from the satisfying assignment.

Note that such a counterexample does not necessarily comply with the values of the predicates given by \hat{t} , as F_n only follows the program locations. The constraints in Eq. 20.12 are sufficient, since we are satisfied with *any* feasible concrete counterexample.

The tools SLAM and BLAST rely on the First-Order logic theorem provers ZAPATO [BCLZ04] and Simplify [DNS03], respectively, for the simulation of abstract counterexamples. There is no guarantee that these decision procedures provide a definite answer, since the counterexample trace may contain transitions that make use of multiplication, division, or bit-wise operators. In these cases, false negatives are reported. Furthermore, bugs that originate from an integer overflow may go undetected, as neither SLAM nor BLAST provide an accurate axiomatization of bit-vector arithmetic.

A SAT-based procedure as described in Sec. 20.3 mends these problems. SAT solvers provide a witness for satisfiability, which can be mapped back to a valuation to the variables of the feasible counterexample. This additional information makes counterexamples significantly easier to understand for programmers. It should be mentioned that SLAM is not restricted to its default theorem prover

ZAPATO: The SAT-based theorem prover Cogent, which supports bit-vectors and provides countermodels, has been integrated into an experimental version of SLAM [CKS05a].

What if Eq. 20.12 is unsatisfiable? In this case, there is no concrete counterexample that follows the locations $l(1), \dots, l(n)$, and the abstract counterexample is *spurious*. There may be two reasons for a spurious counterexample: we either lack some important predicate, or the counterexample is caused by our over-approximation of \hat{R} , as described in Sec. 20.5.4. In either case, we have to *refine* our abstraction, which is described next.

20.5.7. Refinement

The accuracy of the abstract model depends on the set of predicates. Coarser abstractions contain more “undesirable” traces. There are two kinds of artifacts introduced by the abstraction mechanism: (a) An insufficient set of predicates results in *spurious traces*, and (b) over-approximation of the abstract transition function yields *spurious transitions*. We first describe how to refine spurious transitions, and then present predicate refinement techniques.

Spurious Transitions Predicate abstraction techniques like lazy abstraction, the Cartesian approximation [BPR03] or predicate partitioning (see Sec. 20.5.4) trade precision for performance. Therefore, important correlations between predicates may be lost. Ball et al. present a technique that refines these correlations only in the cases in which they are relevant [BCDR04]. The approach is based on Das and Dill’s algorithm, which refines an abstract transition relation by eliminating *spurious transitions* by means of the predicates already available [DD01].

An abstract transition in a counterexample is spurious if it does not have a corresponding concrete transition (Eq. 20.5). For each transition, an abstract counterexample provides the abstract states before (\hat{s}) and after (\hat{s}') that transition. One way of checking if an abstract error trace contains spurious transitions is to verify Eq. 20.5 for each of the steps in the trace individually using a decision procedure for bit-vector arithmetic. If Eq. 20.5 does not hold for a pair $\langle \hat{s}, \hat{s}' \rangle$, then the corresponding abstract transition is spurious. The abstract transition relation is then refined by ruling out the combination $\langle \hat{s}, \hat{s}' \rangle$ of states.

Example 2 *As an example, consider a program with an integer variable x , and let the instruction at the program location that we check be $x++$. The abstraction is based on the three predicates $x = 1$, $x = 2$, and $x = 3$, called π_1 , π_2 , and π_3 , respectively, and is initially just unconstrained:*

$$p1, p2, p3 := *, *, *;$$

The transition we consider is $\langle T, F, F \rangle$ to $\langle T, F, F \rangle$, which corresponds to the following instance of Eq. 20.5:

$$\exists x, x'. x = 1 \wedge x \neq 2 \wedge x \neq 3 \wedge x' = x + 1 \wedge x' = 1 \wedge x' \neq 2 \wedge x' \neq 3 \quad (20.13)$$

As there is no model for this formula, the transition is spurious. One way to refine the abstract model is to add a constraint to \hat{R} that rules out this particu-

lar transition. Boolean programs offer a constrained assignment for exactly this purpose³:

```
p1, p2, p3 := *,*,* constrain !(p1 & !p2 & !p3 & 'p1 & 'p2 & 'p3);
```

Obviously, ruling out spurious transitions one-by-one as in the example above might require an exponential number of refinement iterations. One way of eliminating multiple spurious transitions with a single iteration is to examine the *unsatisfiable core* of Eq. 20.5. The unsatisfiable core contains only those clauses that contribute to the proof of unsatisfiability. As SAT-solvers attempt to construct small proofs, and thus, details of the input formula that are irrelevant are usually not in the core. Algorithms for the construction of the smallest core are described in Part 1, Chapter 14. It is easy to see that the predicates that are irrelevant to the proof of unsatisfiability can be removed from the constraint that is added.

Example 3 *Continuing our example, observe that the following subset of the constraints of Eq. 20.13 is already unsatisfiable:*

$$x = 1 \wedge x' = x + 1 \wedge x' \neq 2 \quad (20.14)$$

Only two of the literals of the constrain clause in Example 2 are actually used, and we therefore may replace it with the following much stronger statement:

```
p1, p2, p3 := *,*,* constrain !(p1 & !'p2);
```

While this does not rule out all spurious transitions, it may result in an exponential reduction of the number of refinement iterations.

In SLAM, the abstract counterexample is examined for spurious transitions whenever a set of refinement predicates fails to eliminate the spurious counterexample it is derived from. The corresponding SLAM component is called CON-STRAIN [BCDR04]. CON-STRAIN uses the decision procedure ZAPATO [BCLZ04] in order to decide if a given abstract transition is spurious. SATABS performs the check for spurious transitions before the predicate refinement is done: in many cases, this prevents that unnecessary predicates are added. BLAST only performs a very simplistic initial abstraction.

Spurious Traces Even if an abstract counterexample is free of spurious transitions, the combination of the transitions together might not have a corresponding path in the original program. Spurious traces can be eliminated by adding additional predicates.

All refinement techniques rely on heuristics to extract a small subset of predicates that explain the infeasibility of the counterexample. As example, consider the programs in Fig. 20.9. The assertion in the program is automatically generated to assure that the array index operation in the C program does not exceed the upper bound. Assume that our initial set of predicate consists of those mentioned in the assertion, i.e., we have $i < 10$ as only predicate. The Boolean

³Note that Boolean programs use $'p$ to denote the next-state value of p , instead of the more commonly used notation p' .

<pre> int a[10], i; ... L1: i=0; L2: while(i!=10) { L3: assert(i<10); L4: a[i]=0; L5: i++; } </pre>	<pre> decl p1; ... L1: p1 := T; L2: while * do L3: assert(p1); L4: skip; L5: p1 := *; od; </pre>
---	---

Figure 20.9. The C program on the left initializes an array with zero by means of an index variable. It contains an automatically generated assertion that checks that the index stays within the range of the array. The Boolean program on the right uses the predicate $i < 10$ from the property.

program on the right hand side of the figure is trivial, as only two instructions do actually affect the predicate. For the sake of this example, we assume that \hat{R} is computed precisely, and thus, $p1$ is assigned T in $L1$ and non-deterministically in $L5$.

The verification phase reveals that there is a counterexample in the Boolean program. The first iteration through the loop may reach a state in which $p1$ is F , and this violates the assertion at the beginning of the second iteration. The simulation phase could build the following formula to check if that path is feasible in the original program (we omit the values of the array for brevity):

$$\underbrace{i_1 = 0}_{L1} \wedge \underbrace{i_1 \neq 10}_{L2} \wedge \underbrace{i_2 = i_1 + 1}_{L5} \wedge \underbrace{i_2 \neq 10}_{L2} \wedge \underbrace{i_2 \geq 10}_{L3} \quad (20.15)$$

As Eq. 20.15 is unsatisfiable, the counterexample is spurious. As we did not use an over-approximation of \hat{R} , no spurious transitions can be found in the counterexample, and thus, we must refine the set of predicates. One way of refining the predicates is to compute the *strongest post-condition* along the path given by the counterexample, and add the predicates that are found in this process.

The strongest post-condition of $L1$ is $i = 0$, and the strongest post-condition of $i = 0$ with respect to $L5$ is $i = 1$. Adding the predicates $i = 0$ and $i = 1$ eliminates the spurious counterexample we have obtained. We name the new predicates $p2$ and $p3$, respectively. Fig. 20.10 shows the Boolean program after adding these predicates, where ‘ $p2 \rightarrow p3$ ’ denotes the logical implication of $p3$ by $p2$. The constrained assignment at $L5$ could be generated by the procedure described above, and is strong enough to rule out the spurious counterexample.

However, the refined model still contains a counterexample: after iterating through the loop twice, the assertion in the Boolean program is violated. This corresponds to the concrete state in which $i = 2$. Due to lack of appropriate predicates, the abstraction is unable to distinguish this state from states that

```

    decl p1, p2, p3;
    ...
L1: p1 := T, T, F;

L2: while * do
L3:   assert (p1);
L4:   skip;
L5:   p1, p2, p3 := *, *, * constrain p2 -> p3 & p3 -> p1;
    od;

```

Figure 20.10. A refined abstraction of the C program in Fig. 20.9.

violate $i < 10$. Continuing the refinement using strongest post-conditions eventually eliminates all spurious counterexamples, and thus, proves the property. However, this requires already nine refinement iterations for our little example. The reason for this is that a predicate for an essential part of the loop invariant is missing: given the predicate $i \geq 0$, predicate abstraction is able to prove the property without additional refinement iteration.⁴

Various techniques to speed up the refinement and the simulation have been proposed. *Path slicing* eliminates instructions from the counterexample that do not contribute to the violation of the property in question [JM05]. *Loop detection* is a technique that considers an arbitrary number of iterations of potential loops in the counterexample in a single simulation step [KW06]. Jain et al. suggest to add statically inferred program invariants in order to speed up the refinement [JIG⁺06].

Craig interpolation [Cra57] is an alternative approach that aims at finding parsimonious predicates that are just sufficient for eliminating a given spurious counterexample [HJMM04]. If augmented with techniques that force a generalization of the interpolants, the predicates needed for representing the loop invariant are frequently obtained [JM06]. Craig interpolants for propositional formulas are explained in Part 2, Chapter 18.

Predicate abstraction is typically restricted to safety properties. However, predicate abstraction can be combined with algorithms for the computation of *ranking functions* in order to argue termination of program fragments [CPR05]. As an example, this permits showing that a lock that is acquired is eventually released.

20.6. Conclusion

BMC is the best technique to find shallow bugs. It supports the widest range of program constructions. BMC does not rely on built-in knowledge about the data structures the program maintains. On the other hand, completeness is only obtainable on very 'shallow' programs, i.e., programs without deep loops.

⁴Recall that the addition may overflow!

Predicate abstraction is known to be powerful when applied to light-weight control-flow dominated property. As it removes detail that is irrelevant to the property from the program, it can scale to larger programs. Considerations with respect to the depth of the model are not required. Predicate abstraction has to rely on additional knowledge about the data structures that the property depends on.

In both cases, SAT-based decision procedures enable the verification engine to reason about bit-vector logic, and to treat variable overflow in a sound manner. The countermodels generated by typical SAT-solvers provide an important debugging aid to the programmer.

Chapter 21

Combinatorial Designs by SAT Solvers¹

Hantao Zhang²

21.1. Introduction

The theory of combinatorial designs has extensive interactions with numerous areas of mathematics. Group theory, graph theory, number theory, finite geometry, and linear algebra all have close connections with design theory. Design theory also has applications in numerous disciplines: experimental design, coding theory, cryptography, and many areas of computer science such as data structures, algorithms, and AI. Needless to say, design theory provides a rich source of structured, parameterized families of hard propositional theories, and provides numerous application problems for SAT solvers. As the language of the first NP-complete problem, the propositional logic is expressive enough to encode many problems in design theory. Dramatic improvements in the efficiency of SAT solvers encourage people to attack design theory problems simply by encoding problems as propositional formulas, and then searching for their models using general purpose off-the-shelf SAT solvers. In this chapter, we will present several case studies of such attempts.

Most mathematicians working in the field of design theory have access to modern computers and have worked on various special-purpose software tools for problems in this field [Ce96]. Some of these tools are incomplete and are based on the special knowledge of the field; some of them are complete, based on exhaustive backtrack search algorithms.

Since 1990, general-purpose model generation tools, including SAT solvers, are used extensively to find finite structures of many design theory problems [Zha97]. The so-called general-purpose model generation tools (or simply model generators) are the software tools to solve constraint satisfaction problems in AI, to prove theorems in finite domains, or to produce counterexamples to false conjectures.

While both special-purpose complete tools and general-purpose model generators rely on exhaustive search, there are fundamental differences. For the latter,

¹This chapter is dedicated to Dr. Masayuki Fujita, who passed away while traveling in China, in 2005.

every problem has a uniform internal representation (i.e., propositional clauses for SAT solvers). This uniform representation may introduce redundancies and inefficiencies. However, since a single search engine is used for all the problems, any improvement to the search engine is significant. Moreover, we have an accumulated knowledge of three decades on how to make such a uniform search engine efficient. Using general-purpose model generators to solve combinatorial design theory problems deserves the attention for at least two reasons.

- It is much easier to specify a problem for a general-purpose model generator than to write a special program to solve it. Similarly, fine-tuning a specification is much easier than fine-tuning a special program.
- General-purpose model generators can provide competitive and complementary results for certain combinatorial design theory problems. Evidences will be provided in the following sections.

It appears that the first report of attacking design theory problems using a general-purpose model generator came out in 1991, when Jian Zhang solved a previously-open quasigroup problem using an early version of FALCON [Zha96] and reported this result to the community of Automated Reasoning [ZW91]. FALCON is a general-purpose model generation software based on backtracking search. In 1992, Masayuki Fujita of ICOT, Tokyo, applied their model generation based theorem prover, MGTP [HFKS02], to some quasigroup problems and solved a dozen of the previously-open cases. In the same year, John Slaney at Australian National University applied his general-purpose model generator called FINDER [Sla94] to the quasigroup problems. In addition to confirm Fujita's results, he also reported results for four previously-open problems. These results were reported at IJCAI in 1993 in their award-winning paper [FSB93].

Around the same time, there was a renewed interests on high performance SAT solvers. The quasigroup problems provided a significant spur to the independent developments of SAT solvers by Mark Stickel, William McCune, the author of the present chapter, among others. Stickel's DDPP and LDPP, the author's SATO and McCune's MACE were used to solve several dozen cases of previously-open quasigroup problems [McC94]. It turned out that SAT solvers performed surprisingly well on the quasigroup problems, providing an excellent example that general-purpose search tools may beat special-purpose search tools for certain design theory problems. Many previously-open cases of quasigroups with specified properties were first solved by these model generators. It shows that SAT solvers are very competitive against other general-purpose model generators as well as against special-purpose software tools for many combinatorial design theory problems. In the earlier stage of our study of Latin square problems, the author wrote two special-purpose programs. After observing that these two programs could not do better than SATO, the author has not written any special-purpose search programs since then.

In this chapter, we will present several combinatorial design problems solved by general-purpose model generators. Many of these problems have been collected at CSPLIB [GW99], a problem library for constraints, initially created by Ian Gent and Toby Walsh. Since all the finite model problems can be encoded in SAT, SAT solvers can be regarded as a special kind of general-purpose model

generators.

A typical SAT-based model generator consists of three components:

- an *encoder* which transforms a given problem into a propositional formula (in most cases, a set of clauses) such that the original problem has a model if and only if the formula is satisfiable;
- a SAT solver which decides if the clauses obtained from the encoder are satisfiable;
- a *decoder* which interprets the outcome of the SAT solver.

A software program which combines the above three components into one with a general-purpose input language is called *Mace-style* model generator, named after McCune's Mace 1.0 system.³

21.2. Combinatorial Design Problems

In this chapter, we present the following combinatorial design problems.

- Quasigroups and Latin squares,
- Ramsey numbers,
- Van der Waerden numbers,
- Covering arrays,
- Orthogonal arrays,
- Covering array numbers of small strength,
- Steiner systems,
- Mendelsohn designs, and
- Magic squares

Along the presentation, we show what are the problems solved by model generators and what are the remaining open problems. The issues of building an effective and efficient encoders for SAT solvers will be addressed near the end of this chapter.

21.2.1. Quasigroup Problems

The information on quasigroup and its related structures provided in this chapter is mainly drawn from a survey paper by Bennett and Zhu [BZ92] and the CRC Handbook of Combinatorial Designs [Ce96]; the interested reader may refer to that work for more information on quasigroup, their importance in design theory, and some other related applications.

Given a set S , a *Latin square indexed by S* is an $|S| \times |S|$ matrix such that each row and each column of the matrix is a permutation of the elements in S . $|S|$ is called the *order* of the Latin square.

From the algebraic point of view, a Latin square indexed by S defines a binary operator $*$ over the domain S and the Latin square is the “multiplication table” of $*$. The pair $(S, *)$ is a special *cancellative groupoid* in algebra, called *quasigroup*. Quasigroup is often used as a synonym of Latin square in the literature. By

³Before Mace 1.0, the less-known ModGen system [KZ94] has the same functionality as Mace 1.0.

abuse of notation, throughout this chapter, we use $(S, *)$ to denote a Latin square indexed by S . Latin squares have rich connection with many other fields of design theory. For instance, a Latin square of size n is equivalent to a transversal design of index one, a $(3, n)$ -net, an orthogonal array of strength two and index one, a 1-factorization of the complete bipartite graph $K_{n,n}$, an edge-partition of the complete tripartite graph $K_{n,n,n}$ into triangles, a set of n^2 mutually non-attacking rooks on a $n \times n \times n$ board, and a single error-detecting code of word length 3, with n^2 words from an n -symbol alphabet. Moreover, the underlying structure of Latin squares has many similarity comparing to many real-world applications, such as scheduling and time-tabling, experimental design, and wavelength routing in fiber optics networks [KRS99].

Without loss of generality, let S be $\{0, 1, \dots, (n-1)\}$. The following formulas, which are first-order logic clauses, specify a quasigroup $(S, *)$, or equivalently, a Latin square of order n . For all elements $x, y, u, w \in S$,

$$x * u = y, x * w = y \Rightarrow u = w \quad : \text{ the left-cancellation law} \quad (21.1)$$

$$u * x = y, w * x = y \Rightarrow u = w \quad : \text{ the right-cancellation law} \quad (21.2)$$

$$x * y = u, x * y = w \Rightarrow u = w \quad : \text{ the unique-image property} \quad (21.3)$$

$$(x * y = 0) \vee \dots \vee (x * y = (n-1)) \quad : \text{ the closure property} \quad (21.4)$$

The left-cancellation law states that no symbol appears in any column more than once and the right-cancellation law states that no symbol appears in any row more than once. The unique-image property states that each cell of the square can hold at most one symbol.

It is straightforward to convert the above formulas into the propositional clauses if we represent each $a * b = c$ by a propositional variable $p_{a,b,c}$. The number of propositional clauses generated from such a first-order clause is n^k , where n is the order of the Latin square to be searched and k is the number of free variables in the first-order clause. This is true for transforming flattened first-order clauses into propositional clauses.

In addition to the above clauses, Slaney, Fujita and Stickel [FSB93] have used the following two clauses, which are valid consequences of the above clauses, in their model generators:

$$(x * 0 = y) \vee \dots \vee (x * (n-1) = y) \quad : \text{ the closure property (a)} \quad (21.5)$$

$$(0 * x = y) \vee \dots \vee ((n-1) * x = y) \quad : \text{ the closure property (b)} \quad (21.6)$$

Another justification for the above two clauses is that the binary representation of a Latin square can be viewed as a cube, where the dimensions are the row, the column, and the symbol. Under this view, any set of variables determined by holding two of the dimensions fixed must contain exactly one true variable in the third dimension [GS02]. The effect of these two-clause schemes to the search time varies. For small order Latin squares, the effect is sometimes negative. When these two clauses are used together with the isomorphism-cutting clause (see section 21.3.2), the run time can be faster by a factor greater than 2. Carla Gomes and David Shmoys also found that these two clauses are very useful for the SAT-based approach to solve the quasigroup completion problem (see [GS02] and the next subsection for details).

21.2.1.1. Completion of a Partial Latin Square

An $n \times n$ matrix L (i.e., of order n) with cells that are either empty or contain exactly one symbol of S is a *partial* Latin square if no symbol occurs more than once in any row or column. If the first k rows of a partial Latin square ($k \leq n$) are all filled and the remaining cells are all empty, then L is a $k \times n$ *Latin rectangle*. A partial Latin square P of order n is *embedded* in a Latin square L of order t if the upper left corner of L agrees with P , where $n \leq t$.

Theorem 21.2.1. [Ce96]

(a) *A partial Latin square of order n with at most $n - 1$ filled cells can always be completed to a Latin square of size n .*

(b) *A $k \times n$ Latin rectangle, $k < n$, can always be completed to a Latin square of order n .*

(c) *A partial Latin square of order n can be embedded into a Latin square of order t for every $t \geq 2n$.*

A well-known example of the quasigroup completion problem is perhaps the Sudoku puzzle, which appears on many newspapers and magazines. The most popular form of Sudoku has a 9×9 grid made up of nine 3×3 subgrids called “regions”. In addition to the constraints that every row and every column is a permutation of 1 through 9, each region is also a permutation of 1 through 9. The less the number of filled cells (also called *entries* or *hints*) in a Sudoku puzzle, the more difficult the puzzle (for human). Gordon Royle has a collection of 47,386 distinct Sudoku configurations with exact 17 filled cells [Roy07]. It is an open question whether 17 is the minimum number of entries for a standard Sudoku puzzle to have a unique solution. It is also an open question whether Royle’s collection of 47,386 puzzles is complete (up to isomorphism).

Results obtained by model generators

Since the standard Sudoku puzzle is an easy problem for SAT solvers, several people created SAT-based Sudoku solvers [Web05, Hal07, LO06].

For completing a general partial quasigroup problem, Gomes and Shmoys suggested it as a structured benchmark domain for the study of constraint satisfaction (CSP) and SAT methods [GS02]. The quasigroup completion problem provides a good alternative to other benchmarks because it has structure not found in other randomly generated SAT problems and it can be set to generate only satisfiable instances (e.g., good for testing local search methods). Moreover, the underlying structure of Latin squares has many similarity comparing to many real-world applications. In [GS02], Gomes and Shmoys compared three approaches to this problem: (1) the CSP approach; (2) a hybrid linear programming/CSP approach and (3) the SAT-based approach. It has been shown that none of these methods uniformly dominates the others on this domain and the SAT-based approach can solve some of the hardest problem instances, providing the number of SAT clauses remains manageable.

To complete a partial quasigroup using a SAT solver, we generate a positive unit clause for each filled cell and then use the clauses (21.1)-(21.6) presented in the beginning of this section. This is called “extended encoding” in [GS02]. If

the clauses 21.3, 21.5 and 21.6 are dropped, it is called “minimal encoding”. It is reported that the extra clauses in the extended encoding increase propagation dramatically and allow them to solve much larger problems considerably faster. Using the extended encoding, they could complete Latin squares of size up to 60, using SAT solvers.

21.2.1.2. Orthogonality of Latin Squares

People are interested in Latin squares that satisfy a set of constraints. For instance, the Sudoku puzzle requires that a Latin square also satisfies the constraint that each one of the nine regions is a permutation of 1 through 9. These constraints are often expressed in terms of the operator $*$ plus some free (or universally quantified) variables. For example, idempotent Latin squares are those that satisfy $x * x = x$. In this section, all the Latin squares are assumed to be idempotent, unless stated otherwise. Some constraints involve more than one Latin square.

The first constraint we consider here, and perhaps the most important constraint in the study of Latin squares, is the orthogonality of two Latin squares. Two $n \times n$ matrices over the domain S ($S, *$) and (S, \star) are said to be *orthogonal* if for any two elements s, t of S , the set $\{(x, y) \mid x * y = s, x \star y = t\}$ is singleton. Intuitively, if both matrices are viewed as two chessboards and are placed one over the other, the pair of values at any position (i.e., the pair (s, t) at position (x, y)) is unique. Note that the definition of orthogonality does not require that the two matrices being Latin squares; when the two orthogonal matrices are Latin squares, we say they are a pair of orthogonal Latin squares.

The orthogonality of two matrices of the same order can be specified as the following constraint: For all elements x, y, z, w of S

$$(x * y = z * w) \wedge (x \star y = z \star w) \Rightarrow (x = z \wedge y = w) \quad (21.7)$$

One problem of great interests is to prove the existence of a set of mutually orthogonal Latin squares (MOLS) of certain size. The following remark is quoted from [Ce96]:

Euler’s 36 Officers Problem. A very curious question, which has exercised for some time the ingenuity of many people, has involved me in the following studies, which seem to open a new field of analysis, in particular the study of combinations. The question revolves around arranging 36 officers to be drawn from 6 different ranks and also from 6 different regiments so that they are arranged in a square so that in each line (both horizontal and vertical) there are 6 officers of different ranks and different regiments.

If the ranks and regiments of these 36 officers arranged in a square are represented, respectively, by two 6×6 Latin squares, Euler’s 36 officers problem asks if there exist two MOLS of size 6. Euler went on to conjecture that such an $n \times n$ square does not exist for $n = 6$, nor does one exist whenever $n \equiv 2 \pmod{4}$. This was known as the *Euler conjecture* until its disproof in 1959. That year, Parker, Bose and Shrikhande were able to construct a pair of orthogonal Latin squares of order 10, and provided a construction for the remaining even values of n that are not divisible by 4 (of course, excepting $n = 2$ and $n = 6$) [BS60]. Today’s model

generators can find a pair of such Latin squares in no time. However, it remains a great challenge to find a set of three mutually orthogonal Latin squares of order 10.

Let $N(n)$ be the maximum number of Latin squares in a set of MOLS of size n .

Theorem 21.2.2. [Ce96]

- (a) For every $n > 1$, $1 \leq N(n) \leq n - 1$.
- (b) If $q = p^e$, where p is a prime, then $N(q) = q - 1$.
- (c) If n is sufficiently large, $N(n) \geq n^{\frac{1}{14.8}}$.
- (d) For small n , which is not a prime power, the following results are known:

n	6	10	12	14	15	18	20	21	22	24
$N(n)$	1	≥ 2	≥ 5	≥ 3	≥ 4	≥ 3	≥ 4	≥ 5	≥ 3	≥ 5

The above table shows that there are many open problems for $N(n)$. For instance, it is still unknown if there exists a set of three pairwise-orthogonal Latin squares of size 10. A positive answer to this problem will have a tremendous effect in combinatorial theory. In 1989, Lam reported that no finite projective plane of order 10 exists [Lam91]. This result implies that $N(10) < 9$, i.e., there are no nine MOLS of size 10. This example shows that Latin squares have a rich relationship with other objects in combinatorics.

Given three mutually orthogonal Latin squares of order n , say A , B , and C , if $A = B^T$ and $C = C^T$, where X^T is the transpose of X , we say (A, B, C) is an SOLSSOM(n) (Self-Orthogonal Latin Square with a Symmetric Orthogonal Mate).

Theorem 21.2.3. [ABZZ00] An SOLSSOM(n) exists if and only if $n \geq 4$, except for $n = 6$ and possibly for $n = 10, 14$.

Results obtained by model generators

The orthogonality of two Latin squares defined by formula 21.7 can be easily converted into two clauses:

$$x * y = s \wedge z * w = s \wedge x * y = t \wedge z * w = t \Rightarrow x = z \quad (21.8)$$

$$x * y = s \wedge z * w = s \wedge x * y = t \wedge z * w = t \Rightarrow y = w \quad (21.9)$$

In [Zha97] as well as in section 21.3.1, how to encode the orthogonality constraint is discussed.

The author of the present chapter has spent a huge amount of effort to decide if $N(10) \geq 3$. Since 1997, at least 10 linux workstations have been used day and night to crack this problem. Except that we confirmed the nonexistence of three MOLS of size 10 satisfying some additional constraints, we have not succeeded in this problem. Despite the fact that we spent 10 years, sometimes using a cluster of 40 linux machines, only a small portion of the whole search space has been explored. Because of the randomization of the search method [Zha02], we believe that the maximum number of MOLS of size 10 is most likely 2, that is, $N(10) = 2$.

For Theorem 21.2.3 regarding the existence of SOLSSOM(n), the model generator solved indirectly two previously-open cases: $n = 66, 70$ [ABZZ00].

21.2.1.3. Conjugates of Latin Squares

Given a Latin square $(S, *)$ and values of any two variables in $x * y = z$, we can uniquely determine the value of the third variable. We may therefore associate with $(S, *)$ an operation \star such that $x \star z = y$ if and only if $x * y = z$. It is easy to see that (S, \star) is also a Latin square. (S, \star) is one of the six *conjugates* of $(S, *)$. These are defined via the six operations $*_{ijk}$, where $\{i, j, k\} = \{1, 2, 3\}$:

$$(x_i *_{ijk} x_j = x_k) \iff (x_1 * x_2 = x_3)$$

We shall refer to $(S, *_{ijk})$ as the (i, j, k) -conjugate of $(S, *)$. Whenever S is understood to be common, we will simply refer to $*_{ijk}$ as the (i, j, k) -conjugate of $*$. It is easy to see that the $(1, 2, 3)$ -conjugate is the same as the original Latin square, and the $(2, 1, 3)$ -conjugate is the transpose of the original Latin square.

Example 21.2.1. Here are the six conjugates of a small Latin square:

(a)	(b)	(c)	(d)	(e)	(f)
1 4 2 3	1 2 4 3	1 3 2 4	1 2 4 3	1 3 4 2	1 3 2 4
2 3 1 4	4 3 1 2	2 4 1 3	3 4 2 1	3 1 2 4	3 1 4 2
4 1 3 2	2 1 3 4	4 2 3 1	2 1 3 4	2 4 3 1	4 2 3 1
3 2 4 1	3 4 2 1	3 1 4 2	4 3 1 2	4 2 1 3	2 4 1 3

(a) a Latin square; (b) its $(2, 1, 3)$ -conjugate; (c) its $(3, 2, 1)$ -conjugate; (d) its $(2, 3, 1)$ -conjugate; (e) its $(1, 3, 2)$ -conjugate; (f) its $(3, 1, 2)$ -conjugate. \square

In this subsection, let us focus on orthogonality of conjugate Latin squares. If we replace \star in formula 21.7 by $*_{213}$, $*_{321}$, and $*_{312}$, respectively, we have the following constraints:⁴

$$\text{QG0: } (x * y = z * w \wedge x *_{213} y = z *_{213} w) \Rightarrow (x = z \wedge y = w)$$

$$\text{QG1: } (x * y = z * w \wedge x *_{321} y = z *_{321} w) \Rightarrow (x = z \wedge y = w)$$

$$\text{QG2: } (x * y = z * w \wedge x *_{312} y = z *_{312} w) \Rightarrow (x = z \wedge y = w)$$

These constraints can be rephrased uniformly in $*$ as:

$$\text{QG0: } (x * y = z * w \wedge y * x = w * z) \Rightarrow (x = z \wedge y = w)$$

$$\text{QG1: } (x * y = z * w \wedge u * y = x \wedge u * w = z) \Rightarrow (x = z \wedge y = w)$$

$$\text{QG2: } (x * y = z * w \wedge y * u = x \wedge w * u = z) \Rightarrow (x = z \wedge y = w)$$

That is, a Latin square satisfying QG0, QG1 or QG2, will be orthogonal to its $(2, 1, 3)$ -, $(3, 2, 1)$ -, or $(3, 1, 2)$ -conjugates, respectively. For example, the Latin square (a) in Example 21.2.1 satisfies QG2, since it is orthogonal to (f), its $(3, 1, 2)$ -conjugate. A Latin square satisfying QG0 is said to be *self-orthogonal*. It is easy to see that the first Latin square of an SOLSSOM(n) is self-orthogonal.

We say that constraint C' is a *conjugate-implicant* of constraint C if whenever a Latin square satisfies C , one of its conjugates satisfies C' . We say two constraints are *conjugate-equivalent* if they are conjugate-implicants of each other.

⁴We will continue to use the nomenclature QG0–QG15 introduced in [FSB93, SZ94, Zha97]. These meaningless code names may facilitate the communication among the users of model generators who have little knowledge of Latin squares. SATO uses these code names to generate propositional clauses. For instance, the command `sato -Q2 -G10 -o3` will output the propositional clauses for Latin squares of order 10 satisfying QG2.

Table 21.1. Conjugate-Orthogonality Constraints

	*	*132	*213	*231	*312	*321
*	—	QG1'	QG0	QG2'	QG2	QG1
*132	QG1'	—	QG2	QG1''	QG0''	QG2''
*213	QG0	QG2	—	QG1	QG1'	QG2'
*231	QG2'	QG1''	QG1	—	QG2''	QG0'
*312	QG2	QG0''	QG1'	QG2''	—	QG1''
*321	QG1	QG2''	QG2'	QG0'	QG1''	—

The orthogonality of a pair of conjugates can be logically equivalent to, or conjugate-equivalent to, orthogonality of other pairs of conjugates. These relationships are summarized in Table 21.1 (taken from [SZ94]). Each table entry is a code name for a constraint that is defined to be logically equivalent to the orthogonality of its row and column labels. For example, QG1 is defined by orthogonality of * and *₃₂₁, but could have been defined equivalently by orthogonality of *₂₁₃ and *₂₃₁. The constraints QG0, QG0' and QG0'' are conjugate-equivalent; so are QG1, QG1' and QG1'', and so are QG2, QG2' and QG2''.

We will use $QG_i(v)$ to denote an idempotent Latin square of order v satisfying constraint QG_i .

Theorem 21.2.4. [Ce96, Zha97]

- There exists a $QG_0(n)$ for $n \geq 1$, except $n = 2, 3, 6$.
- There exists a $QG_1(n)$ for $n \geq 1$, except $n = 2, 3, 6$.
- There exists a $QG_2(n)$ for $n \geq 1$, except $n = 2, 3, 4, 6, 10$.

Results obtained by model generators

Despite of all the developments of new model generators, QG0, QG1 and QG2 remain to be difficult model generation problems. It is noteworthy to point out that model generators removed five previously-open cases in Theorem 21.2.4. That is, using some incomplete methods, the existence of QG2(12) was first established by Stickel's DDPP [SFS95], and the existences of QG1(12), QG2(14) and QG2(15) were first established by SATO [ZBH96]. The nonexistence of QG2(10) was first established by Olivier Dubois and Gilles Dequen using a special-purpose program [DD01] where the constraints are treated in the form of CSP. This result was confirmed subsequently by SATO. Note that the accumulated time spent by SATO on QG2(10) has been over one year on three linux workstations and the search space has finally been exhausted.

21.2.1.4. Holey Latin Squares

Among the Latin squares satisfying certain constraints, people are often interested in those squares with holes, i.e., some subsquares of the square are missing. Holey Latin squares are special cases of partial Latin squares. The existence of these holey Latin squares is very useful in the construction of Latin squares of large orders.

Formally, let S be a set and $\mathcal{H} = \{S_1, \dots, S_m\}$ be a set of subsets of S . A *holey Latin square* having *hole set* \mathcal{H} , denoted by $(S, \mathcal{H}, *)$, is a $|S| \times |S|$ matrix L , indexed by S , satisfying the following properties:

1. every cell of L either contains an element of S or is empty,
2. every element of S occurs at most once in any row or column of L ,
3. the sub-matrices indexed by $S_i \times S_i$ are empty for $1 \leq i \leq m$ (these sub-matrices are referred to as *holes*),
4. element $s \in S$ occurs in row or column t if and only if $(s, t) \notin S_i \times S_i$ for any $1 \leq i \leq m$.

A holey Latin square is a partial Latin square but the opposite may not be true because of Constraints 3 and 4. Two types of holey Latin squares are of particular interests: (a) $\mathcal{H} = \{S_1\}$ and (b) $\mathcal{H} = \{S_1, \dots, S_m\}$ is a partition of S .

Holey Latin squares in case (a) are called *incomplete Latin squares*. Given a Latin square constraint QGi , an incomplete idempotent Latin square indexed by S with a single hole S_1 is often denoted by $IQGi(|S|, |S_1|)$. We may consider an incomplete Latin square as one indexed by S with a subsquare indexed by S_1 “missing”; if we fill a Latin square indexed by S_1 into the hole, the result should be a Latin square of order $|S|$. Without loss of generality, the missing subsquare can be assumed to be in the bottom right corner of the Latin square.

Holey Latin squares in case (b) are called *frame Latin squares*. If $|S_1| = \dots = |S_m|$, any frame Latin square satisfying QGi is often denoted by $FQGi(h^m)$, where $h = |S_1| = \dots = |S_m|$ and $|S| = hm$. Note that every idempotent $QGi(n)$ can be considered as an $FQGi(1^n)$.

A necessary condition for the existence of incomplete Latin squares satisfying $IQGi(n, k)$, $i = 0, 1, 2$, is $n \geq 3k + 1$. The known results regarding the existences of incomplete idempotent $IQGi(n, k)$, $i = 0, 1, 2$, are summarized in the following theorem:

Theorem 21.2.5. [Ce96, Zha97]

(a) For every integer $n \geq 1$, an $IQG0(n, k)$ exists if and only if $n \geq 3k + 1$, except $(n, k) = (6, 1), (8, 2)$, and except possibly $(n, k) = (20, 6)$.

(b) For every integer $n \geq 1$, an $IQG1(n, k)$ exists if $n \geq (13/4)k + 88$. For $2 \leq k \leq 6$, an $IQG1(n, k)$ exists if and only if $n \geq 3k + 1$ except possibly $(n, k) = (11, 3)$.

(c) For any integer $n \geq 1$, an $IQG2(n, k)$ exists if $n \geq (10/3)k + 68$. For $2 \leq k \leq 5$, an $IQG2(n, k)$ exists if and only if $n \geq 3k + 1$ except $(n, k) = (8, 2)$ and except possibly $k = 4$ and $n \in \{35, 38\}$.

The existence of frame $FQGi(h^n)$, $i = 0, 1, 2$, have almost completely decided.

Theorem 21.2.6. [Ce96, Zha97]

(a) For any $h \geq 2$, there exists an $FQG0(h^n)$ if and only if $n \geq 4$.

(b) For any $h \geq 2$, there exists an $FQG1(h^n)$ if and only if $n \geq 4$, except possibly $(h, n) = (13, 6)$.

(c) For any $h \geq 2$, there exists an $FQG2(h^n)$ if and only if $n \geq 4$, except possibly $(h, n) = (2t + 1, 4)$ for $t \geq 1$.

Results obtained by model generators

Many cases in Theorem 21.2.5 were first solved by a model generator. For instance, 16 cases of IQG0(n, k), including $(n, k) = (14, 4)$, was found by SATO. The last two cases, $(26, 8)$ and $(32, 10)$, were solved by SATO after the publication of the first edition of this Handbook. It is reported in [ZB95] that the existence of IQG1(n, k) was established by SATO for $(n, k) = (30, 5)$, $k = 2$ and $n \in \{16, 17, 19, 20, 21, 23\}$ and $k = 3$ and $n \in \{20, 21, 24, 25, 26, 28, 29, 30\}$. For IQG2(n, k), the nonexistence of IQG2(8, 2) was first established by FINDER [SFS95]. SATO solved more than forty previously-open cases [BZ98].

Again, model generators made a contribution in Theorem 21.2.6. It is reported in [ZB95] and [BZ98] that more than thirty cases in this theorem were solved by SATO.

In [Zha97], an easy way of encoding holey quasigroups in SAT is presented which involves only adding some negative units clauses in the encoding of normal quasigroups.

21.2.1.5. Short Conjugate-Orthogonal Identities

Many Latin square constraints are in the form of equations, called *quasigroup identities* [BZ92]. For instance, QG5, i.e., $((y * x) * y) * y = x$, is one of the first constraints studied by many model generators. A Latin square identity is said to be *nontrivial* if it is not a tautology and it is consistent with the specification of a Latin square. In this subsection as well as in the next subsections, we will focus on several nontrivial quasigroup identities.

A quasigroup identity is called a *short conjugate-orthogonal identity* if it is of the form $(x *_{ijk} y) * (x *_{abc} y) = x$, where $*_{ijk}, *_{abc} \in \{*, *_{213}, *_{132}, *_{312}, *_{231}, *_{321}\}$ [Eva75].

Theorem 21.2.7. [Eva75, Ben87] *Every nontrivial short conjugate-orthogonal identity is conjugate-equivalent to one of the following:*

Code Name	Identity
QG3	$(x * y) * (y * x) = x$
QG4	$(y * x) * (x * y) = x$
QG5	$((y * x) * y) * y = x$
QG6	$(x * y) * y = x * (x * y)$
QG7	$(y * x) * y = x * (y * x)$
QG8	$x * (x * y) = y * x$
QG9	$((x * y) * y) * y = x$

Many short conjugate-orthogonal identities possess interesting properties [BZ92]. Given a Latin square identity, people are interested in whether some of the three constraints, QG0, QG1 and QG2, are its conjugate-implicants. For instance, it is known that QG2 is a conjugate-implicant of QG4; if you are interested in a QG2(12), you may look for a QG4(12). Indeed, that is how QG2(12) was found by Mark Stickel [SFS95].

Table 21.2. Conjugate-Orthogonality Implications for QG3–QG9

Identity	Conjugate-Implicants
QG3	QG0
QG4	QG0, QG2
QG5	QG1, QG2
QG6	QG1
QG7	QG1, QG2
QG8	QG0, QG1
QG9	QG1

Evans [Eva75] shows that if a Latin square satisfies the short conjugate-orthogonal identity $(x *_{ijk} y) * (x *_{abc} y) = x$, then its (i, j, k) -conjugate is orthogonal to its (a, b, c) -conjugate. Table 21.2 (taken from [SZ94]) shows which of QG0–QG2 are conjugate-implicants of QG3–QG9 [SZ94].

The existences of idempotent $QGi(n)$, $3 \leq i \leq 9$, are summarized in the following theorem:

Theorem 21.2.8. [Ce96, Zha97]

- (a) *There exists a $QG3(n)$ if and only if $n \equiv 0$ or $1 \pmod{4}$.*
- (b) *There exists a $QG4(n)$ if and only if $n \equiv 0$ or $1 \pmod{4}$, except $n = 4$ and 8 .*
- (c) *There exists a $QG5(n)$ for $n \geq 1$, except $n \in \{2, 3, 4, 6, 9, 10, 12, 13, 14, 15, 16\}$ and except possibly $n \in \{18, 20, 22, 24, 26, 28, 30, 34, 38, 39, 42, 44, 46, 51, 52, 58, 60, 62, 66, 68, 70, 72, 74, 75, 76, 86, 87, 90, 949, 96, 98, 99, 100, 102, 106, 108, 110, 114, 116, 118, 122, 132, 142, 146, 154, 158, 164, 174\}$.*
- (d) *There exists a $QG6(n)$ for $n \equiv 0$ or $1 \pmod{4}$, except $n = 5, 12$ and except possibly $n \in \{20, 21, 24, 41, 44, 48, 53, 60, 69, 77, 93, 96, 101, 161, 164, 173\}$; for $n \equiv 2$ or $3 \pmod{4}$, there does not exist a $QG6(n)$ for $n \leq 15$.*
- (e) *There exists a $QG7(n)$ for all $n \equiv 1 \pmod{4}$ except possibly $n = 33$; for $n \not\equiv 1 \pmod{4}$, there does not exist a $QG7(n)$ for $n \leq 16$.*
- (f) *There exists a $QG8(n)$ for all $n \geq 1$, except $n \in \{2, 3, 6, 7, 8, 10, 12, 14, 15, 18\}$, and except possibly $n \in \{22, 23, 26, 27, 30, 34, 38, 42, 43, 46, 50, 54, 62, 66, 74, 78, 90, 98, 102, 114, 126\}$.*
- (g) *There exists a $QG9(n)$ if and only if $n \equiv 1 \pmod{3}$.*

Theorem 21.2.9. [Ce96, Zha97]

- (a) *For any $n \geq 7$, an $IQG3(n, 2)$ exists if and only if $n \equiv 2$ or $3 \pmod{4}$ except $n = 10$.*
- (b) *For $h \geq 2$, an $FQG3(h^n)$ exists if and only if $hn(n-1) \equiv 0 \pmod{4}$ with exceptions of $(h, n) \in \{(1, 5), (1, 9), (2, 4)\}$ and possible exception of $(h, n) = (6, 4)$.*
- (c) *For any $n \geq 7$, an $IQG4(n, 2)$ exists if and only if $n \equiv 2$ or $3 \pmod{4}$ except possibly $n = 19, 23, 27$; for any $n \geq 10$ and $k = 3$ or 7 , an $IQG4(n, k)$ exists if and only if $n \equiv 2$ or $3 \pmod{4}$.*
- (d) *For $h \geq 2$, an $FQG4(h^n)$ exists if and only if $h^2n(n-1) \equiv 0 \pmod{4}$ with exception of $(h, n) = 2^4$ and $(2k+1)^4$ for $k \geq 1$.*

In [MZ07], Ma and Zhang studied the existence of *large sets* satisfying the short quasigroup identities. Two idempotent quasigroups $(S, *)$ and (S, \star) are said to be *disjoint* if for any $x, y \in S$, $x * y \neq x \star y$ whenever $x \neq y$. A set of $n - 2$ idempotent quasigroups over S , where $|S| = n$, is said to be a *large set* if any two quasigroups in the set are disjoint. For i from 3 to 9, let $LSQG_i(n)$ denote a large set of order n such that each quasigroup in the large set satisfies QG_i .

Theorem 21.2.10. [Ce96, MZ07]

- (a) *There exist $LSQG_i(n)$ for $(i, n) \in \{(3, 8), (6, 8), (8, 4), (9, 4)\}$;*
- (b) *There exist no $LSQG_i(n)$ for $(i, n) \in \{(5, 7), (5, 8), (8, 4), (9, 2), (9, 4), (9, 6), (9, 7), (11, 4), (11, 5)\}$.*

Results obtained by model generators

Model generators have been used to establish several cases in Theorem 21.2.8: $QG_3(12)$ was first found by FINDER [SFS95]; $QG_4(12)$ was first found by DDPP [SFS95].

All the new results regarding QG_5 were negative: the nonexistence of $QG_5(9)$ was first established by FALCON [Zha96]; the nonexistence of $QG_5(10)$ (without idempotency) and $QG_5(12)$ was by MGTP [SFS95]; the nonexistence of $QG_5(13)$, $QG_5(14)$ and $QG_5(15)$ was by DDPP [SFS95]; the nonexistence of $QG_5(14)$ (without idempotency) and $QG_5(16)$ was by SATO [ZBH96].

$QG_6(9)$ was first found by MGTP [SFS95] and $QG_6(17)$ was by MACE [McC94]. The nonexistence of $QG_6(12)$ was first established by MGTP [SFS95]. For the orders not congruent to 0 or 1 (mod 4), the nonexistence of $QG_6(10)$, $QG_6(11)$ and $QG_6(14)$ was reported in [SFS95] and that of $QG_6(15)$ was by SATO [ZBH96]; the other cases remain open.

All the new results regarding QG_7 were negative: the nonexistence of $QG_7(i)$ was first established by MGTP for $i = 7, 8, 10$ [SFS95]; by FINDER for $i = 11, 14, 15$ [SFS95]; by DDPP for $i = 12$ and 16 [SFS95].

The nonexistence of $QG_8(15)$ was first established by DDPP [SFS95].

Model generators are also used in the establishment of Theorem 21.2.9. In particular, Slaney, Fujita and Stichel reported the following results in [SFS95]: the existence of $IQG_3(11, 3)$, $IQG_4(10, 2)$ and $IQG_4(11, 2)$; the nonexistence of $IQG_3(10, 2)$. Later, Stichel found an $IQG_3(14, 2)$. SATO found an $IQG_4(14, 2)$ and an $IQG_4(15, 2)$ [ZBH96].

Holey Latin squares satisfying QG_5 – QG_9 have not been fully investigated. Slaney, Fujita and Stichel reported the following nonexistence results in [SFS95]: $IQG_5(n, k)$ for $(n, k) = (7, 2), (9, 2), (11, 2), (14, 3)$ and $(16, 6)$, and $IQG_6(n, k)$ for $2 \leq k < n \leq 11$.

The results in Theorem 21.2.10 are obtained with the help of SEM [ZZ95] for generating subproblems with additional constraints of symmetry breaking [HMG⁺18]. By exhaustive search, they found that the maximum set size of mutually disjoint $QG_i(n)$ quasigroups is 6 for $(i, n) = (9, 2), (9, 4), (9, 6)$, and $(9, 7)$; 4 for $(i, n) = (4, 11)$; and 2 for $(i, n) = (5, 11)$, respectively [HMG⁺18]. There are remaining open cases for small orders [MZ07, HMG⁺18].

In [SFS95, Zha97], the issue of how to encode short quasigroup identities into SAT is discussed and it is shown that adding extra constraints helps the search

when the size of problems increases.

21.2.2. Ramsey Numbers

Given two positive integers r and s , Ramsey's Theorem [Ram30] of graph theory states that a sufficiently-large simple graph either contains a clique of size r (there exists an edge between any pair of these vertices) or an independent set of size s (no edges among these vertices). That is, there exists an integer $R(r, s)$ such that for every graph of size at least $R(r, s)$, it contains either a clique of size r , or an independent set of size s . Ramsey first proved this result in 1930 which initiated the combinatorial theory, now called Ramsey theory [GRS90], that seeks regularity amid disorder: general conditions for the existence of substructures with regular properties. In this example, the regular properties are either cliques or independent sets, that is, subsets of vertices either all connected or with no edges at all.

The least number $R(r, s)$ in Ramsey's theorem is known as *Ramsey number*. An upper bound for $R(r, s)$ can be extracted from Ramsey's proof of the theorem, and other arguments give lower bounds. Since there is a vast gap between the tightest lower bounds and the tightest upper bounds, there are very few numbers r and s for which we know the exact value of $R(r, s)$. The following table shows the latest information regarding these numbers [Rad05].

$r \setminus s$	2	3	4	5	6	7	8
2	2						
3	3	6					
4	4	9	18	76			
5	5	14	25	43 – 49			
6	6	18	35 – 41	59 – 87	102 – 165		
7	7	23	49 – 61	80 – 143	113 – 298	205 – 540	
8	8	28	56 – 84	101 – 216	127 – 495	216 – 1031	282 – 1870

For instance, we do not know the exact value of $R(5, 5)$, although we know that it lies between 43 and 49. Computing a lower bound n for $R(r, s)$ usually requires finding a simple graph of $n - 1$ vertices which has neither an r -clique nor an s -independent set. For instance, if we could find a graph of 43 vertices which has neither a clique of size 5 nor an independent set of size 5, we would increase the lower bound of $R(5, 5)$ to 44. Modern SAT solvers may be used for this task. In fact, we define a set $LR(r, s, n)$ of propositional clauses such that $LR(r, s, l)$ are satisfiable if and only if there exists a graph of l vertices which has neither clique of size r and nor independent set of size s . Then $LR(r, s, l)$ is fed to a SAT solver which decides its satisfiability.

Let $V = \{1, 2, \dots, n\}$ be the set of vertices of a simple graph. Let $p_{i,j}$ be the propositional variable which is true if and only if edge (i, j) is in the graph, where $1 \leq i < j \leq n$. Then for any subset $S \subset V$, the subgraph induced by S is not a clique if the following clause is true:

$$\text{not-a-clique}(S): \bigvee_{i,j \in S} \neg p_{i,j}$$

Note that the above clause has $m(m-1)/2$ literals, where $m = |S|$. Similarly, the subgraph induced by S is not an independent set if the following clause is true:

$$\text{not-an-independent-set}(S): \bigvee_{i,j \in S} p_{i,j}$$

Using $\text{not-a-clique}(S)$ and $\text{not-an-independent-set}(S)$, $LR(r, s, n)$ can be defined as follows:

$$\text{not-a-clique}(X) \text{ for every subset } X \in V, |X| = r; \quad (21.10)$$

$$\text{not-an-independent-set}(Y) \text{ for every subset } Y \in V, |Y| = s. \quad (21.11)$$

Some earlier SAT solvers use $LR(r, s, n)$ as benchmark problems.⁵ While a complete SAT solver can check lower bounds for small r and s , it becomes intractable for large values. For instance, $LR(5, 5, 43)$ contains more than 1.7 millions clauses. In general, the number of clauses in $LR(r, s, n)$ is $\frac{1}{2}r(r-1)\binom{r}{n} + \frac{1}{2}s(s-1)\binom{s}{n}$, where $\binom{m}{n} = n!/(m!(n-m)!)$. While the SAT approach has not yet improved any lower bound in the above table, it is worth pointing out that the SAT approach is successful in solving another problem of the Ramsey theory, i.e., the Van der Waerden numbers.

21.2.3. Van der Waerden Numbers

Given a positive integer m , let $[m]$ denote the set $\{1, \dots, m\}$. A *partition* of a set X is a collection $\mathcal{A} = \{A_1, \dots, A_k\}$ of mutually disjoint subsets of X such that $A_1 \cup \dots \cup A_k = X$. Elements of \mathcal{A} are commonly called *blocks*. An *arithmetic progression* of length n is a sequence of n integers a_1, \dots, a_n such that $a_i = a_1 + (i-1)b$ for all $1 \leq i \leq n$ and some integer b .

The Van der Waerden theorem [DMT04] says that, for sufficiently large m , if $[m]$ is partitioned into a few blocks, then one of these blocks has to contain an arithmetic progression of a desired length.

Theorem 21.2.11. (Van der Waerden theorem) *For any positive integers k and l , there exists m such that for every partition $\langle A_1, \dots, A_k \rangle$ of $[m]$, there exists a block A_i which contains an arithmetic progression of length at least l .*

The *Van der Waerden number* $W(k, l)$ is defined to be the least number m for which the assertion in the above theorem holds. For $l = 2$, $W(k, 2) = k + 1$. For $l > 2$, little is known about $W(k, l)$ as no closed formulas have been found so far. Only five exact values are known:

$k \setminus l$	3	4	5
2	9	35	178
3	27	?	?
4	76	?	?

⁵Earlier versions of SATO can be used to produce $LR(r, s, n)$ as follows: `sato -Rn -Pr -Qs -o3`.

The following general results regarding the lower bounds of $W(w, l)$ are known: Erdős and Rado [ER52] provided a non-constructive proof for the inequality

$$W(k, l) > (2(l-1)k^{l-1})^{1/2}.$$

When $k = 2$ and $l - 1$ is a prime number, Berlekamp [Ber68] showed that

$$W(k, l) > (l-1)2^{l-1}.$$

This implies that $W(2, 6) > 160$ and $W(2, 8) > 896$.

Using SAT solvers, Dransfield, Marek and Truszczynski [DMT04] found larger lower bounds for several small Van der Waerden numbers and improved significantly the results implied by the general results of Erdős and Rado [ER52] and Berlekamp [Ber68]. Also using SAT solvers, Kouril and Franco reported $W(2, 6) \geq 1132$ in [KF05] and claimed $W(2, 6) = 1132$ after 253 days of computational time. Herwig, Heule, Van Lambalgen and Van Maaren [HHvLvM07] reported exciting results using a new approach called the *cyclic zipper method*.

Following the notation used in [DMT04], let $\text{vdW}_{k,l,m}$ denote a set of propositional clauses such that $\text{vdW}_{k,l,m}$ is satisfiable if and only if there exists a partition of $[w]$ into k blocks and none of the blocks contains an arithmetic progression of length l . Such a partition is called a *Van der Waerden certificate* of $W(k, l) > m$. That is, if $\text{vdW}_{k,l,m}$ is satisfiable, then $W(k, l) > m$. The following mk propositional variables are used in $\text{vdW}_{k,l,m}$: $\text{in}(i, b)$ for each $i \in [m]$ and each $b \in [k]$. Intuitively, $\text{in}(i, b)$ is true if and only if integer i is in block b .

The set $\text{vdW}_{k,l,m}$ contains the following three types of propositional clauses: For every $i, d \in [m]$, $b, b' \in [k]$, where $b < b'$ and $i + (l-1)d \leq m$,

$$\begin{aligned} (\text{vdW1}) \quad & \neg \text{in}(i, b) \vee \neg \text{in}(i, b') \\ (\text{vdW2}) \quad & \text{in}(i, 1) \vee \dots \vee \text{in}(i, k) \\ (\text{vdW3}) \quad & \neg \text{in}(i, b) \vee \neg \text{in}(i + d, b) \vee \dots \vee \neg \text{in}(i + (l-1)d, b) \end{aligned}$$

Intuitively, vdW1 and vdW2 together specify that each integer of $[m]$ is in exactly one of the k blocks. The last clause, vdW3, says that no block contains an arithmetic progression of length l .

Proposition 21.2.1. [DMT04] For positive integers k, l and m , with $l \geq 2$, $m < W(k, l)$ if and only if $\text{vdW}_{k,l,m}$ is satisfiable.

Results obtained by model generators

Using complete SAT solvers, Dransfield et al. could verify that $W(4, 3) = 76$ by proving that $\text{vdW}_{4,3,75}$ is satisfiable and $\text{vdW}_{4,3,76}$ is unsatisfiable. However, complete SAT solvers become ineffective as the size grows. Dransfield et al. estimated that the total size of clauses (vdW1) is $\Theta(mk^2)$; the size of (vdW2) is $\Theta(mk)$ and the size of (vdW3) is $\Theta(m^2)$. So the total size of $\text{vdW}_{k,l,m}$ is $\Theta(mk^2 + m^2)$. Using an incomplete SAT solver, Dransfield et al. believed that they found nine new lower bounds of $W(k, l)$, including $W(5, 3) > 125$ and $W(2, 6) > 341$, as they were unaware of the work of Rabung [Rab79].

Dransfield et al. used the well-known incomplete SAT solver WSAT. Their way of using WSAT is quite interesting. Let $m_1 < \dots < m_s = m$ be a sequence of

positive integers. To find a model of $\text{vdW}_{k,l,m}$, they look for models of vdW_{k,l,m_1} , ..., vdW_{k,l,m_s} , in consecutive order. The algorithm proceeds as follows.

1. Let $i = 1$, generate a random interpretation of vdW_{k,l,m_1} .
2. Call $\text{wsat}(\text{vdW}_{k,l,m_i})$ until it stops.
3. When a model of vdW_{k,l,m_i} is found in step 2, if $i = s$, stop and output this model; otherwise, use the model as the initial interpretation of $\text{vdW}_{k,l,m_{i+1}}$, let $i = i + 1$ and go to step 2.
4. If $\text{wsat}(\text{vdW}_{k,l,m_i})$ fails to find a model at step 2 and the time allows, let $i = 1$ and goto step 1.

Dransfield et al.'s work caught the attention of the SAT community. In [KF05], Kouril and Franco reported that $W(2, 6) > 1131$. Using the cyclic zipper method, Herwig et al [HHvLvM07] found ten new lower bounds of $W(k, l)$. Their approach stems from the SAT approach by first visualizing the Van der Waerden certificates of small orders and observing their regularities such as symmetry and repetition. They then look for special certificates of large sizes which possess these regularities using SAT solvers. These latest results are listed in the following table, where $W(5, 3) > 125$ was established in [DMT04], $W(2, 6) > 1131$ was done in [KF05]. Ten entries were established in [HHvLvM07]. While this chapter is being written, four new lower bounds are found: $W(5, 3) > 170$, $W(6, 5) > W(5, 5) > 98740$, and $W(5, 6) > 540025$.⁶ The case of $W(5, 3) > 170$ is particularly interesting as it was found by a SAT solver.

$k \setminus l$	3	4	5	6	7	8	9
2	9	35	178	> 1131	> 3703	> 11495	> 41265
3	27	> 292	> 2173	> 11191	> 43855	> 238400	
4	76	> 1048	> 17705	> 91331	> 393469		
5	> 170	> 2254	> 98740	> 540025			
6	> 207	> 9778	> 98740	> 633981			

Given the success of the various SAT approaches on the Van der Waerden numbers, it can be expected that the same strategy may work for other problems of the Ramsey theory, including the Ramsey numbers in the previous subsection.

21.2.4. Covering Arrays

A *covering array*, $\text{CA}(n; t, k, v)$, of size n , strength t , degree k , and order v is an $n \times k$ matrix (n rows and k columns) A on v symbols with the property that the projection of each row on any t columns contains all possible t -tuples of v symbols (v^t possibilities). That is, suppose A is on a set V of v symbols, for any t -tuples $\vec{x} \in V^t$ and any t columns $1 \leq c_1 < c_2 < \dots < c_t \leq k$, there exists a row i such that $\vec{x} = A[i, c_1]A[i, c_2] \cdots A[i, c_t]$.

Figure 21.2.4 displays a $\text{CA}(8; 3, 4, 2)$ and a $\text{CA}(10; 3, 5, 2)$, where $V = \{0, 1\}$. In $\text{CA}(10; 3, 5, 2)$, if we choose columns 1, 3 and 4, the projection of these columns on row 1 produces $\langle 0, 0, 0 \rangle$. Every element of $\{0, 1\}^3$ can be produced at least once from row 1 to row 10.

Covering arrays have been found useful in designing tests for software and hardware testing [CDFP97]. For instance, to test a circuit of k Boolean inputs, if the cost of testing all 2^k possible cases is too high, we may want to test only a small number of cases, but ensure that for any t inputs, $t < k$, all the 2^t cases of these t inputs are tested. A covering array CA($n; t, k, 2$) can serve this purpose by regarding each row of the array as a testing case. To reduce the cost of testing, we wish that n is as small as possible. A covering array is optimal if it has the smallest possible number of rows. This number is the *covering array number*,

$$\text{CAN}(t, k, v) = \min n : \exists \text{CN}(n; t, k, v).$$

A great challenge in design theory is to decide the value of $\text{CAN}(t, k, v)$. Over the last decade, there has been a large body of work done in this field of design theory (see [Har02] for a survey). Other applications related to covering arrays include authentication [WC81], block ciphers [KJS97], data compression [SMM98], intersecting codes [CZ94], etc. Other names used in the literature for covering arrays are *covering suites*, (k, v) -*universal sets*, and t -*surjective arrays*.

The following general results are known about the lower and upper bounds of $\text{CAN}(t, k, v)$.

Theorem 21.2.12. [Ce96, CDFP97]

- (a) $v^t \leq \text{CAN}(t, k, v) \leq v^k$;
- (b) if $j < k$, then $\text{CAN}(t, j, v) < \text{CAN}(t, k, v)$;
- (c) if $u < v$, then $\text{CAN}(t, k, u) < \text{CAN}(t, k, v)$;
- (d) if $s < t$, then $\text{CAN}(s, k, v) < \text{CAN}(t, k, v)$;
- (e) $\text{CAN}(t, k, v) \leq v \text{CAN}(t + 1, k + 1, v)$;
- (f) $\text{CAN}(t, k, vw) \leq \text{CAN}(t, k, v) \cdot \text{CAN}(t, k, w)$.

The above results are hardly useful to deduce the exact values of $\text{CAN}(t, k, v)$. However, *orthogonal arrays*, another subject of design theory, have been found useful to decide some of these numbers.

21.2.5. Orthogonal Arrays

Orthogonal arrays are structures that have been used in the design of experiments for over 50 years. An *orthogonal array*, $\text{OA}(v; k, t, \lambda)$, with degree k (or k constraints), order v (or v levels), strength t , and index λ is an $n \times k$ matrix on v symbols, where $n = \lambda v^t$, with the property that for any t columns, each of v^t vectors of length t on the v symbols appears exactly λ times as the projection of a row on the t columns. It is clear that an orthogonal array of index $\lambda = 1$ is a special case of a covering array since in a covering array, each t -vector is required to appear at least once. In fact, an orthogonal array of index 1 is always a minimal covering array.

In the literature, orthogonal arrays of strength $t = 2$ and index $\lambda = 1$ are extensively studied. In this case, an $\text{OA}(v; k, 2, 1)$ is equivalent to $k - 2$ mutually orthogonal Latin squares (MOLS) of order v . Suppose L_1, L_2, \dots, L_m are a set of MOLS over $V = \{0, 1, \dots, (v - 1)\}$ and we define a $v^2 \times (m + 2)$ table, each row of which is

$$\langle i, j, L_1(i, j), L_2(i, j), \dots, L_m(i, j) \rangle$$

where $0 \leq i, j \leq v - 1$. Then such a table is an $\text{OA}(v; m + 2, 2, 1)$ [Ce96], which is also a minimal $\text{CA}(v^2; 2, m + 2, v)$. Figure 21.2.5 gives an $\text{OA}(3; 4, 2, 1)$ and the corresponding two $\text{MOLS}(3)$.

When looking for the existence of orthogonal arrays, the concept of so-called *incomplete* orthogonal array with index λ have been proved to be useful in the singular product construction of large orthogonal arrays and other constructions of various combinatorial designs. An *incomplete orthogonal array* $\text{OA}(v, u; k, t, \lambda)$ over an alphabet V , $|V| = v$, with a hole $H \subset V$, $|H| = u$, degree k , order v , hole size u , strength t , and index λ is an $n \times k$ matrix on V , where $n = \lambda(v^t - u^t)$, with the property that for any t columns, each vector in $V^t - H^t$ appears exactly λ times as the projection of a row on the t columns.

Theorem 21.2.13. [ACYZ97] *An $\text{OA}(v, u; 5, 2, \lambda)$ exists if and only if $v \geq 4u$, with one exception of $(v, u, \lambda) = (6, 1, 1)$, and three possible exceptions of $(v, u) = (10, 1)$, $(48, 6)$ and $(52, 6)$.*

Note that an incomplete $\text{OA}(v, 1; k, t, \lambda)$ is the same as an ordinary $\text{OA}(v; k, t, \lambda)$ and the existence of $\text{OA}(10, 1; 5, 2, 1)$ implies the existence of three $\text{MOLS}(10)$ (see section 21.2.1.2).

Results obtained by model generators

SATO has been used to establish several cases in Theorem 21.2.13: They are $OA(v, u; 5, 1, 1)$ for $(v, u) \in \{(20, 3), (26, 3), (30, 3), (32, 3), (22, 5), (28, 5), (34, 5)\}$ [ACYZ97].

21.2.5.1. Covering Array Numbers of Small Strength

Charlie Colbourn is maintaining a list of lower bounds for hundreds of covering array numbers of strength from 2 to 6 [Col08]. Some of these results are obtained from orthogonal arrays, some from theoretic work in design theory, some from other search methods, such as greedy search, tabu search, or simulated annealing. Special software has been created for covering arrays of small sizes [YZ08]. At this moment, only one result, i.e., $CAN(3, 7, 3) \leq 40$, is obtained by a SAT-based model generator [HPS04].

Recall that $N(v)$ is the maximum number of Latin squares in a set of MOLS of order v (see section 21.2.1.2). The following result is useful for $CAN(2, k, v)$.

Theorem 21.2.14. *For any $2 \leq k \leq N(v) + 2$, $CAN(2, k, v) = v^2$.*

Proof From $N(v)$ MOLS, we may build an $OA(v^2; N(v) + 2, v, 2, 1)$ which is also $CA(v^2; 2, N(v) + 2, v)$, so $CAN(2, N(v) + 2, v) \leq v^2$. By Theorem 21.2.12 (a), $CAN(2, k, v) \geq v^2$ for any k . So $CAN(2, N(v) + 2, v) = v^2$. By Theorem 21.2.12 (b), the theorem holds.

For unknown $N(v)$ or $k \geq N(v) + 3$, $CAN(2, k, v)$ are less known. We have the following results.

Theorem 21.2.15. (Metsch’s Theorem) *$CAN(2, k, v) > v^2$ for all k satisfying one of the following conditions:*

1. $k > n - 4$ and $n = 14, 21, 22$,
2. $k > n - 5$ and $n = 30, 33, 38, 42, 46, 52, 57, 62, 66, 69, 70, 77, 78$, or
3. $k > n - 6$ and $n = 86, 93, 94$.

However, these lower bounds are of little use in that they do not tell us how fast $CAN(2, k, v)$ grows as a function of k . The only case when $CAN(2, k, v)$ can be defined as a function of k is when $v = 2$.

Theorem 21.2.16. *For all $k > 1$, $CAN(2, k, 2) = n$, where n is the smallest integer satisfying*

$$k \leq \binom{n - 1}{\lceil n/2 \rceil}$$

The above theorem yields the following precise values for $CAN(2, k, 2)$ [Har02].

k	2 – 3	4	5 – 10	11 – 15	16 – 35	36 – 56	57 – 126
n	4	5	6	7	8	9	10

In Tables 21.3 and 21.4, we list the latest known values of $CAN(t, k, v)$ for small k and v and $t = 2, 3$ [CK02, Col08]. If an entry at row k and column

v is a single integer a , it means $\text{CAN}(t, k, v) = a$; if it is a, b , it means $a \leq \text{CAN}(2, k, v) \leq b$.

If $v = p^\alpha$ is a prime power, then $N(v) = v - 1$. By Theorem 21.2.16, $\text{CAN}(2, k, v) = v^2$ for $2 \leq k \leq v + 1$. This result has been generalized to any strength $t < v$.

Theorem 21.2.17. [Har02] *Let $v = p^\alpha$ be a prime power and $v > t$. Then $\text{CAN}(t, k, v) = v^t$ for all $2 \leq k \leq v + 1$. Moreover, if $v \geq 4$ is a power of 2, then $\text{CAN}(3, k, v) = v^3$ for all $2 \leq k \leq v + 2$.*

Results obtained by model generators

In [HPS04], Hnich, Prestwich, Selensky, and Smith studied four different ways of specifying the covering array number problem in propositional logic: the naive matrix approach, the alternative matrix approach, the integrated matrix approach, and the weakened matrix approach. Using incomplete SAT solvers, they reproduced many results in the list maintained by Colbourn. They also found an improved bound for a large problem: $\text{CAN}(3, 7, 3) \leq 40$. This result is still the best known today. Their experimental results showed that incomplete

SAT solvers produce the best results in the weakened matrix approach.

21.2.6. Steiner Systems

Given three integers t, k, n such that $2 \leq t < k < n$, a *Steiner system* $S(t, k, n)$ is a pair (V, \mathcal{B}) , where $|V| = n$ and $\mathcal{B} = \{B \subset V : |B| = k\}$ and B is called a *block*, with the property that every subset of V of size t is contained in exactly one block. Unaware of the earlier work of Thomas Kirkman, in 1853 Steiner first asked about the existence of $S(2, 3, n)$ and went on to ask about $S(t, t + 1, n)$ systems.

Steiner systems have a rich relationship with other structures in design theory. For instance, $S(2, k, n)$ is a *balanced incomplete block design*. Let K_n be the complete undirected graph with n vertices. An $S(4, 5, n)$ is equivalent to a collection \mathcal{B} of edge disjoint pentagons which partition the edges of K_n with the additional property that every pair of vertices are joined by a path of length 2 in exactly one pentagon of \mathcal{B} .

For small $t \geq 4$, only finitely many $S(t, k, n)$ are known and none are known for $t \geq 6$. In the following, we will present some results when $k = 3, 4, 5$.

21.2.6.1. Steiner Triple Systems

An $S(2, 3, n)$ is called *Steiner triple system* of order n , noted as STS(n). It is known that an STS(n) exists if and only if $n \equiv 1$ or $3 \pmod{6}$. Kirkman first proved it in 1847 (six years before Steiner posed the question of its existence!).

If (V, \mathcal{B}) is an $S(t, k, n)$ and if there exists a partition R of the block set \mathcal{B} into *parallel classes*, each of which in turn is a partition of the set V , $S(t, k, n)$ is said to be *resolvable* and R is called a *resolution*. A resolvable STS(n) is called *Kirkman triple system* KTS(n). In 1850, Kirkman posed the following problem.

Kirkman's schoolgirl problem. Fifteen young ladies in a school walk of three abreast for seven days in succession: it is required to arrange them daily, so that no two walk twice abreast.

This problem is equivalent to finding a KTS(15), i.e., a resolvable STS(15). Among the eighty non-isomorphic STS(15)s, exactly four are resolvable. However, there are seven non-isomorphic KTS(15)s [Ce96].

It is known after 1970 that a Kirkman triple system of order n exists if and only if $n \equiv 3 \pmod{6}$ [Ce96].

Results obtained by model generators

While the existence problems for STS(n) and KTS(n) are known, they can serve as interesting SAT benchmarks. Hartley used genetic algorithms on an SAT encoding of STS(n) and found its performance unsatisfactory [Har96].

21.2.6.2. Steiner Quadruple Systems

A Steiner system $S(3, 4, n)$ is called *Steiner quadruple system* of order n , i.e., SQS(n). It is known that an SQS(n) exists if and only if $n \equiv 2$ or $4 \pmod{6}$. For resolvable Steiner quadruple systems, the complete existence result was

established in 2005: A resolvable SQS(n) exists if and only if $n \equiv 4$ or $8 \pmod{12}$ [JZ05].

The most famous problem related to Steiner quadruple systems is the so-called *social golfer problem*:

Social Golfer Problem. A golf club has n members and each member plays golf once a week. Golfers always play in groups of 4 and each golfer will play in the same group with any other golfer exactly once. Can you provide a schedule for this club?

This is apparently a generalization of Kirkman's schoolgirl problem. A solution to the problem is a solution of the resolvable Steiner system $S(2, 4, n)$. For instance, when $n = 16$, and the golfers are named by A to P, a schedule of five weeks is given below:

1	ABCD	EFGH	IJKL	MNOP
2	AEIM	BFJN	CGKO	DHLP
3	AFKP	BELO	CHIN	DGJM
4	AGLN	BHKM	CEJP	DFIO
5	AHJO	BGIP	CFLM	DEKN

The number of weeks can be computed as $(n-1)/3$ as each week a golfer plays with three new friends. Apparently, n must be divisible by 4 so that we can have groups of four. If $n-1$ is not divisible by 3, to allow a solution for such n 's, the problem is relaxed by that "no golfer will play in the same group with any other golfer more than once". In this case, an optimal solution is a schedule of $\lfloor (n-1)/3 \rfloor$ weeks. When $n = 32$, it is problem 10 in CSPLIB (<http://www.csplib.org>) and has drawn a lot of attention. A solution of $n = 32$ is first reported by Hao Shen in 1996, and independently solved by Charles Colbourn in 1999 [Col99]. For $n = 36$, an optimal solution has not been reported. The web site created by Ed Pegg Jr.,

http://www.maa.org/editorial/mathgames/mathgames_08_14_07.html

provides useful information regarding the social golfer problem.

Results obtained by model generators

Like Steiner triple systems, Steiner quadruple systems are interesting benchmark problems for SAT solvers. In particular, Ian Gent and Ines Lynce studied different SAT encoding for the social golfer problem and showed that these encodings may improve or degrade search dramatically depending on the solver [GL05].

21.2.6.3. Steiner Pentagon Systems

When $t = 4$ and $k = 5$, $S(4, 5, n)$ is called *Steiner pentagon system* of order n , denoted by SPS(n). It is known [ABZ99] that a Latin square $(Q, *)$ satisfying the three identities, $x * x = x$, QG11 and QG12 is equivalent to a SPS($|Q|$), where

$$\begin{aligned} \text{QG11: } & (y * x) * x = y \\ \text{QG12: } & x * (y * x) = y * (x * y) \end{aligned}$$

Here a block $(x, y, z, u, v) \in \mathcal{B}$ if and only if $x * y = z, y * x = v$, for $x \neq y$ and $x * x = x$ for all $x \in Q$. It can be deduced that $u = y * z = x * v$. That is, a Latin square $(S, *)$ defines blocks $(x, y, x * y, y * (x * y), y * x)$ for $x, y \in S$. An idempotent Latin square associated with a SPS will be denoted by QG10 (i.e., QG10 is the conjunction of QG11 and QG12).

Theorem 21.2.18. [Ce96, Zha97]

(a) A QG10(n) exists if and only if $n \equiv 1$ or $5 \pmod{10}$, except $n = 15$.
 (b) An FQG10(h^n) exists if and only if $n \geq 5$, $n(n-1)h^2 \equiv 0 \pmod{5}$, and if h is odd, then n is odd, except possibly for the following cases:

1. $h \equiv 10 \pmod{20}$, where $h \neq 30$, and $n = 28$;
2. $h = 30$ and $n \in \{7, 12, 18, 19, 22, 23, 24, 27\}$;
3. $h \equiv 1, 3, 7$, or $9 \pmod{10}$, where $h \neq 3$, and $n = 15$;
4. the pairs $(h, n) \in \{(6, 6), (6, 35), (6, 36), (15, 19), (15, 23), (15, 27)\}$.

Results obtained by model generators

Stickel was the first to study QG10 using a model generator. Using DDPP, he found FQG10(2^5) and FQG10(2^6). Later, the author found a dozen cases of FQG10(h^n) using SATO, including the cases when $(h, n) = (2, 10), (2, 11), (3, 15)$ [ABZ99]. These small order designs were very useful in the recursive constructions of FQG10(h^n) for large h and n . For instance, from FQG10(10^5) we can obtain FQG10(2^{25}) by filling five copies of FQG10(2^5) into the five holes of FQG10(10^5).

21.2.7. Mendelsohn Designs

In Steiner systems, a block is a set of elements. If a block is a list (also called *tuple*) of elements, we have the concept of Mendelsohn designs. A cyclic k -tuple (a_1, a_2, \dots, a_k) is defined to be $\{(a_i, a_{i+1}), (a_k, a_1) \mid 1 \leq i \leq k-1\}$. The elements a_i, a_{i+t} are said to be t -*apart* in a cyclic k -tuple (a_1, a_2, \dots, a_k) , where $i+t$ is taken as $1 + ((i+t-1) \bmod k)$.

Given numbers n, k and λ , a *perfect Mendelsohn design* (briefly (n, k, λ) -PMD) is a pair (X, \mathcal{B}) where

1. X is a set of points,
2. \mathcal{B} is a collection of cyclic k -tuples of X (called blocks),
3. every ordered pair of points appears t -apart in exactly λ blocks for $1 \leq t \leq k-1$.

In this section, we are only interested in (n, k, λ) -PMD where $\lambda = 1$, because they are related to Latin squares. That is, a $(n, k, 1)$ -PMD exists if and only if an idempotent Latin square of order n exists that satisfies the following constraint:

$$x_1 * x_2 = x_3, x_2 * x_3 = x_4, \dots, x_{k-2} * x_{k-1} = x_k \Rightarrow x_{k-1} * x_k = x_1 \quad (21.12)$$

By fixing $k = 3, 4, 5$ in constraint 21.12 and then remove some variables, we obtain the constraints QG13, QG14, and QG5, for $(n, k, 1)$ -PMD, $k = 3, 4, 5$, respectively.

$$\text{QG13: } y * (x * y) = x$$

$$\text{QG14: } (x * y) * (y * (x * y)) = x$$

$$\text{QG15: } (y * (x * y)) * ((x * y) * (y * (x * y))) = x$$

A Latin squares satisfying QG13, QG14, and QG15 correspond to, respectively, perfect Mendelsohn triple, quadruple, pentagon systems.

It is well-known that a QG13(n) exists if and only if $n \equiv 0$ or $1 \pmod{3}$. So people are interested in some combined constraints. For instance, since any conjugate of a QG13(n) also satisfies QG13, if QG13(n) also satisfies QG0, then we have a pair of orthogonal Latin squares, i.e., $(S, *)$ and $(S, *_{213})$, that satisfy QG13. Such a Latin square corresponds to a self-orthogonal perfect Mendelsohn system.

Theorem 21.2.19. [Ce96, Zha97]

(a) *A Latin square of order n satisfying both QG0 and QG13 exists if and only if $n \equiv 0$ or $1 \pmod{3}$, except $n = 3, 6, 9, 10, 12$ and except possibly $n = 18$.*

(b) *A pair of orthogonal QG13(n) exists if and only if $n \equiv 0$ or $1 \pmod{3}$, except $n = 3, 6, 10$ and except possibly $n = 12$.*

QG14 is conjugate-equivalent to QG4, so any existence result regarding QG4 applies to QG14.

The existence results regarding QG15 are mostly known:

Theorem 21.2.20. [Ce96, Zha97] *A QG15(n) exists if and only if $n(n-1) \equiv 0 \pmod{5}$, except $n = 6, 10$ and except possibly $n = 15$ and 20 .*

Results obtained by model generators

For the Latin squares satisfying QG0 and QG13, SATO solved 11 cases in Theorem 21.2.19, 21 being the smallest and 72 being the largest [BZZ96]. McCune is the first to find a pair of orthogonal QG13(9)'s. Later, SATO proved that there exist no pairs of orthogonal QG13(10)'s. SATO also found a pair of orthogonal QG13(18). In the proof of Theorem 21.2.20, SATO found five new cases [BCYZ97, BYZ98].

21.2.8. Magic Squares

A *magic square* of order n , $M = (a_{i,j})$, $0 \leq i, j \leq n-1$, is an $n \times n$ matrix of n^2 distinct nonnegative integers with the property that the sum of the n numbers in every row, in every column and in each diagonal is the same. The sum is called the *magic number*.

The study of magic squares probably dates back to prehistoric times [And60]. A lot of work had been done on the constructions of magic squares, and the interested readers may refer to [Abe94, Cam73, KM06]. Recently, magic squares with some properties are investigated, see [CCZ15, WL12, ZCWZ17].

Given any positive integer n , let $Z_n = \{0, 1, \dots, n-1\}$. A magic square M of order n is called *normal* if the entries of M are the members of Z_{n^2} . In the following, we consider only normal magic squares.

In [KM06], the concept of *symmetric magic square* is introduced. A magic square $M = (m_{i,j})$ of order n is called *symmetric*, SMS(n) for short, if

$$m_{i,j} + m_{n-1-i,n-1-j} = n^2 - 1, \text{ for all } 0 \leq i, j \leq n - 1.$$

In [Gar98], it is shown that if there exists a symmetric magic square of order n , then $n \neq 4k + 2$ for any positive integer k .

For any magic square M of order n over the set Z_{n^2} , we can factor M into (A, B) , where $A = (a_{i,j})$, $B = (b_{i,j})$ are two $n \times n$ matrices over the set Z_n , such that $M = nA + B$, i.e., $m_{i,j} = na_{i,j} + b_{i,j}$, $0 \leq a_{i,j}, b_{i,j} \leq n - 1$, and $M = (m_{i,j}) = nA + B$. It is not difficult to check that A and B are orthogonal if M is a normal magic square [Abe94].

Following the definitions from [Abe94], M is called *elementary* if both A and B are Latin squares; otherwise, M is said to be *nonelementary*. If both A and B possess the property that the sums of the n numbers in every row and every column are the same, then M is called *rational*; otherwise, M is said to be *irrational*. It is clear that an elementary magic square is also rational, an irrational magic square is also nonelementary. The concept of elementary, nonelementary, irrational was introduced in [Abe94] in 1994, however, they did not get enough attention.

In [GS04], streamlining constraints were introduced for constraint reasoning. To see the effectiveness of streamlining constraints, the concept of *diagonally ordered magic square* is introduced. A magic square $M = (m_{i,j})$ of order n is called *diagonally ordered*, DOMS(n) for short, if both the main diagonal and the back diagonal, when traversed from left to right, have strictly increasing values, i.e.,

$$m_{i,i} < m_{i+1,i+1} \quad \text{and} \quad m_{n-1-i,i} < m_{n-2-i,i+1} \quad \text{for all } 0 \leq i \leq n - 2.$$

Here are the existence results regarding normal magic squares with various properties:

Theorem 21.2.21. [ZCWZ17, ZCWZar, YWZ16, YWZar]

(a) *There exists an elementary symmetrical DOMS(n) if and only if $n \equiv 0, 1, 3 \pmod{4}$.*

(b) *There exists an elementary DOMS(n) for or each positive integer n with two exceptions of $n = 2, 6$ and two possible exceptions of $n = 22, 26$.*

(c) *There exists a nonelementary rational symmetric DOMS(n) if and only if $n \equiv 0, 1, 3 \pmod{4}$, and $n \geq 4$.*

(d) *There exists a nonelementary rational DOMS(n) if and only if $n \neq 2, 3$.*

(e) *There exists an irrational symmetric DOMS(n) if and only if $n \equiv 0, 1, 3 \pmod{4}$, and $n \geq 5$.*

(f) *There exists an irrational DOMS(n) if and only if $n \geq 5$.*

Results obtained by model generators

Model generators played an important role in Theorem 21.2.21 by finding designs of small orders for all the six cases. Designs of large orders are then

obtained from recursive construction techniques [ZCWZ17, ZCWZar, YWZ16, YWZar].

Since every magic square of order n can be factored into a pair of orthogonal matrices (A, B) over Z_n , we may use model generators to search for a pair of orthogonal (A, B) over Z_n instead of M directly. The elementary, non-elementary, rational and irrational properties of M are defined from (A, B) . All other properties on M can be defined similarly over (A, B) . To ensure that M is symmetric, we require that both A and B be *strongly symmetric*: An $n \times n$ matrix $A = (a_{i,j})$ of order n is called *strongly symmetric* if $a_{i,j} + a_{n-1-i, n-1-j} = n-1$, $0 \leq i, j \leq n-1$. To ensure that M is a diagonally ordered magic square, let $A = (a_{i,j})$ and $B = (b_{i,j})$ for $0 \leq i, j \leq n-1$, we require that $(a_{i,i}, b_{i,i}) < (a_{i+1, i+1}, b_{i+1, i+1})$, and $(a_{n-i-1, i}, b_{n-i-1, i}) < (a_{n-i-2, i+1}, b_{n-i-2, i+1})$, $0 \leq i < n-1$, by the natural lexicographical ordering.

In search for a pair of orthogonal matrices (A, B) , we may ask that the matrix B is the transpose of A , that is, A is self-orthogonal. For example, for the order $n = 4$, we found the following A by model generators:

$$A = \begin{pmatrix} 0 & 2 & 1 & 3 \\ 3 & 1 & 2 & 0 \\ 3 & 1 & 2 & 0 \\ 0 & 2 & 1 & 3 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 3 & 3 & 0 \\ 2 & 1 & 1 & 2 \\ 1 & 2 & 2 & 1 \\ 3 & 0 & 0 & 3 \end{pmatrix}, \quad M = \begin{pmatrix} 0 & 11 & 7 & 12 \\ 14 & 5 & 9 & 2 \\ 13 & 6 & 10 & 1 \\ 3 & 8 & 4 & 15 \end{pmatrix}$$

Here the sum of each row, each column and each diagonal of A is the same, i.e., 6. $B = A^T$ and $M = 4A + B$ is a nonelementary rational DOM(4). In this way, we obtained the same type of structures by model generators for order $n = 5, 6, 7, 9, 11, 13, 15, 19$, and 23, thus obtained the corresponding DOM(n).

21.3. Encoding Design Theory Problems

If we regard an off-the-shelf general-purpose SAT solver in a Mace-style model generator as the “hardware”, then the design of the encoder, that is, how to encode these problems for SAT solvers, would be the “software” issues. Indeed, the encoding is one of the most crucial issues to the success of solving these combinatorial problems. In this section, we will discuss some general issues of how to specify combinatorial designs in propositional logic. We examine performance enhancing techniques used in the study, such as adding extra constraints, eliminating isomorphism, etc.

21.3.1. Transforming Specification into Clauses

Most design theory problems that could be attacked by a Mace-style model generator can be specified by a first-order formula over a finite domain. Transforming the first-order formula into propositional clauses is often straightforward but also very important to the success of model generators. First, the transformation must be sound so that the first-order formula is satisfiable if and only if the propositional clauses are satisfiable. Secondly, the clause size should be as small as possible in terms of numbers of literals.

We assume the conventional concepts of a first-order language such as predicates, (non-Boolean) functions (including constants), variables, terms, atoms, clauses, etc. Let u, \dots, z denote free variables, s, t denote terms, and c denote constants. Let S be a set of first-order clauses over a finite domain D , where $D = \{0, 1, \dots, (n-1)\}$. For each predicate p of arity k , we define a propositional variable for every $p(d_1, \dots, d_k)$, where $d_1, \dots, d_k \in D$. For each function of arity k , we define a propositional variable for every equality $f(d_1, \dots, d_k) = d$, where $d_1, \dots, d_k, d \in D$. The transformation of S into a set of propositional clauses can be summarized as the following rules [CS03]:

- **instantiation**

$$\frac{S \cup \{C[x]\}}{S \cup \{C[x/0], C[x/1], \dots, C[x/(n-1)]\}}$$

where $C[x]$ denotes a clause containing the variable x and $C[x/d]$ denote the clause obtained from C by replacing every occurrence of x by d .

- **flattening**

$$\frac{S \cup \{C \vee L[t]\}}{S \cup \{(x \neq t) \vee C \vee L[t/x]\}}$$

where $L[t]$ denotes a literal containing a term t , and t is neither a variable nor an element of D ; L is neither of form $t = s$ nor $t \neq s$, where s is either a variable or an element of D ; x is a fresh variable. $L[t/x]$ represents the literal obtained from L by replacing t by x .

- **term definition**

$$\frac{S \cup \{C \vee L[t]\}}{S \cup \{(c = t), C \vee L[t/c]\}}$$

where t is a non-constant ground term and contains at least one constant other than elements of D ; L is neither of form $t = s$ nor $t \neq s$, where s is either a variable or a constant, or an element of D ; c is a fresh constant. The same c can be reused for all the occurrence of t in S .

- **splitting**

$$\frac{S \cup \{C[\mathbf{x}] \vee D[\mathbf{y}]\}}{S \cup \{C[\mathbf{x}] \vee p(\mathbf{x} \cap \mathbf{y}), D[\mathbf{y}] \vee \neg p(\mathbf{x} \cap \mathbf{y})\}}$$

where \mathbf{x} and \mathbf{y} are the set of variables, occurring in C and D , respectively; neither $\mathbf{x} - \mathbf{y}$ nor $\mathbf{y} - \mathbf{x}$ is empty; p is a fresh predicate.

- **functional definition**

$$\frac{S}{S \cup \{f(d_1, \dots, d_k) \neq d \vee f(d_1, \dots, d_k) \neq d'\}}$$

where f is a function of arity k , and $d_1, \dots, d_k, d, d' \in D$. This rule applies to every function once and for all.

- **totality definition**

$$\frac{S}{S \cup \{f(d_1, \dots, d_k) = 0 \vee \dots \vee f(d_1, \dots, d_k) = (n-1)\}}$$

where f is a function of arity k , and $d_1, \dots, d_k \in D$. This rule applies to every function once and for all.

Let $S \Rightarrow S'$ if $S' \neq S$ and S' is derived from S by one of the above rules and let \Rightarrow^+ be the transitive closure of \Rightarrow . We also write $S \Rightarrow^+ S'$ if $S \Rightarrow^+ S'$ and there exists no $S'' \neq S'$ such that $S' \Rightarrow S''$.

Theorem 21.3.1. [CS03]

(a) \Rightarrow^+ is terminating.

(b) If $S \Rightarrow^+ S'$ then every clause of S' corresponds to a single propositional clause.

(c) If $S \Rightarrow^+ S'$ then S is satisfiable in the domain D if and only if the set of propositional clauses corresponding to S' is satisfiable.

The reader may consult [CS03] for a proof of the above theorem. In the above rules, the **splitting** and **term definition** rules are optional. However, they can help to reduce the number of clauses substantially, as illustrated next by two examples.

If a clause has k variables, the **instantiation** rule will generate n^k ground clauses, where n is the domain size. If each ground clause cannot be represented by a single propositional clause, then the **flattening** rule can be used first which introduces new variables. For instance, for the QG3 constraint in section 21.2.1.5,

$$\text{QG3: } (x * y) * (y * x) = x$$

The **flattening** rule can be used twice to generate

$$(x * y) \neq w \vee (y * x) \neq z \vee (w * z) = x$$

and the **instantiation** rule would generate n^4 ground clauses, each of which corresponds to a propositional clause.

Suppose we are given an identity $(x * y) * (y * a) = x$ where a is a constant. If we follow the same procedure, we will get

$$(u \neq a) \vee (x * y) \neq w \vee (y * u) \neq z \vee (w * z) = x$$

which would generate n^5 propositional clauses. On the other hand, if we apply the **instantiation** rule on y first in $(x * y) * (y * a) = x$, we get n instances of form $(x * d) * (d * a) = x$, where $d \in D$. Applying the **term definition** rule on $(d * a)$, we have two clauses: $c = (d * a)$ and $(x * d) * c = x$. The flattened clause of $c = (d * a)$ is $c \neq z \vee a \neq y \vee z = (d * y)$ which generates n^2 propositional clauses; the flattened clause of $(x * d) * c = x$ is $c \neq z \vee (x * d) \neq y \vee y * z = x$, which generates n^3 propositional clauses. Altogether, $n^4 + n^3$ propositional clauses will be generated. In other words, using the **term definition** rule n times (with n new constants), we reduce the number of propositional clauses from n^5 to $n^4 + n^3$.

In the above example, the **instantiation** rule was used once before the **term definition** rule. In the Paradox system of Claessen and Sörensson [CS03], the **instantiation** rule is the last rule to be used, thus the reduction of clauses illustrated in the above example is not available in Paradox. On the other hand, if we always use the **instantiation** rule first, then it may not be possible to use the **splitting** rule, which is very important as illustrated in the next example. Note also that the **term definition** rule should be used before the **flattening** rule. It

is an interesting research problem to develop useful heuristics to decide the order of using these rules.

For the second example, let us take a look at

$$x * y \neq s \vee z * w \neq s \vee x \star y \neq t \vee z \star w \neq t \vee x = z \quad (21.8)$$

in section 21.2.1.2, which comes from the orthogonality of two matrices. We need to convert this clause into propositional clauses and it is expensive to use only the **instantiation** rule as it contains 6 variables. However, applying the **splitting** rule twice, we obtain three clauses with only four free variables each.

At first, the above clause is split into

$$x * y \neq s \vee x \star y \neq t \vee x = z \vee p(z, s, t), \quad (21.13)$$

$$z * w \neq s \vee z \star w \neq t \vee \neg p(z, s, t) \quad (21.14)$$

where $p(z, s, t)$ is a new predicate. Then clause (21.13) is split into

$$x * y \neq s \vee x \star y \neq t \vee q(x, s, t), \quad (21.15)$$

$$x = z \vee p(z, s, t) \vee \neg q(x, s, t) \quad (21.16)$$

where $q(x, s, t)$ is a new predicate.

In [Zha97], clause (21.8) is manually split into two clauses as shown by the following lemma.

Lemma 21.3.2. ([Zha97]) *For any set C of clauses, $C \cup \{(21.8)\}$ is satisfiable if and only if $C \cup \{(21.17), (21.18)\}$ is satisfiable, where*

$$x * y = s \wedge x \star y = t \Rightarrow \Phi(x, s, t), \quad (21.17)$$

$$\Phi(x, s, t) \wedge \Phi(z, s, t) \Rightarrow x = z, \quad (21.18)$$

and Φ is a new predicate not appearing in C .

As reported in [Zha97], quite a number of quasigroup problems could not be solved without using the new predicate Φ . To attack the open problem of deciding if $N(10) \geq 3$ in section 21.2.1.2, we need to specify three Latin quares of size 10, which requires 3000 propositional variables. To use the above lemma, we need another 3000 propositional variables to specify $\Phi(x, s, t)$. Even though the number of clauses is over 85,000, it is much smaller than 10^6 when without Φ . It is a challenge to develop a method which can automatically generate the predicates like Φ which involves more than one literal in a clause.

21.3.2. Isomorphic Model Elimination

For most design theory problems, including all the problems presented in the previous sections, one solution may generate another by switching names of elements, switching rows or columns in a table, etc. In other words, there exist many isomorphic models satisfying the same constraints. In any model generator based on exhaustive search, it is often too expensive to search all the possible models. Thus isomorphism elimination is crucial to the efficiency of model generators.

Let us first take a look at how numerous Latin squares for some small orders. Two quasigroups $(S, *)$ and (S, \star) are said to be *isomorphic* if there is a bijection $\phi : S \rightarrow S$ such that $\phi(x*y) = \phi(x)\star\phi(y)$. $(S, *)$ and (S, \star) are said to be *isotopic* (or *equivalent*) if there exist three bijections from the rows, columns, and symbols of $(S, *)$ to the rows, columns, and symbols, respectively, of (S, \star) , that map $(S, *)$ to (S, \star) . A Latin square is said to be *reduced* if the first row and the first column contain the elements in natural order. The following table gives the numbers of isotopic, isomorphic, and reduced Latin squares of order less than nine.

$n =$	1	2	3	4	5	6	7	8
isotopy classes	1	1	1	2	2	22	563	1,676,267
isomorphism classes	1	1	5	35	1,411	1,130,531	12,198,455,835	$> 1.52 \times 10^{22}$
reduced squares	1	1	1	4	56	9,408	16,942,080	535,281,401,856

Many people realized the importance of effectively detecting symmetries in a set of propositional clauses [BS94, CGLR96, ARMS03]. Fujita, Slaney and Stickel used a single clause to eliminate some isomorphic Latin squares [SFS95]. To search a Latin square $(S, *)$, where $S = \{0, 1, \dots, (n-1)\}$, the single clause to be added to the input is:

$$y > (x+1) \Rightarrow (x*0 \neq y) \quad (21.19)$$

where $0 \leq x < y < n$ for a Latin square of order n . When converting into SAT clauses, this clause generates only unit clauses. This approach is simple and effective in reducing search time no matter whether the instance is satisfiable or not. In [Zha97], various ways of using similar clauses like the above one are discussed.

Deciding the exact number of non-isomorphic Latin squares satisfying certain constraints is a computationally expensive and interesting problem. For instance, only recently, it is found that there are only six non-isomorphic QG4(9). For quasigroups of orders bigger than 9 and for other types of short identities, we know many of them exist, but we do not know the total number of non-isomorphic ones.

Jian Zhang used the so-called least number heuristic (LNH) [Zha91] in his program FALCON [Zha96] and later in SEM [ZZ95] to avoid exploring isomorphic subspaces. It is based on the observation that, at the early stage of the search, many value names (which have not yet been used in the search) are symmetric. When choosing a value for a variable of the constraints, we need not consider all the values of a given sort. It makes no difference to assign the value e or e' to the variable, if neither of them has been assigned to some other variables. The so-called *least number heuristic* used in FALCON and SEM is that when all the unused values for a variable are symmetric for the constraints, you need only the least one, plus all the used values, for the next variable [Zha96].

The least number heuristic has been shown very effective in reducing isomorphic subspaces in Latin square problems as well as in many other design theory problems. However, this technique in general cannot be fully used without modifying model generation programs. For SAT-based (i.e., Mace-style) model generators, an off-shelf SAT solver is often used, and in such case, it is very difficult

to use techniques like the least number heuristic because it involves the internal working of SAT solvers. Claessen and Sörensson [CS03] investigated the way of using the idea of the least number heuristic in a Mace-style model generator. For constant symbols (other than the ones introduced by **term definition**, they can be assigned the least numbers in the domain. Let $k > 0$ be the number of constants and f be a function of arity 1. They suggest the following clauses which subsume the *totality definitions* of f :

$$\begin{aligned} f(0) = 0 \vee f(0) = 1 \vee \dots \vee f(0) = k \\ f(1) = 0 \vee f(1) = 1 \vee \dots \vee f(1) = k \vee f(1) = k + 1 \\ f(2) = 0 \vee f(2) = 1 \vee \dots \vee f(2) = k \vee f(2) = k + 1 \vee f(2) = k + 2 \\ \dots \end{aligned}$$

The rationale here is that, in order to pick a value for a particular $f(d)$, we simply use an element that we have already used, or the least element that has not been used yet. A more efficient way would be to generate only unit clauses. That is, suppose the number of elements is n , we generate the following unit clauses:

$$\begin{aligned} f(0) \neq k + 1, f(0) \neq k + 2, \dots, f(0) \neq n - 1 \\ f(1) \neq k + 2, f(1) \neq k + 3, \dots, f(1) \neq n - 1 \\ f(2) \neq k + 3, f(2) \neq k + 4, \dots, f(2) \neq n - 1 \\ \dots \end{aligned}$$

These unit clauses can not only generate the previous set of clauses with the totality definitions, but also subsume many other input clauses.

For function g of arity greater than 1, Claessen and Sörensson suggested to define a fresh function f in terms of g by e.g. $f(x) = g(x, 0)$. In this case, the effect is the same as the isomorphic cutting clause used by Fujita, Slaney and Stickel.

Of course, it is possible to encode fully the idea of the least number heuristic for any function as a set of propositional clauses by introducing the canonicity requirement [CS03]. However, adding a large set of clauses to the original set often leads to a longer search time. The same experience has been shared by other researchers. For instance, to search for lower bounds of Van der Waerden numbers, Dransfield, Marek and Truszczynski [DMT04] have tried to add extra clauses to eliminate some isomorphic models. However, adding such clauses hurt the performance of their incomplete SAT solver. Gent and Lynce [GL05] and Azevedo [Aze06] also have tried different ways of removing isomorphic models in the study of the social golfer problem. Depending on the types of SAT solvers, the performance varies.

The symmetries of these design theory problems are easy to detect in their specification. As the clauses converted from the specification is often numerous, it is much harder to detect symmetries in the propositional clauses, because checking the symmetry of a set of propositional clauses itself is also NP-complete [Cra92]. It remains a challenge to develop a generic tool which takes the specification of a design theory problem and produces powerful isomorphic-cutting clauses. Huang et al. [HMG⁺18] used the least number heuristic implemented in SEM to generate many SAT instances which are subproblems of the large set problems in Theorem 21.2.10 and solved several previously open cases. It appears that this

approach of combining model generators like SEM with SAT solvers is effective and easy to use.

21.3.3. Satisfiability modulo SAT

In section 21.2.8, we introduced the concept of magic squares with various constraints. To avoid large numbers appearing in the encoding of magic squares for propositional logic, it recommends to represent a magic square by a pair of orthogonal matrices. The existence of a magic square M of order n becomes the existence of (A, B) , where $M = nA + B$, which can be easily specified as an instance of SAT. To search for a rational magic square, we require that the sum of every row, column and diagonal of both A and B is equal to the same number, i.e., $(n - 1)n/2$. This constraint is troublesome for SAT solvers.

Let $p_{x,y,z}$ be the Boolean variable with the meaning that the entry at row x and column y in the matrix A is z , where $0 \leq x, y, z < n$. To specify that the sum of the entries in row x is $(n - 1)n/2$, we may use the following clause:

$$\neg p_{x,0,z_0} \vee \neg p_{x,1,z_1} \vee \cdots \vee \neg p_{x,n-1,z_{n-1}}$$

where $0 \leq x, z_i < n$, and $z_0 + z_1 + \cdots + z_{n-1} \neq (n - 1)n/2$. Similarly, we may specify that the sum of the entries in each column (and the two diagonals) is the same. The number of propositional clauses represented by the above clause is $O(n^{n+1})$. For $n = 10$, it will be around 10^{11} , far exceeding the limit of today's SAT solvers.

Using the linear pseudo-boolean logic, we may specify that the sum of the entries in row x is $(n - 1)n/2$ as follows:

$$\sum_{y=0}^{n-1} \sum_{z=0}^{n-1} (z + 1)p_{x,y,z} = (n + 1)n/2.$$

For $n = 10$, there are 100 variables in the above formula and this large number of variables is a source of inefficiency for pseudo-boolean solvers.

Using the so-called satisfiability modulo SAT approach proposed in [Zha16], we may create a simple procedure for checking that in A and B , the sum of the entries in each row, column and the two diagonals is the same. Using this decision procedure in a SMT solver, we can apply the advanced techniques of modern SAT solvers to the existence problem of magic squares presented in section 21.2.8. In fact, all the solved cases in section 21.2.8 by a model generator are done by satisfiability modulo SAT.

The idea of satisfiability modulo SAT [Zha16] can be described in the context of the SMT (*satisfiability modulo theories*) approach [NOT06, BSST09], where the interpretation of some propositional variables are constrained by a background theory. For our case, this background theory can be either linear pseudo-boolean logic or simply propositional logic; notably, this background theory can be expressed in propositional logic and easily implemented by a procedure in the framework of the Davis-Putnam-Logemann-Loveland (DPLL) procedure. While this idea does not provide any contribution to the theory of SMT, it is a fresh way

of using the SMT approach and the experiment is a successful practice of a SAT solver based on SMT modulo a procedural theory.

Suppose the SAT instance is described by a set S of propositional clauses and we search for a model of S . In the satisfiability modulo SAT approach, we partition S into Φ and Ψ , and treat Φ as the base constraints and Ψ as a theory. One reason for not treating Ψ as normal clauses is the huge size of Ψ ; it will be much more effective if we use a piece of software code to simulate the effect of Ψ . For instance, the above example of specifying the sum of each row (column, diagonal) of a matrix is equal to the same number, is a good candidate to go to in Ψ . Because propositional logic is well-studied, the completeness and soundness of a decision procedure for Ψ can be easily established. Because of similarity between Φ and Ψ , we may implement an effective SMT procedure which is different from the standard SMT procedure. The details of this approach can be found in [Zha16].

21.4. Conclusions and Open Problems

In this chapter, we have presented various design theory problems where SAT-based model generators are used and some previously-open problems were answered by these model generators. There are still many open problems. Below is a list of open design theory problems presented in the chapter.

1. What is the minimum number of entries for a 9×9 Sudoku puzzle to have a unique solution (section 21.2.1.1)?
2. Are there 3 mutually orthogonal Latin square of size 10 (section 21.2.1.2)?
3. Does SOLSSOM(n) exist for $n = 10$ and 14 (section 21.2.1.2)?
4. Does IQG0(20, 6) exist (section 21.2.1.4)?
5. Does IQG1(11, 3) exist (section 21.2.1.4)?
6. Does IQG2(n, k) exist for $(n, k) = (35, 4)$ and $(38, 4)$ (section 21.2.1.4)?
7. Does FQG1(13^6) exist (section 21.2.1.4)?
8. Does FQG2(h^4) exist for $h = 3, 5$ and 7 (section 21.2.1.4)?
9. Does FQG2(h^4) exist for $h = 3, 5$ and 7 (section 21.2.1.4)?
10. Does QG5(v) exists for $v = 18, 20$ or 22 (section 21.2.1.5)?
11. Does QG6(v) exist for $v = 18, 19, 20$, or 21 (section 21.2.1.5)?
12. Does QG7(v) exist for $v = 18, 19, 20$, or 33 (section 21.2.1.5)?
13. Does QG8(v) exist for $v = 22, 23$, or 26 (section 21.2.1.5)?
14. Does LSQG3(v) exist for $v \in \{12, 13\}$ (section 21.2.1.5)?
15. Does LSQG4(v) exist for $v \in \{9, 12\}$ (section 21.2.1.5)?
16. Does LSQG5(11) exist (section 21.2.1.5)?
17. Does LSQG6(v) exist for $v \in \{9, 13\}$ (section 21.2.1.5)?
18. Does LSQG7(v) exist for $v \in \{9, 13\}$ (section 21.2.1.5)?
19. Does LSQG8(v) exist for $v \in \{9, 11\}$ (section 21.2.1.5)?
20. Does LSQG9(v) exist for $v \in \{10, 13\}$ (section 21.2.1.5)?
21. Is the Ramsey number $R(5, 5)$ greater than 43? Is $R(6, 4)$ greater than 35 (section 21.2.2)?
22. Is the Van der Waerden number $W(2, 7)$ greater than 3704? Is $W(3, 4)$ greater than 293? Is $W(5, 3)$ greater than 171 (section 21.2.3)?

23. Is $\text{CAN}(2, 8, 3) = 12$, $\text{CAN}(2, 7, 4) \leq 20$, or $\text{CAN}(2, 5, 6) \leq 38$ (section 21.2.5.1)?
24. Is $\text{CAN}(3, 12, 2) = 14$, $\text{CAN}(3, 5, 3) \leq 32$, or $\text{CAN}(3, 7, 4) \leq 87$ (section 21.2.5.1)?
25. Can we find a schedule of 11 weeks for 36 golfers in the social golfer problem (section 21.2.6.2)?
26. Does $\text{FQG}10(h^n)$ exist for $(h, n) = (6, 6)$ and $(7, 15)$ (section 21.2.6.3)?
27. Does there exist a self-orthogonal perfect Mendelsohn triple system of order 18 (section 21.2.7)?
28. Do there exist a pair of orthogonal perfect Mendelsohn triple system of order 12 (section 21.2.7)?
29. Does there exist a perfect Mendelsohn pentagon system of order 15 (section 21.2.7)?
30. Does there exist an elementary diagonally ordered magic square of order 22 (section 21.2.8)?
31. What are the exact numbers of non-isomorphic quasigroups of $\text{QG}3(12)$, $\text{QG}4(12)$, and $\text{QG}5(11)$, respectively (section 21.3.2)?

We hope that the developers of model generators will find these design theory problems useful as these problems provide a strong motivation and great challenge for them to develop new techniques to attack them. You will find it how satisfactory and exciting as a researcher if you could solve a problem no one else in the world could.

Chapter 22

Connections to Statistical Physics

Fabrizio Altarelli, Rémi Monasson, Guilhem Semerjian and Francesco Zamponi

22.1. Introduction

The connection between statistical physics of disordered systems and optimization problems in computer science dates back from twenty years at least [MPV87]. In combinatorial optimization one is given a cost function (the length of a tour in the traveling salesman problem (TSP), the number of violated constraints in constraint satisfaction problems, ...) of (Boolean) variables and attempts to minimize costs. Finding the true minimum may be complicated, and requires more and more computational effort as the number of variables increases [PS98]. Statistical physics is at first sight very different. The scope is to deduce the macroscopic, that is, global properties of a physical system, for instance, whether gas, a liquid or a solid, from the knowledge of the energetic interactions of its elementary components (molecules, atoms or ions). However, at very low temperature, these elementary components are essentially forced to occupy the spatial conformation minimizing the global energy of the system. Hence low-temperature-statistical-physics can be seen as the search for minimizing a cost function whose expression reflects the laws of Nature or, more specifically, the degree of accuracy retained in its description. This problem is generally not difficult to solve for non-disordered systems where the lowest energy conformation are crystals in which components are regularly spaced from each other. Yet the presence of disorder, e.g. impurities, makes the problem very difficult and finding the conformation with minimal energy is a true optimization problem.

At the beginning of the eighties, following the work of G. Parisi and others on systems called spin glasses [MPV87], important progress was made in the statistical physics of disordered systems. The properties of systems given some distribution of the disorder (for instance the location of impurities) such as the average minimal energy and its fluctuations became amenable to quantitative studies. The application to optimization problems was natural and led to beautiful studies on (among others) the average properties of the minimal tour length in the TSP and the minimal cost in Bipartite Matching, for some specific instance distributions [MPV87]. Unfortunately statistical physicists and computer scientists did not establish close ties on a large scale at that time, probably due to

differences of methodological nature [FA86]. While physicists were making statistical statements, true for a given distribution of inputs, computer scientists were rather interested in solving one (or several) arbitrary instances of a problem. The focus was thus on efficient ways to do so, that is, requiring a computational effort growing not too quickly with the number of data defining the instance. Knowing precisely the typical properties for a given, academic distribution of instances did not help much to solve practical cases.

At the beginning of the nineties practitioners in artificial intelligence realized that classes of random constraint satisfaction problems used as artificial benchmarks for search algorithms exhibited abrupt changes of behaviour when some control parameters were finely tuned [MSL92]. The most celebrated example was random k -Satisfiability, where one looks for a solution to a set of random logical constraints over a set of Boolean variables. It appeared that, for a large number of variables, there was a critical value of the number of constraints per variable below which there almost surely existed solutions, and above which solutions were absent. An important feature was that the efficiency of known search algorithms drastically decreased in the vicinity of this critical ratio. In addition to its intrinsic mathematical interest the random k -SAT problem was therefore worth to be studied for ‘practical’ reasons.

This critical phenomenon, strongly reminiscent of phase transitions in the physics of condensed matter, led to a revival of research at the interface between statistical physics and computer science. The purpose of the present review is to introduce the non physicist reader to the concepts required to understand the literature in that field and to present some major results. We shall discuss the refined picture of the satisfiable phase in particular as viewed in statistical mechanics and the impact on the algorithmic approach (Survey Propagation, an extension of Belief Propagation used in communication theory and statistical inference) as inspired by this view.

While the presentation will mostly focus on the k -Satisfiability problem (with random constraints) we will occasionally also discuss the computational problem of solving linear systems of Boolean equations, called k -XORSAT. A good reason to do so is that this problem exhibits tremendous ‘syntactic’ similarities with random k -Satisfiability, while being technically simpler to study. In addition k -Satisfiability and k -XORSAT have very different and interesting computational properties as will be discussed in this chapter. Last but not least k -XORSAT is closely related to error-correcting codes in communication theory.

The chapter is divided into four main parts. In Section 22.2 we present the basic statistical physics concepts related to phase transitions, and their nature. Those are illustrated on a simple example of a decision problem, the so-called perceptron problem. In Section 22.3 we review the scenario of the various phase transitions observable in random k -SAT. Section 22.4 and 22.5 present the techniques used to study various type of algorithms in optimization: Local search, backtracking procedures, and message passing algorithms. We close with some conclusive remarks in Sec. 22.6.

22.2. Phase Transitions: Basic Concepts and Illustration

22.2.1. A simple decision problem with a phase transition: the continuous perceptron

For pedagogical reasons we first discuss a simple example exhibiting several important features we shall define more formally in the next subsection. Consider M points $\underline{T}^1, \dots, \underline{T}^M$ of the N -dimensional space \mathbb{R}^N , their coordinates being denoted $\underline{T}^a = (T_1^a, \dots, T_N^a)$. The continuous perceptron problem consists in deciding the existence of a vector $\underline{\sigma} \in \mathbb{R}^N$ which has a positive scalar product with all vectors linking the origin of \mathbb{R}^N to the \underline{T} 's,

$$\underline{\sigma} \cdot \underline{T}^a \equiv \sum_{i=1}^N \sigma_i T_i^a > 0, \quad \forall a = 1, \dots, M, \quad (22.1)$$

or in other words determining whether the M points belong to the same half-space. The term continuous in the name of the problem emphasizes the domain \mathbb{R}^N of the variable $\underline{\sigma}$. This makes the problem polynomial from worst-case complexity point of view [HKP91].

Suppose now that the points are chosen independently, identically, uniformly on the unit hypersphere, and call

$P(N, M)$ = Probability that a set of M randomly chosen points
belong to the same half-space.

This quantity can be computed exactly [Cov65] (see also Chapter 5.7 of [HKP91]) and is plotted in Fig. 22.1 as a function of the ratio $\alpha = M/N$ for increasing sizes $N = 5, 20, 100$. Obviously P is a decreasing function of the number M of points for a given size N : increasing the number of constraints can only make more difficult the simultaneous satisfaction of all of them. More surprisingly, the figure suggests that, in the large size limit $N \rightarrow \infty$, the probability P reaches a limiting value 0 or 1 depending on whether the ratio α lies, respectively, above or below some 'critical' value $\alpha_s = 2$. This is confirmed by the analytical expression of P obtained in [Cov65],

$$P(N, M) = \frac{1}{2^{M-1}} \sum_{i=0}^{\min(N-1, M-1)} \binom{M-1}{i}, \quad (22.2)$$

from which one can easily show that, indeed,

$$\lim_{N \rightarrow \infty} P(N, M = N\alpha) = \begin{cases} 1 & \text{if } \alpha < \alpha_s \\ 0 & \text{if } \alpha > \alpha_s \end{cases}, \quad \text{with } \alpha_s = 2. \quad (22.3)$$

Actually the analytical expression of P allows to describe more accurately the drop in the probability as α increases. To this aim we make a zoom on the transition region $M \approx N\alpha_s$ and find from (22.2) that

$$\lim_{N \rightarrow \infty} P(N, M = N\alpha_s(1 + \lambda N^{-1/2})) = \int_{\lambda\sqrt{2}}^{\infty} \frac{dx}{\sqrt{2\pi}} e^{-x^2/2}. \quad (22.4)$$

As it should the limits $\lambda \rightarrow \pm\infty$ give back the coarse description of Eq. (22.3)

Figure 22.1. Probability $P(N, M)$ that M random points on the N -dimensional unit hypersphere are located in the same half-space. Symbols correspond to Cover’s exact result [Cov65], see Eq. (22.2), lines serve as guides to the eye.

22.2.2. Generic definitions

We now put this simple example in a broader perspective and introduce some generic concepts that it illustrates, along with the definitions of the problems studied in the following.

- Constraint Satisfaction Problem (CSP)

A CSP is a decision problem where an assignment (or configuration) of N variables $\underline{\sigma} = (\sigma_1, \dots, \sigma_N) \in \mathcal{X}^N$ is required to simultaneously satisfy M constraints. In the continuous perceptron the domain of $\underline{\sigma}$ is \mathbb{R}^N and the constraints impose the positivity of the scalar products (22.1). The instance of the CSP, also called formula in the following, is said satisfiable if there exists a solution (an assignment of $\underline{\sigma}$ fulfilling all the constraints). The k -SAT problem is a boolean CSP ($\mathcal{X} = \{\text{True}, \text{False}\}$) where each constraint (clause) is the disjunction (logical OR) of k literals (a variable or its negation). Similarly in k -XORSAT the literals are combined by an exclusive OR operation, or equivalently an addition modulo 2 of 0/1 boolean variables is required to take a given value. The worst-case complexities of these two problems are very different (k -XORSAT is in the P complexity class for any k while k -SAT is NP-complete for any $k \geq 3$), yet for the issues of this review we shall see that they present a lot of similarities. In the following we use the statistical mechanics convention and represent boolean variables by Ising spins, $\mathcal{X} = \{-1, +1\}$. A k -SAT clause will be defined by k indices $i_1, \dots, i_k \in [1, N]$ and k values $J_{i_1}, \dots, J_{i_k} = \pm 1$, such that the clause is unsatisfied by the assignment $\underline{\sigma}$ if and only if $\sigma_{i_j} = J_{i_j} \quad \forall j \in [1, k]$. A k -XORSAT clause is satisfied if the product of the spins is equal to a fixed value, $\sigma_{i_1} \dots \sigma_{i_k} = J$.

- random Constraint Satisfaction Problem (rCSP)

The set of instances of most CSP can be turned in a probability space by defining a distribution over the sets of instances, as was done in the per-

ceptron case by drawing the vertices \underline{T}^a uniformly on the hypersphere. The random k -SAT formulas considered in the following are obtained by choosing for each clause a independently a k -uplet of distinct indices i_1^a, \dots, i_k^a uniformly over the $\binom{N}{k}$ possible ones, and negating or not the corresponding literals ($J_i^a = \pm 1$) with equal probability one-half. The indices of random XORSAT formulas are chosen similarly, with the constant $J^a = \pm 1$ uniformly.

- thermodynamic limit and phase transitions

These two terms are the physics jargon for, respectively, the large size limit ($N \rightarrow \infty$) and for threshold phenomena as stated for instance in (22.3). In the thermodynamic limit the typical behavior of physical systems is controlled by a small number of parameters, for instance the temperature and pressure of a gas. At a phase transition these systems are drastically altered by a tiny change of a control parameter, think for instance at what happens to water when its temperature crosses 100°C . This critical value of the temperature separates two qualitatively distinct phases, liquid and gaseous. For random CSPs the role of control parameter is usually played by the ratio of constraints per variable, $\alpha = M/N$, kept constant in the thermodynamic limit. Eq. (22.3) describes a satisfiability transition for the continuous perceptron, the critical value $\alpha_s = 2$ separating a satisfiable phase at low α where instances typically have solutions to a phase where they typically do not. Typically is used here as a synonym for with high probability, i.e. with a probability which goes to one in the thermodynamic limit.

- Finite Size Scaling (FSS)

The refined description of the neighborhood of the critical value of α provided by (22.4) is known as a finite size scaling relation. More generally the finite size scaling hypothesis for a threshold phenomenon takes the form

$$\lim_{N \rightarrow \infty} P(N, M = N\alpha_s(1 + \lambda N^{-1/\nu})) = \mathcal{F}(\lambda), \quad (22.5)$$

where ν is called the FSS exponent (2 for the continuous perceptron) and the scaling function $\mathcal{F}(\lambda)$ has limits 1 and 0 at respectively $-\infty$ and $+\infty$. This means that, for a large but finite size N , the transition window for the values of M/N where the probability drops from $1 - \epsilon$ down to ϵ is, for arbitrary small ϵ , of width $N^{-1/\nu}$. Results of this flavour are familiar in the study of random graphs [JLR00]; for instance the appearance of a giant component containing a finite fraction of the vertices of an Erdős-Rényi random graph happens on a window of width $N^{-1/3}$ on the average connectivity. FSS relations are important, not only from the theoretical point of view, but also for practical applications. Indeed numerical experiments are always performed on finite-size instances while theoretical predictions on phase transitions are usually true in the $N \rightarrow \infty$ limit. Finite-size scaling relations help to bridge the gap between the two. We shall review some FSS results in Sec. 22.3.5.

Let us emphasize that random k -SAT, and other random CSP, are expected to share some features of the continuous perceptron model, for instance the existence

of a satisfiability threshold, but of course not its extreme analytical simplicity. In fact, despite an intensive research activity, the mere existence of a satisfiability threshold for random SAT formulas remains a (widely accepted) conjecture. A significant achievement towards the resolution of the conjecture was the proof by Friedgut of the existence of a non-uniform sharp threshold [Fri99]. There exists also upper [Dub01] and lower [Fra01] bounds on the possible location of this putative threshold, which become almost tight for large values of k [AP04]. We refer the reader to Part 1, Chapter 10 of this volume for more details on these issues. This difficulty to obtain tight results with the currently available rigorous techniques is a motivation for the use of heuristic statistical mechanics methods, that provide intuitions on why the standard mathematical ones run into trouble and how to amend them. In the recent years important results first conjectured by physicists were indeed rigorously proven. Before describing in some generality the statistical mechanics approach, it is instructive to study a simple variation of the perceptron model for which the basic probabilistic techniques become inefficient.

22.2.3. The perceptron problem continued: binary variables

The binary perceptron problem consists in looking for solutions of (22.1) on the hypercube i.e. the domain of the variable $\underline{\sigma}$ is $\mathcal{X}^N = \{-1, +1\}^N$ instead of \mathbb{R}^N . This decision problem is NP-complete. Unfortunately Cover's calculation [Cov65] cannot be extended to this case, though it is natural to expect a similar satisfiability threshold phenomenon at an a priori distinct value α_s . Let us first try to study this point with basic probabilistic tools, namely the first and second moment method [AS00]. The former is an application of the Markov inequality,

$$\text{Prob}[Z > 0] \leq \mathbb{E}[Z] , \quad (22.6)$$

valid for positive integer valued random variables Z . We shall use it taking for Z the number of solutions of (22.1),

$$Z = \sum_{\underline{\sigma} \in \mathcal{X}^N} \prod_{a=1}^M \theta(\underline{\sigma} \cdot \underline{T}^a) , \quad (22.7)$$

where $\theta(x) = 1$ if $x > 0$, 0 if $x \leq 0$. The expectation of the number of solutions is easily computed,

$$\mathbb{E}[Z] = 2^N \times 2^{-M} = e^{N G_1} \quad \text{with} \quad G_1 = (1 - \alpha) \ln 2 , \quad (22.8)$$

and vanishes when $N \rightarrow \infty$ if $\alpha > 1$. Hence, from Markov's inequality (22.6), with high probability constraints (22.1) have no solution on the hypercube when the ratio α exceeds unity: if the threshold α_s exists, it must satisfy the bound $\alpha_s \leq 1$. One can look for a lower bound to α_s using the second moment method, relying on the inequality [AS00]

$$\frac{\mathbb{E}[Z]^2}{\mathbb{E}[Z^2]} \leq \text{Prob}[Z > 0] . \quad (22.9)$$

The expectation of the squared number of solutions reads

$$\mathbb{E}[Z^2] = \sum_{\underline{\sigma}, \underline{\sigma}'} (\mathbb{E}[\theta(\underline{\sigma} \cdot \underline{T}) \theta(\underline{\sigma}' \cdot \underline{T})])^M \tag{22.10}$$

since the vertices \underline{T}^a are chosen independently of each other. The expectation on the right hand side of the above expression is simply the probability that the vector pointing to a randomly chosen vertex, \underline{T} , has positive scalar product with both vectors $\underline{\sigma}, \underline{\sigma}'$. Elementary geometrical considerations reveal that

$$\mathbb{E}[\theta(\underline{\sigma} \cdot \underline{T}) \theta(\underline{\sigma}' \cdot \underline{T})] = \frac{1}{2\pi} (\pi - \varphi(\underline{\sigma}, \underline{\sigma}')) \tag{22.11}$$

where φ is the relative angle between the two vectors. This angle can be alternatively parametrized by the overlap between $\underline{\sigma}$ and $\underline{\sigma}'$, i.e. the normalized scalar product,

$$q = \frac{1}{N} \sum_{i=1}^N \sigma_i \sigma'_i = 1 - 2 \frac{1}{N} \sum_{i=1}^N \mathbb{I}(\sigma_i \neq \sigma'_i) . \tag{22.12}$$

The last expression, in which $\mathbb{I}(E)$ denotes the indicator function of the event E , reveals the correspondence between the concept of overlap and the more traditional Hamming distance. The sum over vectors in (22.10) can then be replaced by a sum over overlap values with appropriate combinatorial coefficients counting the number of pairs of vectors at a given overlap. The outcome is

$$\mathbb{E}[Z^2] = 2^N \sum_{q=-1, -1+\frac{2}{N}, -1+\frac{4}{N}, \dots, 1} \binom{N}{N \left(\frac{1+q}{2}\right)} \left(\frac{1}{2} - \frac{1}{2\pi} \text{Arcos } q\right)^M . \tag{22.13}$$

The main point in the above equation is that the sum (22.10) with exponentially many terms is organized as a sum over polynomially many equivalence classes (of exponential size each). It is this reorganization of the sum that makes it possible to essentially replace summation with maximization when N gets large. Using the Laplace method,

$$\lim_{N \rightarrow \infty} \frac{1}{N} \ln \mathbb{E}[Z^2] = \max_{-1 < q < 1} G_2(q) , \tag{22.14}$$

where

$$G_2(q) = \ln 2 - \left(\frac{1+q}{2}\right) \ln \left(\frac{1+q}{2}\right) - \left(\frac{1-q}{2}\right) \ln \left(\frac{1-q}{2}\right) + \alpha \ln \left(\frac{1}{2} - \frac{1}{2\pi} \text{Arcos } q\right) . \tag{22.15}$$

Unfortunately no useful lower bound to α_s can be obtained from such a direct application of the second moment method. Indeed, maximization of G_2 (22.15) over q shows that $\mathbb{E}[Z^2] \gg (\mathbb{E}[Z])^2$ when N diverges, whenever $\alpha > 0$, and in consequence the left hand side of (22.9) vanishes. What causes this failure, and how it can be cured with the use of the 'replica method' will be discussed in Section 22.2.5.

Note that the perceptron problem is not as far as it could seem from the main subject of this review. There exists indeed a natural mapping between the binary perceptron problem and k -SAT. Assume the vertices \underline{T} of the perceptron problem, instead of being drawn on the hypersphere, have coordinates that can take three values: $T_i = -1, 0, 1$. Consider now a k -SAT formula F . To each clause a of F we associate the vertex \underline{T}^a with coordinates $T_i^a = -J_i^a$ if variable i appears in clause a , 0 otherwise. Of course $\sum_i |T_i^a| = k$: exactly k coordinates have non zero values for each vertex. Then replace condition (22.1) with

$$\sum_{i=1}^N \sigma_i T_i^a > -(k-1), \quad \forall a = 1, \dots, M. \quad (22.16)$$

The scalar product is not required to be positive any longer, but to be larger than $-(k-1)$. It is an easy check that the perceptron problem admits a solution on the hypercube ($\sigma_i = \pm 1$) if and only if F is satisfiable. While in the binary perceptron model all coordinates are non-vanishing, only a finite number of them take non zero values in k -SAT. For this reason k -SAT is called a diluted model in statistical physics.

22.2.4. From random CSP to statistical mechanics of disordered systems

The binary perceptron example demonstrated that, while the number of solutions Z of a satisfiable random CSP usually scales exponentially with the size of the problem, large fluctuations can prevent the direct use of standard moment methods¹. The concepts and computation techniques used to tackle this difficulty were in fact developed in an apparently different field, the statistical mechanics of disordered systems [MPV87].

Let us review some basic concepts of statistical mechanics (for introductory books see for example [Ma85, Hua90]). A physical system can be modeled by a space of configuration $\underline{\sigma} \in \mathcal{X}^N$, on which an energy function $E(\underline{\sigma})$ is defined. For instance usual magnets are described by Ising spins $\sigma_i = \pm 1$, the energy being minimized when adjacent spins take the same value. The equilibrium properties of a physical system at temperature T are given by the Gibbs-Boltzmann probability measure on \mathcal{X}^N ,

$$\mu(\underline{\sigma}) = \frac{1}{Z} \exp[-\beta E(\underline{\sigma})], \quad (22.17)$$

where the inverse temperature β equals $1/T$ and Z is a normalization called partition function. The energy function E has a natural scaling, linear in the number N of variables (such a quantity is said to be extensive). In consequence in the thermodynamic limit the Gibbs-Boltzmann measure concentrates on configurations with a given energy density ($e = E/N$), which depends on the conjugated parameter β . The number of such configurations is usually exponentially large, $\approx \exp[Ns]$, with s called the entropy density. The partition function is thus dominated by the contribution of these configurations, hence $\lim(\ln Z/N) = s - \beta e$.

¹The second moment method fails for the random k -SAT problem; yet a refined version of it was used in [AP04], which leads to asymptotically (at large k) tight bounds on the location of the satisfiability threshold.

In the above presentation we supposed the energy to be a simple, known function of the configurations. In fact some magnetic compounds, called spin-glasses, are intrinsically disordered on a microscopic scale. This means that there is no hope in describing exactly their microscopic details, but that one should rather assume their energy to be itself a random function with a known distribution. Hopefully in the thermodynamic limit the fluctuations of the thermodynamic observables as the energy and entropy density vanish, hence the properties of a typical sample will be closely described by the average (over the distribution of the energy function) of the entropy and energy density.

The random CSPs fit naturally in this line of research. The energy function $E(\underline{\sigma})$ of a CSP is defined as the number of constraints violated by the assignment $\underline{\sigma}$, in other words this is the cost function to be minimized in the associated optimization problem (MAXSAT for instance). Moreover the distribution of random instances of CSP is the counterpart of the distribution over the microscopic description of a disordered solid. The study of the optimal configurations of a CSP, and in particular the characterization of a satisfiability phase transition, is achieved by taking the $\beta \rightarrow \infty$ limit. Indeed, when this parameter increases (or equivalently the temperature goes to 0), the law (22.17) favors the lowest energy configurations. In particular if the formula is satisfiable μ becomes the uniform measure over the solutions. Two important features of the formula can be deduced from the behavior of Z at large β : the ground-state energy $E_g = \min_{\underline{\sigma}} E(\underline{\sigma})$, which indicates how good are the optimal configurations, and the ground state entropy $S_g = \ln(|\{\underline{\sigma} : E(\underline{\sigma}) = E_g\}|)$, which counts the number of these optimal configurations. The satisfiability of a formula is equivalent to its ground-state energy being equal to 0. In the large N limit these two thermodynamic quantities are supposed to concentrate around their mean values (this is proven for E in [BFU93]), we thus introduce the associated typical densities,

$$e_g(\alpha) = \lim_{N \rightarrow \infty} \frac{1}{N} \mathbb{E}[E_g], \quad s_g(\alpha) = \lim_{N \rightarrow \infty} \frac{1}{N} \mathbb{E}[S_g]. \quad (22.18)$$

Notice that, in the satisfiable phase, s_g is simply the expected log of the number of solutions.

Some criteria are needed to relate these thermodynamic quantities to the (presumed) satisfiability threshold α_s . A first approach, used for instance in [MZ97], consists in locating it as the point where the ground-state energy density e_g becomes positive. The assumption underlying this reasoning is the absence of an intermediate, typically UNSAT regime, with a sub-extensive positive E_g . In the discussion of the binary perceptron we used another criterion, namely we recognized α_s as the ratio at which the ground-state entropy density vanishes. This argument will be true if the typical number of solutions vanishes continuously at α_s . It is easy to realize that this is not the case for random k -SAT: at any finite value of α a finite fraction $\exp[-\alpha k]$ of the variables do not appear in any clause, which leads to a trivial lower bound $(\ln 2) \exp[-\alpha k]$ on s_g (in the satisfiable regime). This quantity is thus finite at the transition, a large number of solutions disappear suddenly at α_s . Even if it is wrong, the criterion $s_g(\alpha) = 0$ for the determination of the satisfiability transition is instructive for two reasons. First, it becomes asymptotically correct at large k (free variables are very rare

in this limit), this is why it works for the binary perceptron of Section 22.2.3 (which is, as we have seen, close to k -SAT with k of order N). Second, it will reappear below in a refined version: we shall indeed decompose the entropy in two qualitatively distinct contributions, one of the two being indeed vanishing at the satisfiability transition.

22.2.5. Large deviations and the replica method

We have seen in Section 22.2.3 that the number of solutions of the binary perceptron exhibits large fluctuations around its expectation *i.e.* $\mathbb{E}[Z^2] \gg (\mathbb{E}[Z])^2$ when N diverges, whenever $\alpha > 0$. A possible scenario which explains this absence of concentration of the number of solutions is the following. As shown by the moment calculation the natural scaling of Z is exponentially large in N (as is the total configuration space \mathcal{X}^N). We shall thus denote $s = (\ln Z)/N$ the random variable counting the log of the number of solutions. Suppose s follows a large deviation principle [DZ98] that we state in a very rough way as $\text{Prob}[s] \approx \exp[NL(s)]$, with $L(s)$ a negative rate function, assumed for simplicity to be concave. Then the moments of Z are given, at the leading exponential order, by

$$\lim_{N \rightarrow \infty} \frac{1}{N} \ln \mathbb{E}[Z^n] = \max_s [L(s) + ns], \quad (22.19)$$

and are controlled by the values of s such that $L'(s) = -n$. The moments of larger and larger order n are thus dominated by the contribution of rarer and rarer instances with larger and larger numbers of solutions. On the contrary the typical value of the number of solutions is given by the maximum of L , reached in a value we denote $s_g(\alpha)$: with high probability when $N \rightarrow \infty$, Z is comprised between $e^{N(s_g(\alpha) - \epsilon)}$ and $e^{N(s_g(\alpha) + \epsilon)}$, for any $\epsilon > 0$. From this reasoning it appears that the relevant quantity to be computed is

$$s_g(\alpha) = \lim_{N \rightarrow \infty} \frac{1}{N} \mathbb{E}[\ln Z] = \lim_{N \rightarrow \infty} \lim_{n \rightarrow 0} \frac{1}{nN} \ln \mathbb{E}[Z^n]. \quad (22.20)$$

This idea of computing moments of vanishing order is known in statistical mechanics as the replica² method [MPV87]. Its non-rigorous implementation consists in determining the moments of integer order n , which are then continued towards $n = 0$. The outcome of such a computation for the binary perceptron problem reads [KM89]

$$s_g(\alpha) = \max_{q, \hat{q}} \left\{ -\frac{1}{2}q(1 - \hat{q}) + \int_{-\infty}^{\infty} Dz \ln(2 \cosh(z\sqrt{\hat{q}})) + \alpha \int_{-\infty}^{\infty} Dz \ln \left[\int_{z\sqrt{q/(1-q)}}^{\infty} Dy \right] \right\}, \quad (22.21)$$

where $Dz \equiv dz e^{-z^2/2}/\sqrt{2\pi}$. The entropy $s_g(\alpha)$ is a decreasing function of α , which vanishes in $\alpha_s \simeq 0.833$. Numerical experiments support this value for the critical ratio of the satisfiable/unsatisfiable phase transition.

²The vocable replicas comes from the presence of n copies of the vector $\underline{\sigma}$ in the calculation of Z^n (see the $n = 2$ case in formula (22.10)).

The calculation of the second moment is naturally related to the determination of the value of the overlap q between pairs of solutions (or equivalently their Hamming distance, recall Eq. (22.12)). This conclusion extends to the calculation of the n^{th} moment for any integer n , and to the $n \rightarrow 0$ limit. The value of q maximizing the r.h.s. of (22.21), $q^*(\alpha)$, represents the average overlap between two solutions of the same set of constraints (22.1). Actually the distribution of overlaps is highly concentrated in the large N limit around $q^*(\alpha)$, in other words the (reduced) Hamming distance between two solutions is, with high probability, equal to $d^*(\alpha) = (1 - q^*(\alpha))/2$. This distance $d^*(\alpha)$ ranges from $\frac{1}{2}$ for $\alpha = 0$ to $\simeq \frac{1}{4}$ at $\alpha = \alpha_s$. Slightly below the critical ratio solutions are still far away from each other on the hypercube³.

22.3. Phase transitions in random CSPs

22.3.1. The clustering phenomenon

We have seen that the statistical physics approach to the perceptron problem naturally provided us with information about the geometry of the space of its solutions. Maybe one of the most important contribution of physicists to the field of random CSP was to suggest the presence of further phase transitions in the satisfiable regime $\alpha < \alpha_s$, affecting qualitatively the geometry (structure) of the set of solutions [BMW00, MZ02, KMRT⁺07].

This subset of the configuration space is indeed thought to break down into “clusters” in a part of the satisfiable phase, $\alpha \in [\alpha_d, \alpha_s]$, α_d being the threshold value for the clustering transition. Clusters are meant as a partition of the set of solutions having certain properties listed below. Each cluster contains an exponential number of solutions, $\exp[Ns_{\text{int}}]$, and the clusters are themselves exponentially numerous, $\exp[N\Sigma]$. The total entropy density thus decomposes into the sum of s_{int} , the internal entropy of the clusters and Σ , encoding the number of these clusters, usually termed complexity in this context. Furthermore, solutions inside a given cluster should be well-connected, while two solutions of distinct clusters are well-separated. A possible definition for these notions is the following. Suppose $\underline{\sigma}$ and $\underline{\tau}$ are two solutions of a given cluster. Then one can construct a path ($\underline{\sigma} = \underline{\sigma}_0, \underline{\sigma}_1, \dots, \underline{\sigma}_{n-1}, \underline{\sigma}_n = \underline{\tau}$) where any two successive $\underline{\sigma}_i$ are separated by a sub-extensive Hamming distance. On the contrary such a path does not exist if $\underline{\sigma}$ and $\underline{\tau}$ belong to two distinct clusters. Clustered configuration spaces as described above have been often encountered in various contexts, e.g. neural networks [MO94] and mean-field spin glasses [KT87]. A vast body of involved, yet non-rigorous, analytical techniques [MPV87] have been developed in the field of statistical mechanics of disordered systems to tackle such situations, some of them having been justified rigorously [Tal03, PT04, FL03]. In this literature clusters appear under the name of “pure states”, or “lumps” (see for instance the chapter 6 of [Tal03] for a rigorous definition and proof of existence in a related model). As we shall explain in a few lines, this clustering phenomenon has been demonstrated rigorously in the case of random XORSAT

³This situation is very different from the continuous perceptron case, where the typical overlap $q^*(\alpha)$ reaches one when α tends to 2: a single solution is left right at the critical ratio.

instances [MRTZ03, CDMM03]. For random SAT instances, where in fact the detailed picture of the satisfiable phase is thought to be richer [KMRT⁺07], there are some rigorous results [MMZ05, DMMZ08, ART06] on the existence of clusters for $k \geq 8$.

22.3.2. Phase transitions in random XORSAT

Consider an instance F of the XORSAT problem [RTWZ01], i.e. a list of M linear equations each involving k out of N boolean variables, where the additions are computed modulo 2. The study performed in [MRTZ03, CDMM03] provides a detailed picture of the clustering and satisfiability transition sketched above. A crucial point is the construction of a core subformula according to the following algorithm. Let us denote $F_0 = F$ the initial set of equations, and V_0 the set of variables which appear in at least one equation of F_0 . A sequence F_T, V_T is constructed recursively: if there are no variables in V_T which appear in exactly one equation of F_T the algorithm stops. Otherwise one of these “leaf variables” σ_i is chosen arbitrarily, F_{T+1} is constructed from F_T by removing the unique equation in which σ_i appeared, and V_{T+1} is defined as the set of variables which appear at least once in F_{T+1} . Let us call T_* the number of steps performed before the algorithm stops, and $F' = F_{T_*}$, $V' = V_{T_*}$ the remaining clauses and variables. Note first that despite the arbitrariness in the choice of the removed leaves, the output subformula F' is unambiguously determined by F . Indeed, F' can be defined as the maximal (in the inclusion sense) subformula in which all present variables have a minimal occurrence number of 2, and is thus unique. In graph theoretic terminology F' is the 2-core of F , the q -core of hypergraphs being a generalization of the more familiar notion on graphs, thoroughly studied in random graph ensembles in [PSW96]. Extending this study, relying on the approximability of this leaf removal process by differential equations [Kur70], it was shown in [MRTZ03, CDMM03] that there is a threshold phenomenon at $\alpha_d(k)$. For $\alpha < \alpha_d$ the 2-core F' is, with high probability, empty, whereas it contains a finite fraction of the variables and equations for $\alpha > \alpha_d$. α_d is easily determined numerically: it is the smallest value of α such that the equation $x = 1 - \exp[-\alpha k x^{k-1}]$ has a non-trivial solution in $(0, 1]$.

It turns out that F is satisfiable if and only if F' is, and that the number of solutions of these two formulas are related in an enlightening way. It is clear that if the 2-core has no solution, there is no way to find one for the full formula. Suppose on the contrary that an assignment of the variables in V' that satisfy the equations of F' has been found, and let us show how to construct a solution of F (and count in how many possible ways we can do this). Set $\mathcal{N}_0 = 1$, and reintroduce step by step the removed equations, starting from the last: in the n 'th step of this new procedure we reintroduce the clause which was removed at step $T_* - n$ of the leaf removal. This reintroduced clause has $d_n = |V_{T_* - n - 1}| - |V_{T_* - n}| \geq 1$ leaves; their configuration can be chosen in $2^{d_n - 1}$ ways to satisfy the reintroduced clause, irrespectively of the previous choices, and we bookkeep this number of possible extensions by setting $\mathcal{N}_{n+1} = \mathcal{N}_n 2^{d_n - 1}$. Finally the total number of solutions of F compatible with the choice of the solution of F' is obtained by adding the freedom of the variables which appeared in no equations of F , $\mathcal{N}_{\text{int}} = \mathcal{N}_{T_*} 2^{N - |V_0|}$.

Figure 22.2. Complexity and total entropy for 3-XORSAT, in units of $\ln 2$. The inset presents an enlargement of the regime $\alpha \in [\alpha_d, \alpha_s]$.

Let us underline that \mathcal{N}_{int} is independent of the initial satisfying assignment of the variables in V' , as appears clearly from the description of the reconstruction algorithm; this property can be traced back to the linear algebra structure of the problem. This suggests naturally the decomposition of the total number of solutions of F as the product of the number of satisfying assignments of V' , call it $\mathcal{N}_{\text{core}}$, by the number of compatible full solutions \mathcal{N}_{int} . In terms of the associated entropy densities this decomposition is additive

$$s = \Sigma + s_{\text{int}}, \quad \Sigma \equiv \frac{1}{N} \ln \mathcal{N}_{\text{core}}, \quad s_{\text{int}} \equiv \frac{1}{N} \ln \mathcal{N}_{\text{int}}, \quad (22.22)$$

where the quantity Σ is the entropy density associated to the core of the formula. It is in fact much easier technically to compute the statistical (with respect to the choice of the random formula F) properties of Σ and s_{int} once this decomposition has been done (the fluctuations in the number of solutions is much smaller once the non-core part of the formula has been removed, and the second moment method can be applied). The outcome of the computations [MRTZ03, CDMM03] is the determination of the threshold value α_s for the appearance of a solution of the 2-core F' (and thus of the complete formula), along with explicit formulas for the typical values of Σ and s . These two quantities are plotted on Fig. 22.2. The satisfiability threshold corresponds to the cancellation of Σ : the number of solutions of the core vanishes continuously at α_s , while the total entropy remains finite because of the freedom of choice for the variables in the non-core part of the formula.

On top of the simplification in the analytical determination of the satisfiability threshold, this core decomposition of a formula unveils the change in the structure of the set of solutions that occurs at α_d . Indeed, let us call clusters the sets of solutions of F reconstructed from a common solution of F' . Then one can show that this partition of the solution set of F exhibits the properties exposed in Sec. 22.3.1, namely that solutions are well-connected inside a cluster and separated from one cluster to another. The number of clusters is precisely equal to the number of solutions of the core subformula, it thus undergoes a drastic change at

Table 22.1. Critical connectivities for the dynamical, condensation and satisfiability transitions for k -SAT random formulas.

	α_d [KMRT ⁺ 07]	α_c [KMRT ⁺ 07]	α_s [MMZ06]
$k = 3$	3.86	3.86	4.267
$k = 4$	9.38	9.547	9.93
$k = 5$	19.16	20.80	21.12
$k = 6$	36.53	43.08	43.4

α_d . For smaller ratio of constraints the core is typically empty, there is one single cluster containing all solutions; when the threshold α_d is reached there appears an exponential numbers of clusters, the rate of growth of this exponential being given by the complexity Σ . Before considering the extension of this picture to random SAT problems, let us mention that further studies of the geometry of the space of solutions of random XORSAT instances can be found in [MS06a, MM06].

22.3.3. Phase transitions in random SAT

The possibility of a clustering transition in random SAT problems was first studied in [BMW00] by means of variational approximations. Later developments allowed the computation of the complexity and, from the condition of its vanishing, the estimation of the satisfiability threshold α_s . This was first done for $k = 3$ in [MZ02] and generalized for $k \geq 4$ in [MMZ06], some of the values of α_s thus computed are reported in Tab. 22.1. A systematic expansion of α_s at large k was also performed in [MMZ06].

SAT formulas do not share the linear algebra structure of XORSAT, which makes the analysis of the clustering transition much more difficult, and leads to a richer structure of the satisfiable phase $\alpha \leq \alpha_s$. The simple arguments are not valid anymore, one cannot extract a core subformula from which the partition of the solutions into clusters follows directly. It is thus necessary to define them as a partition of the solutions such that each cluster is well-connected and well-separated from the other ones. A second complication arises: there is no reason for the clusters to contain all the same number of solutions, as was ensured by the linear structure of XORSAT. On the contrary, as was observed in [BMW00] and in [MPR05] for the similar random COL problem, one faces a variety of clusters with various internal entropies s_{int} . The complexity Σ becomes a function of s_{int} , in other words the number of clusters of internal entropy density s_{int} is typically exponential, growing at the leading order like $\exp[N\Sigma(s_{\text{int}})]$. Drawing the consequences of these observations, a refined picture of the satisfiable phase, and in particular the existence of a new (so-called condensation) threshold $\alpha_c \in [\alpha_d, \alpha_s]$, was advocated in [KMRT⁺07]. Let us briefly sketch some of these new features and their relationship with the previous results of [MZ02, MMZ06]. Assuming the existence of a positive, concave, complexity function $\Sigma(s_{\text{int}})$, continuously vanishing outside an interval of internal entropy densities $[s_-, s_+]$, the total entropy density is given by

$$s = \lim_{N \rightarrow \infty} \frac{1}{N} \ln \int_{s_-}^{s_+} ds_{\text{int}} e^{N[\Sigma(s_{\text{int}}) + s_{\text{int}}]} . \quad (22.23)$$

In the thermodynamic limit the integral can be evaluated with the Laplace method. Two qualitatively distinct situations can arise, whether the integral is dominated by a critical point in the interior of the interval $[s_-, s_+]$, or by the neighborhood of the upper limit s_+ . In the former case an overwhelming majority of the solutions are contained in an exponential number of clusters, while in the latter the dominant contributions comes from a sub-exponential number of clusters of internal entropy s_+ , as $\Sigma(s_+) = 0$. The threshold α_c separates the first regime $[\alpha_d, \alpha_c]$ where the relevant clusters are exponentially numerous, from the second, condensated situation for $\alpha \in [\alpha_c, \alpha_s]$ with a sub-exponential number of dominant clusters⁴.

The computations of [MZ02, MMZ06] did not take into account the distribution of the various internal entropies of the clusters, which explains the discrepancy in the estimation of the clustering threshold α_d between [MZ02, MMZ06] and [KMRT⁺07]. Let us however emphasize that this refinement of the picture does not contradict the estimation of the satisfiability threshold of [MZ02, MMZ06]: the complexity computed in these works is Σ_{\max} , the maximal value of $\Sigma(s_{\text{int}})$ reached at a local maximum with $\Sigma'(s) = 0$, which indeed vanishes when the whole complexity function disappears.

It is fair to say that the details of the picture proposed by statistical mechanics studies have rapidly evolved in the last years, and might still be improved. They rely indeed on self-consistent assumptions which are rather tedious to check [MPRT04]. Some elements of the clustering scenario have however been established rigorously in [MMZ05] (see also [DMMZ08, ART06] for more results). In particular, for some values of (large enough) k and α in the satisfiable regime, there exist forbidden intermediate Hamming distances between pairs of configurations, which are either close (in the same cluster) or far apart (in two distinct clusters).

Note finally that the consequences of such distributions of clusters internal entropies were investigated on a toy model in [MZ08], and that yet another threshold $\alpha_f > \alpha_d$ for the appearance of frozen variables constrained to take the same values in all solutions of a given cluster was investigated in [Sem08].

22.3.4. A glimpse at the computations

The statistical mechanics of disordered systems [MPV87] was first developed on so-called fully-connected models, where each variable appears in a number of constraints which diverges in the thermodynamic limit. This is for instance the case of the perceptron problem discussed in Sec. 22.2. On the contrary, in a random k -SAT instance a variable is typically involved in a finite number of clauses, one speaks in this case of a diluted model. This finite connectivity is a source of major technical complications. In particular the replica method, alluded to in Sec. 22.2.3 and applied to random k -SAT in [MZ97, BMW00], turns out to be rather cumbersome for diluted models in the presence of clustering [Mon98]. The cavity formalism [MP01, MP03, MZ02], formally equivalent to the replica one, is more adapted to the diluted models. In the following paragraphs we shall

⁴This picture is expected to hold for $k \geq 4$; for $k = 3$, the dominant clusters are expected to be of sub-exponential number in the whole clustered phase, hence $\alpha_c = \alpha_d$ in this case.

try to give a few hints at the strategy underlying the cavity computations, that might hopefully ease the reading of the original literature.

The description of the random formula ensemble has two complementary aspects: a global (thermodynamic) one, which amounts to the computation of the typical energy and number of optimal configurations. A more ambitious description will also provide geometrical information on the organization of this set of optimal configurations inside the N -dimensional hypercube. As discussed above these two aspects are in fact interleaved, the clustering affecting both the thermodynamics (by the decomposition of the entropy into the complexity and the internal entropy) and the geometry of the configuration space. Let us for simplicity concentrate on the $\alpha < \alpha_s$ regime and consider a satisfiable formula F . Both thermodynamic and geometric aspects can be studied in terms of the uniform probability law over the solutions of F :

$$\mu(\underline{\sigma}) = \frac{1}{Z} \prod_{a=1}^M w_a(\underline{\sigma}_a), \quad (22.24)$$

where Z is the number of solutions of F , the product runs over its clauses, and w_a is the indicator function of the event “clause a is satisfied by the assignment $\underline{\sigma}$ ” (in fact this depends only on the configuration of the k variables involved in the clause a , that we denote $\underline{\sigma}_a$). For instance the (information theoretic) entropy of μ is equal to $\ln Z$, the log of the number of solutions, and geometric properties can be studied by computing averages with respect to μ of well-chosen functions of $\underline{\sigma}$.

A convenient representation of such a law are factor graphs [KFL01]. These are bipartite graphs with two types of vertices (see Fig. 22.3 for an illustration): one variable node (filled circle) is associated to each of the N Boolean variables, while the clauses are represented by M constraint nodes (empty squares). By convention we use the indices a, b, \dots for the constraint nodes, i, j, \dots for the variables. An edge is drawn between variable node i and constraint node a if and only if a depends on i . To indicate which value of σ_i satisfies the clause a one can use two type of linestyles, solid and dashed on the figure. A notation repeatedly used in the following is ∂a (resp. ∂i) for the neighborhood of a constraint (resp. variable) node, i.e. the set of adjacent variable (resp. constraint) nodes. In this context \setminus denotes the subtraction from a set. We shall more precisely denote $\partial_+ i(a)$ (resp. $\partial_- i(a)$) the set of clauses in $\partial i \setminus a$ agreeing (resp. disagreeing) with a on the satisfying value of σ_i , and $\partial_\sigma i$ the set of clauses in ∂i which are satisfied by $\sigma_i = \sigma$. This graphical representation naturally suggests a notion of distance between variable nodes i and j , defined as the minimal number of constraint nodes crossed on a path of the factor graph linking nodes i and j .

Suppose now that F is drawn from the random ensemble. The corresponding random factor graph enjoys several interesting properties [JLR00]. The degree $|\partial i|$ of a randomly chosen variable i is, in the thermodynamic limit, a Poisson random variable of average αk . If instead of a node one chooses randomly an edge $a-i$, the outdegree $|\partial i \setminus a|$ of i has again a Poisson distribution with the same parameter. Moreover the sign of the literals being chosen uniformly, independently of the topology of the factor graph, the degrees $|\partial_+ i|$, $|\partial_- i|$, $|\partial_+ i(a)|$ and $|\partial_- i(a)|$ are Poisson random variables of parameter $\alpha k/2$. Another important feature of these

Figure 22.3. The factor graph representation of a small 3-SAT formula: $(x_1 \vee \overline{x_2} \vee x_3) \wedge (\overline{x_3} \vee x_4 \vee \overline{x_5}) \wedge (x_4 \vee x_6 \vee x_7)$.

random factor graphs is their local tree-like character: if the portion of the formula at graph distance smaller than L of a randomly chosen variable is exposed, the probability that this subgraph is a tree goes to 1 if L is kept fixed while the size N goes to infinity.

Let us for a second forget about the rest of the graph and consider a finite formula whose factor graph is a tree, as is the case for the example of Fig. 22.3. The probability law μ of Eq. (22.24) becomes in this case a rather simple object. Tree structures are indeed naturally amenable to a recursive (dynamic programming) treatment, operating first on sub-trees which are then glued together. More precisely, for each edge between a variable node i and a constraint node a one defines the amputated tree $F_{a \rightarrow i}$ (resp. $F_{i \rightarrow a}$) by removing all clauses in ∂i apart from a (resp. removing only a). These subtrees are associated to probability laws $\mu_{a \rightarrow i}$ (resp. $\mu_{i \rightarrow a}$), defined as in Eq. (22.24) but with a product running only on the clauses present in $F_{a \rightarrow i}$ (resp. $F_{i \rightarrow a}$). The marginal law of the root variable i in these amputated probability measures can be parametrized by a single real, as σ_i can take only two values (that, in the Ising spin convention, are ± 1). We thus define these fields, or messages, $h_{i \rightarrow a}$ and $u_{a \rightarrow i}$, by

$$\mu_{i \rightarrow a}(\sigma_i) = \frac{1 - J_i^a \sigma_i \tanh h_{i \rightarrow a}}{2}, \quad \mu_{a \rightarrow i}(\sigma_i) = \frac{1 - J_i^a \sigma_i \tanh u_{a \rightarrow i}}{2}, \quad (22.25)$$

where we recall that $\sigma_i = J_i^a$ is the value of the literal i unsatisfying clause a . A standard reasoning (see for instance [BMZ05]) allows to derive recursive equations (illustrated in Fig. 22.4) on these messages,

$$h_{i \rightarrow a} = \sum_{b \in \partial_+ i(a)} u_{b \rightarrow i} - \sum_{b \in \partial_- i(a)} u_{b \rightarrow i}, \quad (22.26)$$

$$u_{a \rightarrow i} = -\frac{1}{2} \ln \left(1 - \prod_{j \in \partial a \setminus i} \frac{1 - \tanh h_{j \rightarrow a}}{2} \right).$$

Because the factor graph is a tree this set of equations has a unique solution which can be efficiently determined: one start from the leaves (degree 1 variable nodes) which obey the boundary condition $h_{i \rightarrow a} = 0$, and progresses inwards the graph. The law μ can be completely described from the values of the h 's and u 's

solutions of these equations for all edges of the graph. For instance the marginal probability of σ_i can be written as

$$\mu(\sigma_i) = \frac{1 + \sigma_i \tanh h_i}{2}, \quad h_i = \sum_{a \in \partial_+ i} u_{a \rightarrow i} - \sum_{a \in \partial_- i} u_{a \rightarrow i}. \quad (22.27)$$

In addition the entropy s of solutions of such a tree formula, can be computed from the values of the messages h and u [BMZ05].

We shall come back to the equations (22.26), and justify the denomination messages, in Sec. 22.5.3; these can be interpreted as the Belief Propagation [KFL01, YFW01, YFW03] heuristic equations for loopy factor graphs.

The factor graph of random formulas is only locally tree-like; the simple computation sketched above has thus to be amended in order to take into account the effect of the distant, loopy part of the formula. Let us call F_L the factor graph made of variable nodes at graph distance smaller than or equal to L from an arbitrarily chosen variable node i in a large random formula F , and B_L the variable nodes at distance exactly L from i . Without loss of generality in the thermodynamic limit, we can assume that F_L is a tree. The cavity method amounts to an hypothesis on the effect of the distant part of the factor graph, $F \setminus F_L$, i.e. on the boundary condition it induces on F_L . In its simplest (so called replica symmetric) version, that is believed to correctly describe the unclustered situation for $\alpha \leq \alpha_d$, $F \setminus F_L$ is replaced, for each variable node j in the boundary B_L , by a fictitious constraint node which sends a bias $u_{\text{ext} \rightarrow j}$. In other words the boundary condition is factorized on the various nodes of B_L . The factorization property is intuitively sound because, in the amputated factor graph $F \setminus F_L$, the distance between the variables of B_L is typically large (of order $\ln N$), and these variables should thus be weakly correlated. Actually this property holds only when $\alpha \leq \alpha_d$, as strong correlations arise in the clustered phase. The external biases are then turned into random variables to take into account the randomness in the construction of the factor graphs, and Eq. (22.26) acquires a distributional meaning. The messages h (resp. u) are supposed to be i.i.d. random variables drawn from a common distribution, the degrees $\partial_{\pm} i(a)$ being two independent Poisson random variables of parameter $\alpha k/2$. These distributional equations can be numerically solved by a population dynamics algorithm [MP01], also known as a particle representation in the statistics literature. The typical entropy density is then computed by averaging s over these distributions of h and u .

This description fails in the presence of clustering, which induces correlations between the variable nodes of B_L in the amputated factor graph $F \setminus F_L$. To take these correlations into account a refined version of the cavity method (termed one step of replica symmetry breaking, in short 1RSB) has been developed. It relies on the hypothesis that the partition of the solution space into clusters γ has nice decorrelation properties: once decomposed onto this partition, μ restricted to a cluster γ behaves essentially as in the unclustered phase (it is a pure state in statistical mechanics jargon). Each directed edge $a \rightarrow i$ should thus bear a family of messages $u_{a \rightarrow i}^{\gamma}$, one for each cluster, or alternatively a distribution $Q_{a \rightarrow i}(u)$ of the messages with respect to the choice of γ . The equations (22.26) are thus promoted to recursions between distributions $P_{i \rightarrow a}(h)$, $Q_{a \rightarrow i}(u)$, which depends on a real m known as the Parisi breaking parameter. Its role is to select the

Figure 22.4. A schematic representation of Eq. (22.26).

size of the investigated clusters, i.e. the number of solutions they contain. The computation of the typical entropy density is indeed replaced by a more detailed thermodynamic potential [Mon95],

$$\Phi(m) = \frac{1}{N} \ln \sum_{\gamma} Z_{\gamma}^m = \frac{1}{N} \ln \int_{s_{-}}^{s_{+}} ds_{\text{int}} e^{N[\Sigma(s_{\text{int}}) + m s_{\text{int}}]} . \quad (22.28)$$

In this formula Z_{γ} denotes the number of solutions inside a cluster γ , and we used the hypothesis that at the leading order the number of clusters with internal entropy density s_{int} is given by $\exp[N\Sigma(s_{\text{int}})]$. The complexity function $\Sigma(s_{\text{int}})$ can thus be obtained from $\Phi(m)$ by an inverse Legendre transform. For generic values of m this approach is computationally very demanding; following the same steps as in the replica symmetric version of the cavity method one faces a distribution (with respect to the topology of the factor graph) of distributions (with respect to the choice of the clusters) of messages. Simplifications however arise for $m = 1$ and $m = 0$ [KMRT⁺07]; the latter case corresponds in fact to the original Survey Propagation approach of [MZ02]. As appears clearly in Eq. (22.28), for this value of m all clusters are treated on an equal footing and the dominant contribution comes from the most numerous clusters, independently of their sizes. Moreover, as we further explain in Sec. 22.5.3, the structure of the equations can be greatly simplified in this case, the distribution over the cluster of fields being parametrized by a single number.

22.3.5. Finite Size Scaling results

As we explained in Sec. 22.2.2 the threshold phenomenon can be more precisely described by finite size scaling relations. Let us mention some FSS results about the transitions we just discussed.

For random 2-SAT, where the satisfiability property is known [dlV01] to exhibit a sharp threshold at $\alpha_s = 1$, the width of the transition window has been determined in [BBC⁺01]. The range of α where the probability of satisfaction drops significantly is of order $N^{-1/3}$, i.e. the exponent ν is equal to 3, as for the random graph percolation. This similarity is not surprising, the proof of [BBC⁺01] relies indeed on a mapping of 2-SAT formulas onto random (directed) graphs.

The clustering transition for XORSAT was first conjectured in [AMRU04] (in the related context of error-correcting codes) then proved in [DM07] to be described by

$$P(N, M = N(\alpha_d + N^{-1/2}\lambda + N^{-2/3}\delta)) = \mathcal{F}(\lambda) + O(N^{-5/26}) , \quad (22.29)$$

where δ is a subleading shift correction that has been explicitly computed, and the scaling function \mathcal{F} is, upto a multiplicative factor on λ , the same error function as in Eq. (22.4).

A general result has been proved in [Wil02] on the width of transition windows. Under rather unrestrictive conditions one can show that $\nu \geq 2$: the transitions cannot be arbitrarily sharp. Roughly speaking the bound is valid when a finite fraction of the clauses are not decisive for the property of the formulas studied, for instance clauses containing a leaf variable are not relevant for the satisfiability of a formula. The number of these irrelevant clauses is of order N and has thus natural fluctuations of order \sqrt{N} ; these fluctuations blur the transition window which cannot be sharper than $N^{-1/2}$.

Several studies (see for instance [KS94, MZK⁺99, RTWZ01]) have attempted to determine the transition window from numeric evaluations of the probability $P(N, \alpha)$, for instance for the satisfiability threshold of random 3-SAT [KS94, MZK⁺99] and XORSAT [RTWZ01]. These studies are necessarily confined to small formula sizes, as the typical computation cost of complete algorithms grows exponentially around the transition. In consequence the asymptotic regime of the transition window, $N^{-1/\nu}$, is often hidden by subleading corrections which are difficult to evaluate, and in [KS94, MZK⁺99] the reported values of ν were found to be in contradiction with the latter derived rigorous bound. This is not an isolated case, numerical studies are often plagued by uncontrolled finite-size effects, as for instance in the bootstrap percolation [GLBD05], a variation of the classical percolation problem.

22.4. Local search algorithms

The rest of this review will be devoted to the study of various SAT-solving algorithms. Algorithms are, to some extent, similar to dynamical processes studied in statistical physics. In this context the focus is however mainly on stochastic processes that respect detailed balance with respect to the Gibbs-Boltzmann measure [Cug03], a condition which is rarely respected by solving algorithms. Physics inspired techniques can yet be useful, and will emerge in three different ways. The random walk algorithms considered in this Section are stochastic processes in the space of configurations (not fulfilling the detailed balance condition), moving by small steps where one or a few variables are modified. Out-of-equilibrium physics (and in particular growth processes) provide an interesting view on classical complete algorithms (DPLL), as shown in Sec. 22.5.2. Finally, the picture of the satisfiable phase put forward in Sec. 22.3 underlies the message-passing procedures discussed in Sec. 22.5.3.

22.4.1. Pure random walk sat, definition and results valid for all instances

Papadimitriou [Pap91] proposed the following algorithm, called Pure Random Walk Sat (PRWSAT) in the following, to solve k -SAT formulas:

1. Choose an initial assignment $\underline{\sigma}(0)$ uniformly at random and set $T = 0$.

2. If $\underline{\sigma}(T)$ is a solution of the formula (i.e. $E(\underline{\sigma}(T)) = 0$), output SOLUTION and stop. If $T = T_{\max}$, a threshold fixed beforehand, output UNDETERMINED and stop.
3. Otherwise, pick uniformly at random a clause among those that are UNSAT in $\underline{\sigma}(T)$; pick uniformly at random one of the k variables of this clause and flip it (reverse its status from True to False and vice-versa) to define the next assignment $\underline{\sigma}(T + 1)$; set $T \rightarrow T + 1$ and go back to step 2.

This defines a stochastic process $\underline{\sigma}(T)$, a biased random walk in the space of configurations. The modification $\underline{\sigma}(T) \rightarrow \underline{\sigma}(T + 1)$ in step 3 makes the selected clause satisfied; however the flip of a variable i can turn previously satisfied clauses into unsatisfied ones (those which were satisfied solely by i in $\underline{\sigma}(T)$).

This algorithm is not complete: if it outputs a solution one is certain that the formula was satisfiable (and the current configuration provides a certificate of it), but if no solution has been found within the T_{\max} allowed steps one cannot be sure that the formula was unsatisfiable. There are however two rigorous results which makes it a probabilistically almost complete algorithm [MR95].

For $k = 2$, it was shown in [Pap91] that PRWSAT finds a solution in a time of order $O(N^2)$ with high probability for all satisfiable instances. Hence, one is almost certain that the formula was unsatisfiable if the output of the algorithm is UNDETERMINED after $T_{\max} = O(N^2)$ steps.

Schöningh [Sch02] proposed the following variation for $k = 3$. If the algorithm fails to find a solution before $T_{\max} = 3N$ steps, instead of stopping and printing UNDETERMINED, it restarts from step 1, with a new random initial condition $\underline{\sigma}(0)$. Schöningh proved that if after R restarts no solution has been found, then the probability that the instance is satisfiable is upper-bounded by $\exp[-R \times (3/4)^N]$ (asymptotically in N). This means that a computational cost of order $(4/3)^N$ allows to reduce the probability of error of the algorithm to arbitrary small values. Note that if the time scaling of this bound is exponential, it is also exponentially smaller than the 2^N cost of an exhaustive enumeration. Improvements on the factor $4/3$ are reported in [BS04].

22.4.2. Typical behavior on random k -SAT instances

The results quoted above are true for any k -SAT instance. An interesting phenomenology arises when one applies the PRWSAT algorithm to instances drawn from the random k -SAT ensemble [SM03, BHW03]. Figure 22.5 displays the temporal evolution of the number of unsatisfied clauses during the execution of the algorithm, for two random 3-SAT instances of constraint ratio $\alpha = 2$ and 3. The two curves are very different: at low values of α the energy decays rather fast towards 0, until a point where the algorithm finds a solution and stops. On the other hand, for larger values of α , the energy first decays towards a strictly positive value, around which it fluctuates for a long time, until a large fluctuation reaches 0, signaling the discovery of a solution. A more detailed study with formulas of increasing sizes reveals that a threshold value $\alpha_{\text{rw}} \approx 2.7$ (for $k = 3$) sharply separates this two dynamical regimes. In fact the fraction of unsatisfied clauses $\varphi = E/M$, expressed in terms of the reduced time $t = T/M$, concentrates in the thermodynamic limit around a deterministic function $\varphi(t)$. For $\alpha < \alpha_{\text{rw}}$

Figure 22.5. Fraction of unsatisfied constraints $\varphi = E/M$ in function of reduced time $t = T/M$ during the execution of PRWSAT on random 3-SAT formulas with $N = 500$ variables. Top: $\alpha = 2$, Bottom: $\alpha = 3$.

the function $\varphi(t)$ reaches 0 at a finite value $t_{\text{sol}}(\alpha, k)$, which means that the algorithm finds a solution in a linear number of steps, typically close to $Nt_{\text{sol}}(\alpha, k)$. On the contrary for $\alpha > \alpha_{\text{rw}}$ the reduced energy $\varphi(t)$ reaches a positive value $\varphi_{\text{as}}(\alpha, k)$ as $t \rightarrow \infty$; a solution, if any, can be found only through large fluctuations of the energy which occur on a time scale exponentially large in N . This is an example of a metastability phenomenon, found in several other stochastic processes, for instance the contact process [Lig85]. When the threshold α_{rw} is reached from below the solving time $t_{\text{sol}}(\alpha, k)$ diverges, while the height of the plateau $\varphi_{\text{as}}(\alpha, k)$ vanishes when α_{rw} is approached from above.

In [SM03, BHW03] various statistical mechanics inspired techniques have been applied to study analytically this phenomenology, some results are presented in Figure 22.6. The low α regime can be tackled by a systematic expansion of $t_{\text{sol}}(\alpha, k)$ in powers of α . The first three terms of these series have been computed, and are shown on the left panel to be in good agreement with the numerical simulations.

Another approach was followed to characterize the transition α_{rw} , and to compute (approximations of) the asymptotic fraction of unsatisfied clauses φ_{as} and the intensity of the fluctuations around it. The idea is to project the Marko-

Figure 22.6. Top: linear solving time $t_{\text{sol}}(\alpha, 3)$ for random 3-SAT formulas in function of α ; symbols correspond to numerical simulations, solid line to the second order expansion in α obtained in [SM03]. Bottom: fraction of unsatisfied constraints reached at large time for $\alpha > \alpha_{\text{rw}}$ for random 3-SAT formulas; symbols correspond to numerical simulations, solid line to the approximate analytical computations of [SM03, BHW03].

vian evolution of the configuration $\sigma(T)$ on a simpler observable, the energy $E(T)$. Obviously the Markovian property is lost in this transformation, and the dynamics of $E(T)$ is much more complex. One can however approximate it by assuming that all configurations of the same energy $E(T)$ are equiprobable at a given step of execution of the algorithm. This rough approximation of the evolution of $E(T)$ is found to concentrate around its mean value in the thermodynamic limit, as was observed numerically for the original process. Standard techniques allow to compute this average approximated evolution, which exhibits the threshold behavior explained above at a value $\alpha = (2^k - 1)/k$ which is, for $k = 3$, slightly lower than the threshold α_{rw} . The right panel of Fig. 22.6 confronts the results of this approximation with the numerical simulations; given the roughness of the hypothesis the agreement is rather satisfying, and is expected to improve for larger values of k .

The rigorous results on the behavior of PRWSAT on random instances are very few. Let us mention in particular [ABS06], which proved that the solving

time for random 3-SAT formulas is typically polynomial up to $\alpha = 1.63$, a result in agreement yet weaker than the numerical results presented here.

22.4.3. More efficient variants of the algorithm

The threshold α_{rw} for linear time solving of random instances by PRWSAT was found above to be much smaller than the satisfiability threshold α_s . It must however be emphasized that PRWSAT is only the simplest example of a large family of local search algorithms, see for instance [SKC94, MSK97, SAO05, AA06, AAA⁺07]. They all share the same structure: a solution is searched through a random walk in the space of configurations, one variable being modified at each step. The choice of the flipped variable is made according to various heuristics; the goal is to find a compromise between the greediness of the walk which seeks to minimize locally the energy of the current assignment, and the necessity to allow for moves increasing the energy in order to avoid the trapping in local minima of the energy function. A frequently encountered ingredient of the heuristics, which is of a greedy nature, is focusing: the flipped variable necessarily belongs to at least one unsatisfied clause before the flip; this clause thus becomes satisfied after the move. Moreover, instead of choosing randomly one of the k variables of the unsatisfied clause, one can avoid flipping variables which would turn satisfied clauses into unsatisfied ones [SKC94, MSK97]. Another way to implement the greediness [SAO05] consists in bookkeeping the lowest energy found so far during the walk, and forbids flips which will raise the energy of the current assignment above the registered record plus a tolerance threshold. These demanding requirements have to be balanced with noisy, random steps, allowing to escape traps which are only locally minima of the objective function.

These more elaborate heuristics are very numerous, and depend on parameters that are finely tuned to achieve the best performances, hence an exhaustive comparison is out of the scope of this review. Let us only mention that some of these heuristics are reported in [SAO05, AA06] to efficiently find solutions of large (up to $N = 10^6$) random formulas of 3-SAT at ratio α very close to the satisfiability threshold, i.e. for $\alpha \lesssim 4.21$.

22.5. Decimation based algorithms

The algorithms studied in the remainder of the review are of a very different nature compared to the local search procedures described above. Given an initial formula F whose satisfiability has to be decided, they proceed by assigning sequentially (and permanently) the value of some of the variables. The formula can be simplified under such a partial assignment: clauses which are satisfied by at least one of their literal can be removed, while literals unsatisfying a clause are discarded from the clause. It is instructive to consider the following thought experiment: suppose one can consult an oracle who, given a formula, is able to compute the marginal probability of the variables, in the uniform probability measure over the satisfying assignments of the formula. With the help of such an oracle it would be possible to sample uniformly the satisfying assignments of F , by computing these marginals, setting one unassigned variable according to

its marginal, and then proceed in the same way with the simplified formula. A slightly less ambitious, yet still unrealistic, task is to find one satisfying configuration (not necessarily uniformly distributed) of F ; this can be performed if the oracle is able to reveal, for each formula he is questioned about, which of the unassigned variables take the same value in all satisfying assignments, and what is this value. Then it is enough to avoid setting incorrectly such a constrained variable to obtain at the end a satisfying assignment.

Of course such procedures are not meant as practical algorithms; instead of these fictitious oracles one has to resort to simplified evidences gathered from the current formula to guide the choice of the variable to assign. In Sec. 22.5.1 we consider algorithms exploiting basic information on the number of occurrences of each variable, and their behavior in the satisfiable regime of random SAT formulas. They are turned into complete algorithms by allowing for backtracking the heuristic choices, as explained in 22.5.2. Finally in Sec. 22.5.3 we shall use more refined message-passing sub-procedures to provide the information used in the assignment steps.

22.5.1. Heuristic search: the success-to-failure transition

The first algorithm we consider was introduced and analyzed by Franco and his collaborators [CF86, CF90].

1. If a formula contains a *unit clause* i.e. a clause with a single variable, this clause is satisfied through an appropriate assignment of its unique variable (propagation); If the formula contains no *unit-clause* a variable and its truth value are chosen according to some heuristic rule (free choice). Note that the unit clause propagation corresponds to the obvious answer an oracle would provide on such a formula.
2. Then the clauses in which the assigned variable appears are simplified: satisfied clauses are removed, the other ones are reduced.
3. Resume from step 1.

The procedure will end if one of two conditions is verified:

1. The formula is completely empty (all clauses have been removed), and a solution has been found (SUCCESS).
2. A contradiction is generated from the presence of two opposite unit clauses. The algorithm halts. We do not know if a solution exists and has not been found or if there is no solution (FAILURE).

The simplest example of heuristic is called Unit Clause (UC) and consists in choosing a variable uniformly at random among those that are not yet set, and assigning it to TRUE or FALSE uniformly at random. More sophisticated heuristics can take into account the number of occurrences of each variable and of its negation, the length of the clauses in which each variable appears, or they can set more than one variable at a time. For example, in the Generalized Unit Clause (GUC), the variable is always chosen among those appearing in the shortest clauses.

Numerical experiments and theory show that the results of this procedure applied to random k -SAT formulas with ratios α and size N can be classified in two regimes:

- At low ratio $\alpha < \alpha_H$ the search procedure finds a solution with positive probability (over the formulas and the random choices of the algorithm) when $N \rightarrow \infty$.
- At high ratio $\alpha > \alpha_H$ the probability of finding a solution vanishes when $N \rightarrow \infty$. Notice that $\alpha_H < \alpha_s$: solutions do exist in the range $[\alpha_H, \alpha_s]$ but are not found by this heuristic.

The above algorithm *modifies* the formula as it proceeds; during the execution of the algorithm the current formula will contain clauses of length 2 and 3 (we specialize here to $k = 3$ -SAT for the sake of simplicity but higher values of k can be considered). The sub-formulas generated by the search procedure maintain their statistical uniformity (conditioned on the number of clauses of length 2 and 3). Franco and collaborators used this fact to write down differential equations for the evolution of the densities of 2- and 3-clauses as a function of the fraction t of eliminated variables. We do not reproduce those equations here, see [Ach01] for a pedagogical review. Based on this analysis Frieze and Suen [FS96] were able to calculate, in the limit of infinite size, the probability of successful search. The outcome for the UC heuristic is

$$\mathcal{P}_{\text{success}}^{(\text{UC})}(\alpha) = \exp \left\{ -\frac{1}{4\sqrt{8/3\alpha - 1}} \arctan \left[\frac{1}{\sqrt{8/3\alpha - 1}} \right] - \frac{3}{16} \alpha \right\} \quad (22.30)$$

when $\alpha < \frac{8}{3}$, and $\mathcal{P} = 0$ for larger ratios. The probability $\mathcal{P}_{\text{success}}$ is, as expected, a decreasing function of α ; it vanishes in $\alpha_H = \frac{8}{3}$. A similar calculation shows that $\alpha_H \simeq 3.003$ for the GUC heuristic [FS96].

Franco et al's analysis can be recast in the following terms. Under the operation of the algorithm the original 3-SAT formula is turned into a mixed $2+p$ -SAT formula where p denotes the fraction of the clauses with 3 variables: there are $N\alpha \cdot (1-p)$ 2-clauses and $N\alpha p$ 3-clauses. As we mentioned earlier the simplicity of the heuristics maintains a statistical uniformity over the formulas with a given value of α and p . This observation motivated the study of the random $2+p$ -SAT ensemble by statistical mechanics methods [MZK⁺99, BMW00], some of the predictions being later proven by the rigorous analysis of [AKKK01]. At the heuristic level one expects the existence of a p dependent satisfiability threshold $\alpha_s(p)$, interpolating between the 2-SAT known threshold, $\alpha_s(p=0) = 1$, and the conjectured 3-SAT case, $\alpha_s(p=1) \approx 4.267$. The upperbound $\alpha_s(p) \leq 1/(1-p)$ is easily obtained: for the mixed formula to be satisfiable, necessarily the subformula obtained by retaining only the clauses of length 2 must be satisfiable as well. In fact this bound is tight for all values of $p \in [0, 2/5]$. During the execution of the algorithm the ratio α and the fraction p are 'dynamical' parameters, changing with the fraction $t = T/N$ of variables assigned by the algorithm. They define the coordinates of the representative point of the instance at 'time' t in the (p, α) plane of Figure 22.7. The motion of the representative point defines the search trajectory of the algorithm. Trajectories start from the point of coordinates $p(0) = 1, \alpha(0) = \alpha$ and end up on the $\alpha = 0$ axis when a solution is found. A necessary condition for the probability of success to be positive is that the 2-SAT subformula is satisfiable, that is, $\alpha \cdot (1-p) < 1$. In other words success is possible provided the trajectory does not cross the contradiction line

Figure 22.7. Trajectories generated by heuristic search acting on 3-SAT for $\alpha = 2$ and $\alpha = 3.5$. For all heuristics, the starting point is on the $p = 1$ axis, with the initial value of α as ordinate. The curves that end at the origin correspond to UC, those ending on the $p = 1$ axis correspond to GUC. The thick line represents the satisfiability threshold: the part on the left of the critical point $(2/5, 5/3)$ is exact and coincides with the contradiction line, where contradictions are generated with high probability, of equation $\alpha = 1/(1 - p)$, and which is plotted for larger values of p as well; the part on the right of the critical point is only a sketch. When the trajectories hit the satisfiability threshold, at points G for UC and G' for GUC, they enter a region in which massive backtracking takes place, and the trajectory represents the evolution *prior* to backtracking. The dashed part of the curves is “unphysical”, i.e. the trajectories stop when the contradiction curve is reached.

$\alpha = 1/(1 - p)$ (Figure 22.7). The largest initial ratio α such that no crossing occurs defines α_H . Notice that the search trajectory is a stochastic object. However deviations from its average locus in the plane vanish in the $N \rightarrow \infty$ limit (concentration phenomenon). Large deviations from the typical behavior can be calculated e.g. to estimate the probability of success above α_H [CM05].

The precise form of $\mathcal{P}_{\text{success}}$ and the value α_H of the ratio where it vanishes are specific to the heuristic considered (UC in (22.30)). However the behavior of the probability close to α_H is largely independent of the heuristic (provided it preserves the uniformity of the subformulas generated):

$$\ln \mathcal{P}_{\text{success}}(\alpha = \alpha_H(1 - \lambda)) \sim -\lambda^{-1/2}. \quad (22.31)$$

This universality can loosely be interpreted by observing that for α close to α_H the trajectory will pass very close to the contradiction curve $\alpha \cdot (1 - p) = 1$, which characterizes the locus of the points where the probability that a variable is assigned by the heuristics H vanishes (and all the variables are assigned by Unit Propagation). The value of α_H depend on the “shape” of the trajectory far

from this curve, and will therefore depend on the heuristics, but the probability of success (i.e. of avoiding the contradiction curve) for values of α close to α_H will only depend on the local behavior of the trajectory close to the contradiction curve, a region where most variables are assigned through Unit Propagation and not sensitive to the heuristics.

The finite-size corrections to equation (22.30) are also universal (i.e. independent on the heuristics):

$$\ln \mathcal{P}_{\text{success}}(\alpha = \alpha_H(1 - \lambda), N) \sim -N^{1/6} \mathcal{F}(\lambda N^{1/3}), \quad (22.32)$$

where \mathcal{F} is a universal scaling function which can be exactly expressed in terms of the Airy function [DM04]. This result indicates that right at α_H the probability of success decreases as a stretched exponential $\sim \exp(-cst N^{\frac{1}{6}})$.

The exponent $\frac{1}{3}$ suggests that the critical scaling of \mathcal{P} is related to random graphs. After $T = tN$ steps of the procedure, the sub-formula will consist of C_3, C_2 and C_1 clauses of length 3, 2 and 1 respectively (notice that these are *extensive*, i.e. $O(N)$ quantities). We can represent the clauses of length 1 and 2 (which are the relevant ones to understand the generation of contradictions) as an oriented graph \mathcal{G} in the following way. We will have a vertex for each literal, and represent 1-clauses by “marking” the literal appearing in each; a 2-clause will be represented by two directed edges, corresponding to the two implications equivalent to the clause (for example, $x_1 \vee \bar{x}_2$ is represented by the directed edges $\bar{x}_1 \rightarrow \bar{x}_2$ and $x_2 \rightarrow x_1$). The average out-degree of the vertices in the graph is $\gamma = C_2/(N - T) = \alpha(t)(1 - p(t))$.

What is the effect of the algorithm on \mathcal{G} ? The algorithm will proceed in “rounds”: a variable is set by the heuristics, and a series of Unit Propagations are performed until no more unit clauses are left, at which point a new round starts. Notice that during a round, extensive quantities as C_1, C_2, C_3 are likely to vary by bounded amounts and γ to vary by $O(\frac{1}{N})$ (this is the very reason that guarantees that these quantities are concentrated around their mean). At each step of Unit Propagation, a marked literal (say x) is assigned and removed from \mathcal{G} , together with all the edges connected to it, and the “descendants” of x (i.e. the literals at the end of outgoing edges) are marked. Also \bar{x} is removed together with its edges, but its descendants are not marked. Therefore, the marked vertices “diffuse” in a connected component of \mathcal{G} following directed edges. Moreover, at each step new edges corresponding to clauses of length 3 that get simplified into clauses of length 2 are added to the graph.

When $\gamma > 1$, \mathcal{G} undergoes a directed percolation transition, and a giant component of size $O(N)$ appears, in which it is possible to go from any vertex to any other vertex by following a directed path. When this happens, there is a finite probability that two opposite literals x and \bar{x} can be reached from some other literal y following a directed path. If \bar{y} is selected by Unit Propagation, at some time both x and \bar{x} will be marked, and this corresponds to a contradiction. This simple argument explains more than just the condition $\gamma = \alpha \cdot (1 - p) = 1$ for the failure of the heuristic search. It can also be used to explain the the exponent $\frac{1}{6}$ in the scaling (22.32), see [DM04, Mon07] for more details.

22.5.2. Backtrack-based search: the Davis-Putnam-Loveland-Logemann procedure

The heuristic search procedure of the previous Section can be easily turned into a complete procedure for finding solutions or proving that formulas are not satisfiable. When a contradiction is found the algorithm now backtracks to the last assigned variable (by the heuristic; unit clause propagations are merely consequences of previous assignments), invert it, and the search resumes. If another contradiction is found the algorithm backtracks to the last-but-one assigned variable and so on. The algorithm stops either if a solution is found or all possible backtracks have been unsuccessful and a proof of unsatisfiability is obtained. This algorithm was proposed by Davis, Putnam, Loveland and Logemann and is referred to as DPLL in the following.

The history of the search process can be represented by a search tree, where the nodes represent the variables assigned, and the descending edges their values (Figure 22.8). The leaves of the tree correspond to solutions (S), or to contradictions (C). The analysis of the $\alpha < \alpha_H$ regime in the previous Section leads us to the conclusion that search trees look like Figure 22.8A at small ratios⁵.

For ratios $\alpha > \alpha_H$ DPLL is very likely to find a contradiction. Backtracking enters into play, and is responsible for the drastic slowing down of the algorithm. The success-to-failure transition takes place in the non-backtracking algorithm into a polynomial-to-exponential transition in DPLL. The question is to compute the growth exponent of the average tree size, $T \sim e^{N\tau(\alpha)}$, as a function of the ratio α .

22.5.2.1. Exponential regime: Unsatisfiable formulas

Consider first the case of unsatisfiable formulas ($\alpha > \alpha_s$) where all leaves carry contradictions after DPLL halts (Figure 22.8B). DPLL builds the tree in a sequential manner, adding nodes and edges one after the other, and completing branches through backtracking steps. We can think of the same search tree built in a parallel way [CM01]. At time (depth T) our tree is composed of $L(T) \leq 2^T$ branches, each carrying a partial assignment over T variables. Step T consists in assigning one more variable to each branch, according to DPLL rules, that is, through unit-propagation or the heuristic rule. In the latter case we will speak of a splitting event, as two branches will emerge from this node, corresponding to the two possible values of the variable assigned. The possible consequences of this assignment are the emergence of a contradiction (which put an end to the branch), or the simplification of the attached formulas (the branch keeps growing).

The number of branches $L(T)$ is a stochastic variable. Its average value can be calculated as follows [Mon05]. Let us define the average number $L(\vec{C}; T)$ of branches of depth T which bear a formula containing C_3 (resp. C_2, C_1) equations of length 3 (resp. 2,1), with $\vec{C} = (C_1, C_2, C_3)$. Initially $L(\vec{C}; 0) = 1$ for $\vec{C} = (0, 0, \alpha N)$, 0 otherwise. We shall call $M(\vec{C}', \vec{C}; T)$ the average number of branches described by \vec{C}' generated from a \vec{C} branch once the T^{th} variable is

⁵A small amount of backtracking may be necessary to find the solution since $\mathcal{P}_{\text{success}} < 1$ [FS96], but the overall picture of a single branch is not qualitatively affected.

Figure 22.8. Search trees generated by DPLL: **A.** linear, satisfiable ($\alpha < \alpha_H$); **B.** exponential, unsatisfiable ($\alpha > \alpha_c$). **C.** exponential, satisfiable ($\alpha_H < \alpha < \alpha_c$); Leaves are marked with S (solutions) or C (contradictions). G is the highest node to which DPLL backtracks, see Fig. 22.7.

assigned [CM01, Mon07]. We have $0 \leq M \leq 2$, the extreme values corresponding to a contradiction and to a split respectively. We claim that

$$L(\vec{C}'; T+1) = \sum_{\vec{C}} M(\vec{C}', \vec{C}; T) L(\vec{C}; T) . \quad (22.33)$$

Evolution equation (22.33) could look like somewhat suspicious at first sight due to its similarity with the approximation we have sketched in Sec. 22.4.2 for the analysis of PRWSAT. Yet, thanks to the linearity of expectation, the correlations between the branches (or better, the instances carried by the branches) do not matter as far as the average number of branches is concerned.

For large N we expect that the number of alive (not hit by a contradiction) branches grows exponentially with the depth, or, equivalently,

$$\sum_{C_1, C_2, C_3} L(C_1, C_2, C_3; T) \sim e^{N \lambda(t) + o(N)} \quad (22.34)$$

The argument of the exponential, $\lambda(t)$, can be found using partial differential equation techniques generalizing the ordinary differential equation techniques of a single branch in the absence of backtracking (Section 22.5.1). Details can be found in [Mon05]. The outcome is that $\lambda(t)$ is a function growing from $\lambda = 0$ at $t = 0$, reaching a maximum value λ_M for some depth t_M , and decreasing at larger depths. t_M is the depth in the tree of Figure 22.8B where most contradictions are found; the number of contradiction leaves is, to exponential order, $e^{N \lambda_M}$. We conclude that the logarithm of the average size of the tree we were looking for is

$$\tau = \lambda_M . \quad (22.35)$$

For large $\alpha \gg \alpha_s$ one finds $\tau = O(1/\alpha)$, in agreement with the asymptotic scaling of [BKPS02]. The calculation can be extended to higher values of k .

22.5.2.2. Exponential regime: Satisfiable formulas

The above calculation holds for the unsatisfiable, exponential phase. How can we understand the satisfiable but exponential regime $\alpha_H < \alpha < \alpha_s$? The resolution trajectory crosses the SAT/UNSAT critical line $\alpha_s(p)$ at some point G shown in Figure 22.7. Immediately after G the instance left by DPLL is unsatisfiable. A subtree with all its leaves carrying contradictions will develop below G (Figure 22.8C). The size τ^G of this subtree can be easily calculated from the above theory from the knowledge of the coordinates (p_G, α_G) of G . Once this subtree has been built DPLL backtracks to G , flips the attached variable and will finally end up with a solution. Hence the (log of the) number of splits necessary will be equal to $\tau = (1 - t_G) \tau_{\text{split}}^G$ [CM01]. Remark that our calculation gives the logarithm of the average subtree size starting from the typical value of G . Numerical experiments show that the resulting value for τ coincides very accurately with the most likely tree size for finding a solution. The reason is that fluctuations in the sizes are mostly due to fluctuations of the highest backtracking point G , that is, of the first part of the search trajectory [CM05].

22.5.3. Message passing algorithms

According to the thought experiment proposed at the beginning of this Section valuable information could be obtained from the knowledge of the marginal probabilities of variables in the uniform measure over satisfying configurations. This is an inference problem in the graphical model associated to the formula. In this field message passing techniques (for instance Belief Propagation, or the min-sum algorithm) are widely used to compute approximately such marginals [KFL01, YFW01]. These numerical procedures introduce messages on the directed edges of the factor graph representation of the problem (recall the definitions given in Sec. 22.3.4), which are iteratively updated, the new value of a message being computed from the old values of the incoming messages (see Fig. 22.4). When the underlying graph is a tree, the message updates are guaranteed to converge in a finite number of steps, and provide exact results. In the presence of cycles the convergence of these recurrence equations is not guaranteed; they can however be used heuristically, the iterations being repeated until a fixed point has been reached (within a tolerance threshold). Though very few general results on the convergence in presence of loops are known [TJ02] (see also [MS07] for low α random SAT formulas) these heuristic procedures are often found to yield good approximation of the marginals on generic factor graph problems.

The interest in this approach for solving random SAT instances was triggered in the statistical mechanics community by the introduction of the Survey Propagation algorithm [MZ02]. Since then several generalizations and reinterpretations of SP have been put forward, see for instance [BZ04, MMW05, AGK04, Par03b, BKcvZ04, CFMZ05]. In the following paragraph we present three different message passing procedures, which differ in the nature of the messages passed between nodes, following rather closely the presentation of [BMZ05] to which we refer the reader for further details. We then discuss how these procedures have to be interleaved with assignment (decimation) steps in order to constitute a solver algorithm. Finally we shall review results obtained in a particular limit case (large

α satisfiable formulas).

22.5.3.1. Definition of the message-passing algorithms

- Belief Propagation (BP)

For the sake of readability we recall here the recursive equations (22.26) stated in Sec. 22.3.4 for the uniform probability measure over the solutions of a tree formula,

$$\begin{aligned}
 h_{i \rightarrow a} &= \sum_{b \in \partial_+ i(a)} u_{b \rightarrow i} - \sum_{b \in \partial_- i(a)} u_{b \rightarrow i} , \\
 u_{a \rightarrow i} &= -\frac{1}{2} \ln \left(1 - \prod_{j \in \partial a \setminus i} \frac{1 - \tanh h_{j \rightarrow a}}{2} \right) .
 \end{aligned} \tag{22.36}$$

where the h and u 's messages are reals (positive for u), parametrizing the marginal probabilities (beliefs) for the value of a variable in absence of some constraint nodes around it (cf. Eq. (22.25)). These equations can be used in the heuristic way explained above for any formula, and constitute the BP message-passing equations. Note that in the course of the simplification process the degree of the clauses change, we thus adopt here and in the following the natural convention that sums (resp. products) over empty sets of indices are equal to 0 (resp. 1).

- Warning Propagation (WP)

The above-stated version of the BP equations become ill-defined for an unsatisfiable formula, whether this was the case of the original formula or because of some wrong assignment steps; in particular the normalization constant of Eq. (22.24) vanishes. A way to cure this problem consists in introducing a fictitious inverse temperature β and deriving the BP equations corresponding to the regularized Gibbs-Boltzmann probability law (22.17), taking as the energy function the number of unsatisfied constraints. In the limit $\beta \rightarrow \infty$, in which the Gibbs-Boltzmann measure concentrates on the satisfying assignments, one can single out a part of the information conveyed by the BP equations to obtain the simpler Warning Propagation rules. Indeed the messages h, u are at leading order proportional to β , with proportionality coefficients we shall denote \hat{h} and \hat{u} . These messages are less informative than the ones of BP, yet simpler to handle. One finds indeed that instead of reals the WP messages are integers, more precisely $\hat{h} \in \mathbb{Z}$ and $\hat{u} \in \{0, 1\}$. They obey the following recursive equations (with a structure similar to the ones of BP),

$$\begin{aligned}
 \hat{h}_{i \rightarrow a} &= \sum_{b \in \partial_+ i(a)} \hat{u}_{b \rightarrow i} - \sum_{b \in \partial_- i(a)} \hat{u}_{b \rightarrow i} , \\
 \hat{u}_{a \rightarrow i} &= \prod_{j \in \partial a \setminus i} \mathbb{I}(\hat{h}_{j \rightarrow a} < 0) ,
 \end{aligned} \tag{22.37}$$

where $\mathbb{I}(E)$ is the indicator function of the event E . The interpretation of these equations goes as follows. $\hat{u}_{a \rightarrow i}$ is equal to 1 if in all satisfying

assignments of the amputated formula in which i is only constrained by a , i takes the value satisfying a . This happens if all other variables of clause a (i.e. $\partial a \setminus i$) are required to take their values unsatisfying a , hence the form of the right part of (22.37). In such a case we say that a sends a warning to variable i . In the first part of (22.37), the message $\hat{h}_{i \rightarrow a}$ sent by a variable to a clause is computed by pondering the number of warnings sent by all other clauses; it will in particular be negative if a majority of clauses requires i to take the value unsatisfying a .

- Survey Propagation (SP)

The convergence of BP and WP iterations is not ensured on loopy graphs. In particular the clustering phenomenon described in Sec. 22.3.1 is likely to spoil the efficiency of these procedures. The Survey Propagation (SP) algorithm introduced in [MZ02] has been designed to deal with these clustered space of configurations. The underlying idea is that the simple iterations (of BP or WP type) remain valid inside each cluster of satisfying assignments; for each of these clusters γ and each directed edge of the factor graph one has a message $h_{i \rightarrow a}^\gamma$ (and $u_{a \rightarrow i}^\gamma$). One introduces on each edge a survey of these messages, defined as their probability distribution with respect to the choice of the clusters. Then some hypotheses are made on the structure of the cluster decomposition in order to write closed equations on the survey. We now make this approach explicit in a version adapted to satisfiable instances [BMZ05], taking as the basic building block the WP equations. This leads to a rather simple form of the survey. Indeed $\hat{u}_{a \rightarrow i}$ can only take two values, its probability distribution can thus be parametrized by a single real $\delta_{a \rightarrow i} \in [0, 1]$, the probability that $\hat{u}_{a \rightarrow i} = 1$. Similarly the survey $\gamma_{i \rightarrow a}$ is the probability that $\hat{h}_{i \rightarrow a} < 0$. The second part of (22.37) is readily translated in probabilistic terms,

$$\delta_{a \rightarrow i} = \prod_{j \in \partial a \setminus i} \gamma_{j \rightarrow a} . \quad (22.38)$$

The other part of the recursion takes a slightly more complicated form,

$$\gamma_{i \rightarrow a} = \frac{(1 - \pi_{i \rightarrow a}^-) \pi_{i \rightarrow a}^+}{\pi_{i \rightarrow a}^+ + \pi_{i \rightarrow a}^- - \pi_{i \rightarrow a}^+ \pi_{i \rightarrow a}^-} ,$$

$$\text{with } \begin{cases} \pi_{i \rightarrow a}^+ = \prod_{b \in \partial_+ i(a)} (1 - \delta_{b \rightarrow i}) \\ \pi_{i \rightarrow a}^- = \prod_{b \in \partial_- i(a)} (1 - \delta_{b \rightarrow i}) \end{cases} . \quad (22.39)$$

In this equation $\pi_{i \rightarrow a}^+$ (resp. $\pi_{i \rightarrow a}^-$) corresponds to the probability that none of the clauses agreeing (resp. disagreeing) with a on the value of the literal of i sends a warning. For i to be constrained to the value unsatisfying a , at least one of the clauses of $\partial_- i(a)$ should send a warning, and none of $\partial_+ i(a)$, which explains the form of the numerator of $\gamma_{i \rightarrow a}$. The denominator arises from the exclusion of the event that both clauses in $\partial_+ i(a)$ and $\partial_- i(a)$ send messages, a contradictory event in this version of SP which is devised for satisfiable formulas.

From the statistical mechanics point of view the SP equations arise from a 1RSB cavity calculation, as sketched in Sec. 22.3.4, in the zero temperature limit ($\beta \rightarrow \infty$) and vanishing Parisi parameter m , these two limits being either taken simultaneously as in [MZ02, BKcvZ04] or successively [KMRT⁺07]. One can thus compute, from the solution of the recursive equations on a single formula, an estimation of its complexity, i.e. the number of its clusters (irrespective of their sizes). The message passing procedure can also be adapted, at the price of technical complications, to unsatisfiable clustered formulas [BKcvZ04]. Note also that the above SP equations have been shown to correspond to the BP ones in an extended configuration space where variables can take a ‘joker’ value [BZ04, MMW05], mimicking the variables which are not frozen to a single value in all the assignments of a given cluster. Interpolations between the BP and SP equations have been studied in [AGK04, MMW05].

22.5.3.2. Exploiting the information

The information provided by these message passing procedures can be exploited in order to solve satisfiability formulas; in the algorithm sketched at the beginning of Sec. 22.5.1 the heuristic choice of the assigned variable, and its truth value, can be done according to the results of the message passing on the current formula. If BP were an exact inference algorithm, one could choose any unassigned variable, compute its marginal according to Eq. (22.27), and draw it according to this probability. Of course BP is only an approximate procedure, hence a practical implementation of this idea should privilege the variables with marginal probabilities closest to a deterministic law (i.e. with the largest $|h_i|$), motivated by the intuition that these are the least subject to the approximation errors of BP. Similarly, if the message passing procedure used at each assignment step is WP, one can fix the variable with the largest $|\hat{h}_i|$ to the value corresponding to the sign of \hat{h}_i . In the case of SP, the solution of the message passing equations are used to compute, for each unassigned variable i , a triplet of numbers $(\gamma_i^+, \gamma_i^-, \gamma_i^0)$ according to

$$\gamma_i^+ = \frac{(1 - \pi_i^+) \pi_i^-}{\pi_i^+ + \pi_i^- - \pi_i^+ \pi_i^-}, \quad \gamma_i^- = \frac{(1 - \pi_i^-) \pi_i^+}{\pi_i^+ + \pi_i^- - \pi_i^+ \pi_i^-}, \quad \gamma_i^0 = 1 - \gamma_i^+ - \gamma_i^-,$$

$$\text{with } \begin{cases} \pi_i^+ = \prod_{a \in \partial_+ i} (1 - \delta_{a \rightarrow i}) \\ \pi_i^- = \prod_{a \in \partial_- i} (1 - \delta_{a \rightarrow i}) \end{cases} . \quad (22.40)$$

γ_i^+ (resp. γ_i^-) is interpreted as the fraction of clusters in which $\sigma_i = +1$ (resp. $\sigma_i = -1$) in all solutions of the cluster, hence γ_i^0 corresponds to the clusters in which σ_i can take both values. In the version of [BMZ05], one then choose the variable with the largest $|\gamma_i^+ - \gamma_i^-|$, and fix it to $\sigma_i = +1$ (resp. $\sigma_i = -1$) if $\gamma_i^+ > \gamma_i^-$ (resp. $\gamma_i^+ < \gamma_i^-$). In this way one tries to select an assignment preserving the maximal number of clusters.

Of course many variants of these heuristic rules can be devised; for instance after each message passing computation one can fix a finite fraction of the variables (instead of a single one), allows for some amount of backtracking [Par03a],

or increase a soft bias instead of assigning completely a variable [CFMZ05]. Moreover the tolerance on the level of convergence of the message passing itself can also be adjusted. All these implementation choices will affect the performances of the solver, in particular the maximal value of α up to which random SAT instances are solved efficiently, and thus makes difficult a precise statement about the limits of these algorithms. In consequence we shall only report the impressive result of [BMZ05], which presents an implementation ⁶ working for random 3-SAT instances up to $\alpha = 4.24$ (very close to the conjectured satisfiability threshold $\alpha_s \approx 4.267$) for problem sizes as large as $N = 10^7$.

The theoretical understanding of these message passing inspired solvers is still poor compared to the algorithms studied in Sec. 22.5.1, which use much simpler heuristics in their assignment steps. One difficulty is the description of the residual formula after an extensive number of variables have been assigned; because of the correlations between successive steps of the algorithm this residual formula is not uniformly distributed conditioned on a few dynamical parameters, as was the case with $(\alpha(t), p(t))$ for the simpler heuristics of Sec. 22.5.1. One version of BP guided decimation could however be studied analytically in [MRTS07], by means of an analysis of the thought experiment discussed at the beginning of Sec. 22.5. The study of another simple message passing algorithm is presented in the next paragraph.

22.5.3.3. Warning Propagation on dense random formulas

Feige proved in [Fei02] a remarkable connection between the *worst-case* complexity of approximation problems and the structure of *random* 3-SAT at large (but independent of N) values of the ratio α . He introduced the following hardness hypothesis for random 3-SAT formulas:

Hypothesis 1: *Even if α is arbitrarily large (but independent of N), there is no polynomial time algorithm that on most 3-SAT formulas outputs UNSAT, and always outputs SAT on a 3-SAT formula that is satisfiable.*

and used it to derive hardness of approximation results for various computational problems. As we have seen these instances are typically unsatisfiable; the problem of interest is thus to recognize efficiently the rare satisfiable instances of the distribution.

A variant of this problem was studied in [FMV06], where WP was proven to be effective in finding solutions of dense planted random formulas (the planted distribution is the uniform distribution conditioned on being satisfied by a given assignment). More precisely, [FMV06] proves that for α large enough (but independent of N), the following holds with probability $1 - e^{-O(\alpha)}$:

1. WP converges after at most $O(\ln N)$ iterations.
2. If a variable i has $\hat{h}_i \neq 0$, then the sign of \hat{h}_i is equal to the value of σ_i in the planted assignment. The number of such variables is bigger than $N(1 - e^{-O(\alpha)})$ (i.e. almost all variables can be reconstructed from the values of \hat{h}_i).

⁶<http://www.ictp.trieste.it/~zecchina/SP>

3. Once these variables are fixed to their correct assignments, the remaining formula can be satisfied in time $O(N)$ (in fact, it is a tree formula).

On the basis of non-rigorous statistical mechanics methods, these results were argued in [AMZ07] to remain true when the planted distribution is replaced by the uniform distribution conditioned on being satisfiable. In other words by iterating WP for a number of iterations bigger than $O(\ln N)$ one is able to detect the rare satisfiable instances at large α . The argument is based on the similarity of structure between the two distributions at large α , namely the existence of a single, small cluster of solutions where almost all variables are frozen to a given value. This correspondence between the two distributions of instances was proven rigorously in [COKV], where it was also shown that a related polynomial algorithm succeeds with high probability in finding solutions of the satisfiable distribution of large enough density α .

These results indicate that a stronger form of hypothesis 1, obtained by replacing *always* with *with probability p* (with respect to the uniform distribution over the formulas and possibly to some randomness built in the algorithm), is wrong for any $p < 1$. However, the validity of hypothesis 1 is still unknown for random 3-SAT instances. Nevertheless, this result is interesting because it is one of the rare cases in which the performances of a message-passing algorithm could be analyzed in full detail.

22.6. Conclusion

This review was mainly dedicated to the random k -Satisfiability and k -Xor-Satisfiability problems; the approach and results we presented however extend to other random decision problems, in particular random graph q -coloring. This problem consists in deciding whether each vertex of a graph can be assigned one out of q possible colors, without giving the same color to the two extremities of an edge. When input graphs are randomly drawn from Erdős-Renyi (ER) ensemble $G(N, p = c/N)$ a phase diagram similar to the one of k -SAT (Section 22.3) is obtained. There exists a colorable/uncolorable phase transition for some critical average degree $c_s(q)$, with for instance $c_s(3) \simeq 4.69$ [KPW04]. The colorable phase also exhibits the clustering and condensation transitions [ZK07] we explained on the example of the k -Satisfiability. Actually what seems to matter here is rather the structure of inputs and the symmetry properties of the decision problem rather than its specific details. All the above considered input models share a common, underlying ER random graph structure. From this point of view it would be interesting to ‘escape’ from the ER ensemble and consider more structured graphs e.g. embedded in a low dimensional space.

To what extent the similarity between phase diagrams correspond to similar behaviour in terms of hardness of resolution is an open question. Consider the case of rare satisfiable instances for the random k -SAT and k -XORSAT well above their sat/unsat thresholds (Section 22.5). Both problems share very similar statistical features. However, while a simple message-passing algorithm allows one to easily find a (the) solution for the k -SAT problem this algorithm is inefficient for random k -XORSAT. Actually the local or decimation-based algorithms

of Sections 22.4 and 22.5 are efficient to find solution to rare satisfiable instances of random k -SAT [BHL⁺02], but none of them works for random k -XORSAT (while the problem is in P!). This example raises the important question of the relationship between the statistical properties of solutions (or quasi-solutions) encoded in the phase diagram and the (average) computational hardness. Very little is known about this crucial point; on intuitive grounds one could expect the clustering phenomenon to prevent an efficient solving of formulas by local search algorithms of the random walk type. This is indeed true for a particular class of stochastic processes [MS06b], those which respect the so-called detailed balance conditions. This connection between clustering and hardness of resolution for local search algorithms is much less obvious when the detailed balance conditions are not respected, which is the case for most of the efficient variants of PRWSAT.

Chapter 23

MaxSAT, Hard and Soft Constraints

Chu Min Li and Felip Manyà

23.1. Introduction

MaxSAT is an optimization version of SAT which consists in finding an assignment that maximizes the number of satisfied clauses. It is an NP-hard problem that has shown a remarkable activity in the SAT community over the past few years, where some SAT solving techniques have been adapted to MaxSAT and incorporated into contemporary MaxSAT solvers. Examples of such SAT solving techniques include lazy data structures, variable selection heuristics, unsatisfiable core extraction, non-chronological backtracking and clause learning.

SAT solvers provide little information on unsatisfiable instances; they just report that no solution exists. However, assignments violating a minimum number of constraints, or satisfying all the hard constraints and as many soft constraints as possible, can be considered acceptable solutions in real-life scenarios. To cope with this limitation of SAT, MaxSAT, and in particular weighted MaxSAT and Partial MaxSAT, are becoming an alternative for naturally representing and efficiently solving over-constrained problems.

There are two approaches to solving MaxSAT: approximation and heuristic algorithms, which compute near-optimal solutions, and exact algorithms, which compute optimal solutions. Heuristic algorithms are fast and do not provide any guarantee about the quality of their solutions, while approximation algorithms are not so fast but provide a guarantee about the quality of their solutions.

Regarding exact algorithms, we distinguish between SAT-based algorithms and branch-and-bound algorithms. SAT-based algorithms solve MaxSAT by solving a sequence of SAT instances and are presented in a separate chapter of this handbook. The solving techniques that implement branch-and-bound algorithms are the main focus of this chapter, and are explained in detail in subsequent sections.

Nowadays, we count with remarkable results on theoretical, logical and algorithmic aspects of MaxSAT solving. Moreover, the existence of a MaxSAT evaluation, which is held annually since 2006, has been decisive for developing new MaxSAT technology and applications.

The structure of the chapter is as follows. In Section 23.2, we introduce background definitions. In Section 23.3, we present the branch and bound scheme and explain how this scheme can be improved with good quality lower bounds, clever variable selection heuristics and suitable data structures. In Section 23.4, we survey the complete logical calculus for MaxSAT defined so far, which are based on resolution and tableaux. In Section 23.5, we review the main MaxSAT approximation algorithms. In Section 23.6, we present the MaxSAT Evaluation. In Section 23.7, we review other contributions to MaxSAT that have appeared in the literature. In Section 23.8, we survey the works on MinSAT, which is the dual problem of MaxSAT. In Section 23.9, we give the conclusions and point out some future research directions.

23.2. Preliminaries

In propositional logic, a variable x_i may take values 0 (for false) or 1 (for true). A literal l_i is a variable x_i or its negation \bar{x}_i . The complementary of literal l_i is x_i if $l_i = \bar{x}_i$, and is \bar{x}_i if $l_i = x_i$. A clause is a disjunction of literals, and a CNF formula is a multiset of clauses. In MaxSAT, we represent CNF formulas as multisets of clauses instead of sets of clauses because duplicated clauses cannot be collapsed into one clause. For instance, the multiset $\{x_1, \bar{x}_1, \bar{x}_1, x_1 \vee x_2, \bar{x}_2\}$, where a clause is repeated, has a minimum of two unsatisfied clauses.

A weighted clause is a pair (C_i, w_i) , where C_i is a disjunction of literals and w_i , its weight, is a positive number, and a weighted CNF formula is a multiset of weighted clauses. The length of a (weighted) clause is the number of its literals. The size of (weighted) CNF formula ϕ , denoted by $|\phi|$, is the sum of the length of all its clauses.

An assignment of truth values to the propositional variables satisfies a literal x_i if x_i takes the value 1 and satisfies a literal \bar{x}_i if x_i takes the value 0, satisfies a clause if it satisfies at least one literal of the clause, and satisfies a CNF formula if it satisfies all the clauses of the formula. An empty clause, denoted by \square , contains no literals and cannot be satisfied. An assignment for a CNF formula ϕ is complete if all the variables occurring in ϕ have been assigned; otherwise, it is partial.

The MaxSAT problem for a CNF formula ϕ is the problem of finding an assignment that maximizes the number of satisfied clauses. In this sequel we often use the term MaxSAT meaning MinUNSAT. This is because, with respect to exact computations, finding an assignment that minimizes the number of unsatisfied clauses is equivalent to finding an assignment that maximizes the number of satisfied clauses. Notice that an upper (lower) bound in MinUNSAT is greater (smaller) than or equal to the minimum number of clauses that can be unsatisfied by an interpretation. MaxSAT is called Max- k SAT when all the clauses have at most k literals per clause.

MaxSAT instances ϕ_1 and ϕ_2 are equivalent if ϕ_1 and ϕ_2 have the same number of unsatisfied clauses for every complete assignment of ϕ_1 and ϕ_2 .

We will also consider three extensions of MaxSAT which are more well-suited for representing and solving over-constrained problems: Weighted MaxSAT, Partial MaxSAT, and weighted Partial MaxSAT.

The weighted MaxSAT problem for a weighted CNF formula ϕ is the problem of finding an assignment that maximizes the sum of weights of satisfied clauses (or equivalently, that minimizes the sum of weights of unsatisfied clauses).

The Partial MaxSAT problem for a CNF formula, in which some clauses are declared to be *relaxable* or *soft* and the rest are declared to be *non-relaxable* or *hard*, is the problem of finding an assignment that satisfies all the hard clauses and the maximum number of soft clauses.

The weighted Partial MaxSAT problem is the combination of Partial MaxSAT and weighted MaxSAT. In weighted Partial MaxSAT, soft clauses are weighted, and solving a weighted Partial MaxSAT instance amounts to find an assignment that satisfies all the hard clauses and maximizes the sum of weights of satisfied soft clauses (or equivalently, that minimizes the sum of weights of unsatisfied soft clauses).

Notice that MaxSAT could be defined as weighted MaxSAT restricted to formulas whose clauses have weight 1, and as Partial MaxSAT in the case that all the clauses are declared to be soft.

Finally, we introduce the integer linear programming (ILP) formulation of weighted MaxSAT, which is used to compute lower bounds and upper bounds. Let $\phi = \{(C_1, w_1), \dots, (C_m, w_m)\}$ be a weighted MaxSAT instance over the propositional variables x_1, \dots, x_n . With each propositional variable x_i , we associate a variable $y_i \in \{0, 1\}$ such that $y_i = 1$ if variable x_i is true and $y_i = 0$, otherwise. With each clause C_j , we associate a variable $z_j \in \{0, 1\}$ such that $z_j = 1$ if clause C_j is satisfied and $z_j = 0$, otherwise. Let I_j^+ be the set of indices of unnegated variables in clause C_j , and let I_j^- be the set of indices of negated variables in clause C_j . The ILP formulation of the weighted MaxSAT instance ϕ is defined as follows:

$$\max F(y, z) = \sum_{j=1}^m w_j z_j$$

subject to

$$\sum_{i \in I_j^+} y_i + \sum_{i \in I_j^-} (1 - y_i) \geq z_j \quad j = 1, \dots, m$$

$$y_i \in \{0, 1\} \quad i = 1, \dots, n$$

$$z_j \in \{0, 1\} \quad j = 1, \dots, m$$

Assume now that, with each clause C_j , we associate a variable $z_j \in \{0, 1\}$ such that $z_j = 1$ if clause C_j is unsatisfied and $z_j = 0$, otherwise. Then, the ILP formulation of the minimization version of weighted MaxSAT (i.e.; weighted MinUNSAT) for the instance ϕ is defined as follows:

$$\min F(y, z) = \sum_{j=1}^m w_j z_j$$

subject to

$$\sum_{i \in I_j^+} y_i + \sum_{i \in I_j^-} (1 - y_i) + z_j \geq 1 \quad j = 1, \dots, m$$

$$y_i \in \{0, 1\} \quad i = 1, \dots, n$$

$$z_j \in \{0, 1\} \quad j = 1, \dots, m$$

The linear programming (LP) relaxation of both formulations is obtained by allowing the integer variables to take real values in $[0, 1]$.

Ansótegui and Gabàs [AG13] reported an extensive empirical investigation that indicates that solving MaxSAT instances by translating them into ILP and applying a Mixed Integer Programming (MIP) solver is competitive on crafted instances.

Weighted Partial MinSAT for an instance ϕ is the problem of finding an assignment in which the sum of the weights of the satisfied soft clauses is minimal, and all the hard clauses are satisfied. Weighted MinSAT is Weighted Partial MinSAT when there are no hard clauses. Partial MinSAT is Weighted Partial MinSAT when all the soft clauses have the same weight. MinSAT is Partial MinSAT when there are no hard clauses.

23.3. Branch and Bound Algorithms

There are competitive exact MaxSAT solvers—as the ones developed by [AH14a, AMP03, AMP05, AMP08, HLO08, Kue10, LHdG08, LMP07, LS07, LSL08, PPC⁺08, RG07, SZ04, XZ04, XZ05, ZSM03]—that implement variants of the following branch and bound (BnB) scheme for solving the minimization version of MaxSAT: Given a MaxSAT instance ϕ , BnB explores the search tree that represents the space of all possible assignments for ϕ in a depth-first manner. At every node, BnB compares the upper bound (UB), which is the best solution found so far for a complete assignment, with the lower bound (LB), which is the sum of the number of clauses which are unsatisfied by the current partial assignment plus an underestimation of the number of clauses that will become unsatisfied if the current partial assignment is completed. If $LB \geq UB$, the algorithm prunes the subtree below the current node and backtracks chronologically to a higher level in the search tree. If $LB < UB$, the algorithm tries to find a better solution by extending the current partial assignment by instantiating one more variable. The optimal number of unsatisfied clauses in the input MaxSAT instance is the value that UB takes after exploring the entire search tree.

Figure 23.1 shows the pseudo-code of a basic solver for MaxSAT. We use the following notation:

- $simplifyFormula(\phi)$ is a procedure that transforms ϕ into an equivalent and simpler instance by applying inference rules.
- $\#emptyClauses(\phi)$ is a function that returns the number of empty clauses in ϕ .
- LB is a lower bound of the minimum number of unsatisfied clauses in ϕ if the current partial assignment is extended to a complete assignment. We assume that its initial value is 0.
- $underestimation(\phi)$ is a function that returns an underestimation of the minimum number of non-empty clauses in ϕ that will become unsatisfied if the current partial assignment is extended to a complete assignment.

Require: $MaxSAT(\phi, UB)$: A MaxSAT instance ϕ and an upper bound UB

- 1: $\phi \leftarrow simplifyFormula(\phi)$;
- 2: **if** $\phi = \emptyset$ or ϕ only contains empty clauses **then**
- 3: return $\#emptyClauses(\phi)$;
- 4: **end if**
- 5: $LB \leftarrow \#emptyClauses(\phi) + underestimation(\phi)$;
- 6: **if** $LB \geq UB$ **then**
- 7: return UB ;
- 8: **end if**
- 9: $x \leftarrow selectVariable(\phi)$;
- 10: $UB \leftarrow \min(UB, MaxSAT(\phi_x, UB))$;
- 11: return $\min(UB, MaxSAT(\phi_{\bar{x}}, UB))$;

Ensure: The minimal number of unsatisfied clauses in ϕ

Figure 23.1. A basic branch and bound algorithm for MaxSAT

- UB is an upper bound of the number of unsatisfied clauses in an optimal solution. An elementary initial value for UB is the total number of clauses in the input formula, or the number of clauses which are unsatisfied by an arbitrary interpretation. Another alternative is to solve the LP relaxation of the ILP formulation of the input instance and take as upper bound the number of unsatisfied clauses in the interpretation obtained by rounding variable y_i , for $1 \leq i \leq n$, to an integer solution in a randomized way by interpreting the values of $y_i \in [0, 1]$ as probabilities (set propositional variable x_i to true with probability y_i , and set propositional variable x_i to false with probability $1 - y_i$). Nevertheless, most of the solvers take as initial upper bound the number of unsatisfied clauses that can be detected by executing the input formula in a local search solver during a short period of time.
- $selectVariable(\phi)$ is a function that returns a variable of ϕ following an heuristic.
- ϕ_x ($\phi_{\bar{x}}$) is the formula obtained by setting the variable x to true (false); i.e., by applying the one-literal rule to ϕ using the literal x (\bar{x}).

Modern MaxSAT solvers implement the basic algorithm augmented with powerful inference techniques, good quality lower bounds, clever variable selection heuristics, and efficient data structures. Partial MaxSAT solvers are also augmented with learning of hard clauses, and non-chronological backtracking.

23.3.1. Improving the Lower Bound with Underestimations

The simplest method to compute a lower bound, when solving the minimization version of MaxSAT, consists in just counting the number of clauses which are unsatisfied by the current partial assignment [BF99]. One step forward is to incorporate an underestimation of the number of clauses that will become unsatisfied if the current partial assignment is extended to a complete assignment. The most basic method was defined by Wallace and Freuder [WF96]:

$$LB(\phi) = \#emptyClauses(\phi) + \sum_{x \text{ occurs in } \phi} \min(ic(x), ic(\bar{x})),$$

where ϕ is the CNF formula associated with the current partial assignment, and $ic(x)$ ($ic(\bar{x})$) —inconsistency count of x (\bar{x})— is the number of unit clauses of ϕ that contain \bar{x} (x). In other words, that underestimation is the number of disjoint inconsistent subformulas in ϕ formed by a unit clause with a literal l and a unit clause with the complementary of l .

Lower bounds dealing with longer clauses include the star rule and UP. In the star rule [SZ04, AMP04], the underestimation of the lower bound is the number of disjoint inconsistent subformulas of the form $\{l_1, \dots, l_k, \bar{l}_1 \vee \dots \vee \bar{l}_k\}$. When $k = 1$, the star rule is equivalent to the inconsistency counts of Wallace and Freuder.

In UP [LMP05], the underestimation of the lower bound is the number of disjoint inconsistent subformulas that can be detected with unit propagation. UP works as follows: It applies unit propagation until a contradiction is derived. Then, UP identifies, by inspecting the implication graph, a subset of clauses from which a unit refutation can be constructed, and tries to identify new contradictions from the remaining clauses. The order in which unit clauses are propagated has a clear impact on the quality of the lower bound [LMP06].

UP can be enhanced with failed literal detection as follows: Given a MaxSAT instance ϕ and a variable x occurring positively and negatively in ϕ , UP is applied to both $\phi \wedge \{x\}$ and $\phi \wedge \{\bar{x}\}$. If UP derives a contradiction from $\phi \wedge \{x\}$ and another contradiction from $\phi \wedge \{\bar{x}\}$, then the union of the two inconsistent subsets identified by UP, once we have removed the unit clauses x and \bar{x} , is an inconsistent subset of ϕ . UP enhanced with failed literal detection does not need the occurrence of unit clauses in the input formula for deriving a contradiction. While UP only identifies unit refutations, UP enhanced with failed literal detection identifies non-unit refutations too. Since applying failed literal detection to every variable is time consuming, it is applied to a reduced number of variables in practice [LMP06].

MaxSAT solvers like ahmaxsat [AH14a], MaxSatz [LMP07], and Mini-MaxSat [HLO08] apply either UP or UP enhanced with failed literal detection. Nowadays, UP-based lower bounds are the prevailing approach to computing underestimations in branch-and-bound MaxSAT solvers. This technique has also been applied to solve the maximum clique problem [JLM17, LFX13, LJM17, LJX15, LQ10].

Darras et al. [DDDL07] developed a version of UP in which the computation of the lower bound is made more incremental by saving some of the small size disjoint inconsistent subformulas detected by UP. They avoid to redetect the saved inconsistencies if they remain in subsequent nodes of the proof tree, and are able to solve some types of instances faster. Lin et al. [LSL08] defined an improved version of UP that, besides being incremental, guarantees that the lower bound computed at a node of the search tree is not smaller than the lower bound computed at the parent of that node. Abramé and Habet [AH14c] proposed an improved implementation of UP in ahmaxsat that undoes propagations in a non-chronological order and can produce smaller inconsistent subsets. Shen and Zhang [SZ04] defined a lower bound, called LB4, which is similar to UP but restricted to Max-2SAT instances and using a static variable ordering.

A variant of UP enhanced with failed literal detection was implemented in the solver akmaxsat [Kue10]. It can be the case that UP derives a contradiction

from $\phi \wedge \{l\}$ but not from $\phi \wedge \{\bar{l}\}$. In fact, this shows that \bar{l} follows from ϕ . If ϕ' is the result of applying UP to $\phi \wedge \{\bar{l}\}$, then the algorithm tries to find another failed literal l' in ϕ' . If UP derives a contradiction from both $\phi \wedge \{l'\}$ and $\phi \wedge \{\bar{l}'\}$, the algorithm stops and identifies an inconsistent subset. If UP derives a contradiction from $\phi \wedge \{l'\}$ but not from $\phi \wedge \{\bar{l}'\}$, the same process is repeated on the formula resulting of applying UP to $\phi \wedge \{\bar{l}'\}$ until an inconsistent subset is detected or no more failed literals can be found.

Another approach to computing underestimation is based on first reducing the MaxSAT instance to be solved to an instance of another problem, and then solve a relaxation of the obtained instance. For example, the solvers Clone [PD07, PPC⁺08] and SR(w) [RG07], reduce MaxSAT to the minimum cardinality problem. Since the minimum cardinality problem is NP-hard for a CNF formula ϕ and can be solved in time linear in the size of a deterministic decomposable negation normal form (d-DNNF) compilation of ϕ , Clone and SR(w) solve the minimum cardinality problem of a d-DNNF compilation of a relaxation of ϕ . The worst-case complexity of a d-DNNF compilation of ϕ is exponential in the treewidth of its constraint graph, and Clone and SR(w) obtain a relaxation of ϕ with bounded treewidth by renaming different occurrences of some variables.

Xing and Zhang [XZ05] reduce the MaxSAT instance to the ILP formulation of the minimization version of MaxSAT (c.f. Section 23.2), and then solve the LP relaxation. An optimal solution of the LP relaxation provides an underestimation of the lower bound because the LP relaxation is less restricted than the ILP formulation. In practice, they apply that lower bound computation method only to nodes containing unit clauses. If each clause in the MaxSAT instance has more than one literal, then $y_i = \frac{1}{2}$ for all $1 \leq i \leq n$ and $z_j = 0$ for all $1 \leq j \leq m$ is an optimal solution of the LP relaxation. In this case, the underestimation is 0. Nevertheless, LP relaxations do not seem to be as competitive as the rest of approaches.

23.3.2. Improving the Lower Bound with Inference

Another approach to improve the quality of the lower bound consists in applying inference rules that transform a MaxSAT instance ϕ into an *equivalent* but simpler MaxSAT instance ϕ' . In the best case, inference rules produce new empty clauses in ϕ' that allow to increment the lower bound. In contrast with the empty clauses derived when computing underestimations, the empty clauses derived with inference rules do not have to be recomputed at every node of the current subtree so that the lower bound computation is more incremental.

A MaxSAT inference rule is *sound* if it transforms an instance ϕ into an equivalent instance ϕ' . It is not sufficient to preserve satisfiability as in SAT, ϕ and ϕ' must have the same number of unsatisfied clauses for every possible assignment. Unfortunately, unit propagation, which is the most powerful inference technique applied in DPLL-style SAT solvers, is unsound for MaxSAT as the next example shows: The set of clauses $\{x_1, \bar{x}_1 \vee x_2, \bar{x}_1 \vee \bar{x}_2, \bar{x}_1 \vee x_3, \bar{x}_1 \vee \bar{x}_3\}$ has a minimum of one unsatisfied clause (setting x_1 to false), but two empty clauses are derived by applying unit propagation.

MaxSAT inference rules are also called *transformation rules* in the literature

because the premises of the rule are replaced with the conclusion when a rule is applied. If the conclusion is added to the premises as in SAT, the number of clauses which are unsatisfied by an assignment might increase.

The amount of inference enforced by existing BnB MaxSAT solvers at each node of the proof tree is poor compared with the inference enforced by DPLL-style SAT solvers. The simplest inference enforced, when branching on a literal l , consists in applying the one-literal rule: The clauses containing l are removed from the instance and the occurrences of \bar{l} are removed from the clauses in which \bar{l} appears, but the existing unit clauses and the new unit clauses derived as a consequence of removing the occurrences of \bar{l} are not propagated as in unit propagation. That inference is typically enhanced with the MaxSAT inference rules described in the rest of this section.

First, we present simple inference rules that have proved to be useful in a number of solvers [AMP03, AMP05, BF99, SZ04, XZ05], and then some more sophisticated inferences rules which are implemented in solvers like ahmaxsat [AH14a], akmaxsat [Kue10], MaxSatz [LMP07], and MiniMaxSat [HLO08]. Some simple inference rules are:

- The pure literal rule [BF99]: If a literal only appears with either positive or negative polarity in a MaxSAT instance, all the clauses containing that literal are removed.
- The dominating unit clause rule [NR00]: If the number of clauses (of any length) in which a literal l appears is not greater than the number of unit clauses in which \bar{l} appears, all the clauses containing l and all the occurrences of \bar{l} are removed.
- The complementary unit clause rule [NR00]: If a MaxSAT instance contains a unit clause with the literal l and a unit clause with the literal \bar{l} , these two clauses are replaced with one empty clause.
- The almost common clause rule [BR99]: If a MaxSAT instance contains a clause $x \vee D$ and a clause $\bar{x} \vee D$, where D is a disjunction of literals, then both clauses are replaced with D . In practice, this rule is applied when D contains at most one literal.

The resolution rule applied in SAT (i.e., derive $D \vee D'$ from $x \vee D$ and $\bar{x} \vee D'$) preserves satisfiability but not equivalence, and therefore cannot be applied to MaxSAT instances, except for some particular cases like the almost common clause rule. We refer the reader to Section 23.4 for a complete resolution calculus for MaxSAT, and devote the rest of this section to present some sound MaxSAT resolution rules that can be applied in polynomial time.

We start by presenting the *star rule*: If $\phi_1 = \{l_1, \bar{l}_1 \vee \bar{l}_2, l_2\} \cup \phi'$, then $\phi_2 = \{\square, l_1 \vee l_2\} \cup \phi'$ is equivalent to ϕ_1 . This rule, which can be seen as the inference counterpart of the underestimation of the same name, can also be presented as follows:

$$\left\{ \begin{array}{l} l_1 \\ \bar{l}_1 \vee \bar{l}_2 \\ l_2 \end{array} \right\} \Longrightarrow \left\{ \begin{array}{l} \square \\ l_1 \vee l_2 \end{array} \right\} \quad (23.1)$$

Notice that the rule detects a contradiction from $l_1, \bar{l}_1 \vee \bar{l}_2, l_2$ and, therefore,

replaces these clauses with an empty clause. In addition, the rule adds the clause $l_1 \vee l_2$ to ensure the equivalence between ϕ_1 and ϕ_2 . For any assignment containing either $l_1 = 0, l_2 = 1$, or $l_1 = 1, l_2 = 0$, or $l_1 = 1, l_2 = 1$, the number of unsatisfied clauses in $\{l_1, \bar{l}_1 \vee \bar{l}_2, l_2\}$ is 1, but for any assignment containing $l_1 = 0, l_2 = 0$, the number of unsatisfied clauses is 2. Notice that even when any assignment containing $l_1 = 0, l_2 = 0$ is not the best assignment for the subset $\{l_1, \bar{l}_1 \vee \bar{l}_2, l_2\}$, it can be the best for the whole formula. By adding $l_1 \vee l_2$, the rule ensures that the number of unsatisfied clauses in ϕ_1 and ϕ_2 is also the same when $l_1 = 0, l_2 = 0$.

This rule can be generalized in such a way that it captures unit resolution refutations in which clauses and resolvents are used exactly once:

$$\left\{ \begin{array}{c} l_1 \\ \bar{l}_1 \vee l_2 \\ \bar{l}_2 \vee l_3 \\ \dots \\ \bar{l}_k \vee l_{k+1} \\ \bar{l}_{k+1} \end{array} \right\} \Longrightarrow \left\{ \begin{array}{c} \square \\ l_1 \vee \bar{l}_2 \\ l_2 \vee \bar{l}_3 \\ \dots \\ l_k \vee \bar{l}_{k+1} \end{array} \right\} \quad (23.2)$$

The last two rules consume two unit clauses for deriving one contradiction. Next, we define two inference rules that capture unit resolution refutations in which (i) exactly one unit clause is consumed, and (ii) the unit clause is used twice in the derivation of the empty clause. The second rule is a combination of the first rule with a linear derivation.

$$\left\{ \begin{array}{c} l_1 \\ \bar{l}_1 \vee l_2 \\ \bar{l}_1 \vee l_3 \\ \bar{l}_2 \vee \bar{l}_3 \end{array} \right\} \Longrightarrow \left\{ \begin{array}{c} \square \\ l_1 \vee \bar{l}_2 \vee \bar{l}_3 \\ \bar{l}_1 \vee l_2 \vee l_3 \end{array} \right\} \quad (23.3)$$

$$\left\{ \begin{array}{c} l_1 \\ \bar{l}_1 \vee l_2 \\ \bar{l}_2 \vee l_3 \\ \dots \\ \bar{l}_k \vee l_{k+1} \\ \bar{l}_{k+1} \vee l_{k+2} \\ \bar{l}_{k+1} \vee l_{k+3} \\ \bar{l}_{k+2} \vee \bar{l}_{k+3} \end{array} \right\} \Longrightarrow \left\{ \begin{array}{c} \square \\ l_1 \vee \bar{l}_2 \\ l_2 \vee \bar{l}_3 \\ \dots \\ l_k \vee \bar{l}_{k+1} \\ l_{k+1} \vee \bar{l}_{k+2} \vee \bar{l}_{k+3} \\ \bar{l}_{k+1} \vee l_{k+2} \vee l_{k+3} \end{array} \right\} \quad (23.4)$$

MaxSatz implements the almost common clause rule, Rule 23.1, Rule 23.2, Rule 23.3 and Rule 23.4. Some of these rules are also applied in the solvers *ahmaxsat* and *akmaxsat*.

Independently and in parallel to the definition of the rules of MaxSatz, similar inference rules were defined for weighted MaxSAT by Heras and Larrosa [LH05, HL06], and were implemented in Max-DPLL [LHdG08]. These rules were inspired by the soft local consistency properties defined in the constraint programming community [dGLMS03]. The rules implemented in Max-DPLL are the almost common clause rule, chain resolution and cycle resolution. Chain resolution,

which allows one to derive a new empty clause, is defined as follows:

$$\left\{ \begin{array}{l} (l_1, w_1), \\ (\bar{l}_i \vee l_{i+1}, w_{i+1})_{1 \leq i < k}, \\ (\bar{l}_k, w_{k+1}) \end{array} \right\} \Longrightarrow \left\{ \begin{array}{l} (l_i, m_i - m_{i+1})_{1 \leq i \leq k}, \\ (\bar{l}_i \vee l_{i+1}, w_{i+1} - m_{i+1})_{1 \leq i < k}, \\ (l_i \vee \bar{l}_{i+1}, m_{i+1})_{1 \leq i < k}, \\ (\bar{l}_k, w_{k+1} - m_{k+1}), \\ (\square, m_{k+1}) \end{array} \right\} \quad (23.5)$$

where w_i , $1 \leq i \leq k+1$, is the weight of the corresponding clause, and $m_i = \min(w_1, w_2, \dots, w_i)$. Chain resolution is equivalent to Rule 23.2 if it is applied to unweighted MaxSAT.

Cycle resolution, which allows one to derive a new unit clause and whose application is restricted to $k = 3$ in Max-DPLL, is defined as follows:

$$\left\{ \begin{array}{l} (\bar{l}_i \vee l_{i+1}, w_i)_{1 \leq i < k}, \\ (\bar{l}_1 \vee \bar{l}_k, w_k) \end{array} \right\} \Longrightarrow \left\{ \begin{array}{l} (\bar{l}_1 \vee l_i, m_{i-1} - m_i)_{2 \leq i \leq k}, \\ (\bar{l}_i \vee l_{i+1}, w_i - m_i)_{2 \leq i < k}, \\ (\bar{l}_1 \vee l_i \vee \bar{l}_{i+1}, m_i)_{2 \leq i < k}, \\ (l_1 \vee \bar{l}_i \vee l_{i+1}, m_i)_{2 \leq i < k}, \\ (\bar{l}_1 \vee \bar{l}_k, w_k - m_k), \\ (\bar{l}_1, m_k) \end{array} \right\} \quad (23.6)$$

An analysis of the impact of cycle resolution on the performance of MaxSAT solvers can be found in [LMMP08, LMMP09, LMMP10].

A more general inference scheme is implemented in MiniMaxSat [HLO07, HLO08]. It detects a contradiction with unit propagation and identifies an unsatisfiable subset. Then, it creates a refutation for that unsatisfiable subset and applies the MaxSAT resolution rule defined in Section 23.4 if the size of the largest resolvent in the refutation is smaller than 4.

The lower bound computation methods based on unit propagation represent the different derivations of unit clauses in a graph, called implication graph [LMP07]. Looking at that graph, solvers identify the clauses which are involved in the derivation of a contradiction. In contemporary MaxSAT solvers, this graph is also used to decide whether the clauses involved in a contradiction match with the premises of the above mentioned inference rule.

Abramé and Habet [AH15b] showed that in some cases it is better not to apply MaxSAT resolution to certain inconsistent subsets of clauses because the transformations derived do not allow to detect further inconsistent subsets. They also showed that in other cases further inconsistent subsets can be detected if MaxSAT resolution is applied locally [AH14b].

23.3.3. Variable Selection Heuristics

Most of the exact MaxSAT solvers incorporate variable selection heuristics that take into account the number of literal occurrences in such a way that each occurrence has an associated weight that depends on the length of the clause that contains the literal. MaxSAT heuristics give priority to literals occurring in binary clauses instead of literals occurring in unit clauses as SAT heuristics do.

Let us see as an example the variable selection heuristic of MaxSatz [LMP07]: Let $neg1(x)$ ($pos1(x)$) be the number of unit clauses in which x is negative (positive), $neg2(x)$ ($pos2(x)$) be the number of binary clauses in which x is negative (positive), and let $neg3(x)$ ($pos3(x)$) be the number of clauses containing three or more literals in which x is negative (positive). MaxSatz selects the variable x such that $(neg1(x) + 4 * neg2(x) + neg3(x)) * (pos1(x) + 4 * pos2(x) + pos3(x))$ is the largest. Once a variable x is selected, MaxSatz applies the following value selection heuristic: If $neg1(x) + 4 * neg2(x) + neg3(x) < pos1(x) + 4 * pos2(x) + pos3(x)$, set x to true; otherwise, set x to false. The solver `ahmaxsat` [AH14a] implements a variant of this variable selection heuristic.

Earlier MaxSAT solvers (AMP [AMP03], Lazy [AMP05], MaxSolver [XZ05], Max-DPLL [LHdG08], ...) incorporate variants of the two-sided Jeroslow rule that give priority to variables occurring often in binary clauses. MaxSolver changes the weights as the search proceeds.

23.3.4. Data Structures

Data structures for SAT have been naturally adapted to MaxSAT. We can divide the solvers into two classes: solvers like `ahmaxsat`, `akmaxsat` and MaxSatz representing formulas with adjacency lists, and solvers like Lazy and MiniMaxSat which use data structures with watched literals. Lazy data structures are particularly good when there is a big number of clauses; for example, in Partial MaxSAT solvers with clause learning.

23.4. Complete Inference in MaxSAT

23.4.1. MaxSAT Resolution

A natural extension to MaxSAT of the resolution rule applied in SAT was defined by Larrosa and Heras [LH05]:

$$\frac{\begin{array}{c} x \vee A \\ \bar{x} \vee B \end{array}}{\frac{A \vee B}{x \vee A \vee \bar{B}}} \\ \bar{x} \vee \bar{A} \vee B$$

However, two of the conclusions of this rule are not in clausal form, and the application of distributivity results into an unsound rule: Assume that $A = a_1$, and $B = b_1 \vee b_2$. Then, the interpretation that assigns false to x and a_1 , and true to b_1 and b_2 satisfies one clause from the premises ($x \vee a_1$) and unsatisfies two clauses from the conclusion of the rule ($x \vee a_1 \vee \bar{b}_1, x \vee a_1 \vee \bar{b}_2$). Since the rule does not preserve the number of unsatisfied clauses, it is unsound.

Independently and in parallel, Bonet et al. [BLM06, BLM07], and Heras and Larrosa [HL06] defined a sound version of the previous rule with the conclusions in clausal form:

$$\begin{array}{c}
x \vee a_1 \vee \cdots \vee a_s \\
\overline{x} \vee b_1 \vee \cdots \vee b_t \\
\hline
a_1 \vee \cdots \vee a_s \vee b_1 \vee \cdots \vee b_t \\
x \vee a_1 \vee \cdots \vee a_s \vee \overline{b_1} \\
x \vee a_1 \vee \cdots \vee a_s \vee b_1 \vee \overline{b_2} \\
\cdots \\
x \vee a_1 \vee \cdots \vee a_s \vee b_1 \vee \cdots \vee b_{t-1} \vee \overline{b_t} \\
\overline{x} \vee b_1 \vee \cdots \vee b_t \vee \overline{a_1} \\
\overline{x} \vee b_1 \vee \cdots \vee b_t \vee a_1 \vee \overline{a_2} \\
\cdots \\
\overline{x} \vee b_1 \vee \cdots \vee b_t \vee a_1 \vee \cdots \vee a_{s-1} \vee \overline{a_s}
\end{array}$$

This inference rule concludes, apart from the conclusion where a variable has been cut, some additional clauses that contain one of the premises as subclause. We say that the rule *cuts* the variable x . The tautologies concluded by the rule are removed, and the repeated literals in a clause are collapsed into one.

Notice that an instance of MaxSAT resolution not only depends on the two premises and the cut variable (like in resolution), but also on the order of the literals in the premises. Notice also that, like in resolution, this rule concludes a new clause not containing the variable x , except when this clause is a tautology.

Bonet et al. [BLM06, BLM07] proved the completeness of MaxSAT resolution: By *saturating* successively w.r.t. all the variables, one derives as many empty clauses as the minimum number of unsatisfied clauses in the MaxSAT input instance. Saturating w.r.t. a variable amounts to apply the MaxSAT resolution rule to clauses containing that variable until every possible application of the inference rule only introduces clauses containing that variable (since tautologies are eliminated). Once a MaxSAT instance is saturated w.r.t. a variable, all the clauses containing that variable are not considered to saturate w.r.t. another variable. We refer to [BLM07] for further technical details and for the weighted version of the rule.

We consider the multiset of clauses $\phi = \{\overline{x}_1, x_1 \vee x_2, x_1 \vee x_3, \overline{x}_3\}$ to illustrate how a variable saturation algorithm works. We start by considering variable x_1 and resolve the first two clauses, obtaining $\{x_2, \overline{x}_1 \vee \overline{x}_2, x_1 \vee x_3, \overline{x}_3\}$. We then resolve the second and third clause and get a saturation of ϕ w.r.t. x_1 : $\{x_2, \overline{x}_2 \vee x_3, \overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3, x_1 \vee x_2 \vee x_3, \overline{x}_3\}$. From now on, we only consider the clauses not containing x_1 : $C_1 = \{x_2, \overline{x}_2 \vee x_3, \overline{x}_3\}$, and ignore the clauses containing x_1 : $\{\overline{x}_1 \vee \overline{x}_2 \vee \overline{x}_3, x_1 \vee x_2 \vee x_3\}$. We continue by resolving the first two clauses of C_1 ; we get $\{x_3, x_2 \vee \overline{x}_3, \overline{x}_3\}$, which is a saturation of C_1 w.r.t. x_2 . Hence, $C_2 = \{x_3, \overline{x}_3\}$ is the resulting multiset of clauses not containing x_2 and ignore $\{x_2 \vee \overline{x}_3\}$, which is the multiset of clauses containing x_2 . Finally, we resolve $\{x_3, \overline{x}_3\}$ and get the empty clause. Since all the variables have been saturated, the minimum number of unsatisfied clauses in ϕ is 1.

The use of restrictions of MaxSAT resolution has not been limited to branch-and-bound solvers. Narodytska and Bacchus [NB14] used MaxSAT resolution in SAT-based MaxSAT solvers, avoiding the use of cardinality constraints and obtaining very competitive results on industrial instances.

There exists no polynomial-size resolution proof of the pigeon hole principle (PHP). However, Ignatiev et al. [IMM17] showed that there exist polynomial-size MaxSAT resolution proofs of PHP if PHP is encoded as a Partial MaxSAT instance using the dual rail encoding. Indeed, the combination of the dual rail encoding and MaxSAT resolution is a stronger proof system than either general resolution or conflict-driven clause learning [BBI⁺18].

MaxSAT resolution has been extended to the multiple-valued clausal forms known as signed CNF formulas [BHM00]. The defined signed MaxSAT resolution rules are complete and provide a logical framework for weighted constraint satisfaction problems (WCSP) [ABLM07b]. Besides, some restrictions of the rules enforce the defined local consistency properties for WCSPs in a natural way [ABLM07a, ABLM13].

23.4.2. Clause MaxSAT Tableaux

The clause SAT tableau calculus [D'A99, Häh01], which is unsound for MaxSAT, was reformulated to become a sound and complete MaxSAT calculus [LMS16b]. Roughly speaking, the main differences are that the extension rule is applied in a branch until all its clauses have been expanded regardless of the contradictions already detected in that branch, and that clauses and literals cannot be used more than once in a branch.

A clause MaxSAT tableau for a multiset of clauses $\phi = \{C_1, \dots, C_m\}$ is a tree with a finite number of branches whose nodes are labelled with clauses that are declared to be either active or inactive in each branch. It is constructed by a sequence of applications of the following rules:

Initialize: A tree with a single branch with m nodes such that each node is labelled with a clause of ϕ is a clause MaxSAT tableau for ϕ . Such a tableau is called initial tableau and its clauses are declared to be active.

Extension: Given a clause MaxSAT tableau T for ϕ , a branch B of T , and a node of B labelled with an active clause $l_1 \vee \dots \vee l_r$ with $r \geq 2$, the tableau obtained by creating r sibling nodes below B and labelling each node with a different unit clause from $\{l_1, \dots, l_r\}$ is a clause MaxSAT tableau for ϕ . Clause $l_1 \vee \dots \vee l_r$ becomes inactive in the new branches, and unit clauses l_1, \dots, l_r are declared to be active.

Contradiction: Given a clause MaxSAT tableau T for ϕ , a branch B of T , and two nodes of B labelled with two active unit clauses l and \bar{l} , the tableau obtained by appending a node labelled with an empty clause below B is a clause MaxSAT tableau for ϕ . The empty clause becomes active and unit clauses l and \bar{l} become inactive.

A clause MaxSAT tableau is completed when all its branches are saturated, in the sense that all its active clauses are empty and unit clauses, and the contradiction rule cannot be further applied in any branch. The cost of a branch in a completed tableau T is the number of empty clauses in it, and the cost of T is the minimum cost among all its branches.

The soundness and completeness of the clause MaxSAT tableau calculus states that the minimum number of clauses that can be unsatisfied in a multiset of clauses ϕ is k iff the cost of a completed clause MaxSAT tableau for ϕ

is k . Thus, the systematic construction of a completed clause MaxSAT tableau for ϕ provides an exact method for MaxSAT, and each completed tableau is a proof.

Figure 23.2. A completed clause MaxSAT tableau for $\phi = \{\bar{x}_1, \bar{x}_2, \bar{x}_3, x_1 \vee x_2, x_1 \vee x_3, x_2 \vee x_3\}$.

Figure 23.2 shows a completed clause MaxSAT tableau T for the multiset of clauses $\phi = \{\bar{x}_1, \bar{x}_2, \bar{x}_3, x_1 \vee x_2, x_1 \vee x_3, x_2 \vee x_3\}$. The saturated branches of the tableau have cost 2 except for branches 3 and 6 (counting from left to right) that have cost 3. The active clauses in each branch are: $\{\square, \square, x_1, \bar{x}_3\}$ (branch 1), $\{\square, \square, x_1, \bar{x}_2\}$ (branch 2), $\{\square, \square, \square\}$ (branch 3), $\{\square, \square, \bar{x}_2, x_3\}$ (branch 4), $\{\square, \square, x_2, \bar{x}_3\}$ (branch 5), $\{\square, \square, \square\}$ (branch 6), $\{\square, \square, \bar{x}_1, x_2\}$ (branch 7), and $\{\square, \square, \bar{x}_1, x_3\}$ (branch 8). Therefore, the minimum number of unsatisfied clauses in ϕ is 2.

Inspired on the previous calculus, as well as in the clause MinSAT calculus defined in [LMS16a], Argelich et al. [ALMS18] defined a proof procedure that implements a sound and complete clause tableau-style calculus for both MaxSAT and MinSAT. The expansion rules preserves adequately the number of unsatisfied clauses in the generated subproblems. The leaf nodes of a completed tableau contain a number of empty clauses ranging between the minimum and the maximum number of unsatisfied clauses in the input formula, and there is at least one branch with the minimum value and at least one branch with the maximum value.

Casas-Roma et al. [CHM17] defined a complete natural deduction calculus for MaxSAT which was inspired on the previous clause MaxSAT tableau calculus.

23.5. Approximation Algorithms

Heuristic local search algorithms¹ are often quite effective at finding near-optimal solutions. Actually, most of the exact MaxSAT solvers use a local search algorithm to compute an initial upper bound. However, these algorithms, in contrast with approximation algorithms, do not come with rigorous guarantees concerning the quality of the final solution or the required maximum runtime. Informally, an algorithm approximately solves an optimization problem if it always returns a feasible solution whose measure is close to optimal, for example, within a factor bounded by a constant or by a slowly growing function of the input size. Given a constant α , an algorithm is an α -approximation algorithm for a maximization (minimization) problem if it provides a feasible solution in polynomial time which is at least (most) α times the optimum, considering all the possible instances of the problem.

The first MaxSAT approximation algorithm, with a performance guarantee of $\frac{1}{2}$, is a greedy algorithm that was devised by Johnson in 1974 [Joh74]. This result was improved in 1994 by Yannakakis [Yan94], and Goemans and Williamson [GW94b], who described $\frac{3}{4}$ -approximation algorithms for MaxSAT. Then, Goemans and Williamson [GW94b] proposed a .878-approximation algorithm for Max2SAT (which gives a .7584-approximation for MaxSAT [GW95]) based on semidefinite programming [GW94a]. Since then other improvements have been achieved, but there is a limit on approximability: Hastad [Has97] proved that, unless $P = NP$, no approximation algorithm for MaxSAT (even for Max3SAT) can achieve a performance guarantee better than $\frac{7}{8}$. Interestingly, Karloff and Zwick [KZ97] gave a $\frac{7}{8}$ approximation algorithm for Max3SAT, showing that the constant $\frac{7}{8}$ is tight. The most promising approaches from a theoretical and practical point of view are based on semidefinite programming [GvHL06]. We refer the reader to the survey of Anjos [Anj05] to learn more about how to approximate MaxSAT with semidefinite programming.

23.6. The MaxSAT Evaluation

The MaxSAT Evaluation [ALMP08, ALMP11a, ALMP11b] is an affiliated event of the International Conference on Theory and Applications of Satisfiability Testing. It has been held annually since 2006 and has been decisive for promoting and advancing MaxSAT solving.

The main goals of the MaxSAT Evaluation are to assess the state of the art in the field of MaxSAT solvers, collect and re-distribute a heterogeneous MaxSAT benchmark set for further scientific evaluations, and promote MaxSAT as a viable option for solving instances of a wide range of NP-hard optimization problems. In the beginning, only exact solvers were evaluated. Ultimately, an evaluation of non-exact solvers is also conducted.

Until 2016, the MaxSAT Evaluation had the random, crafted and industrial categories and the unweighted MaxSAT, weighted MaxSAT, partial MaxSAT and weighted partial MaxSAT tracks. Since 2017, it has two tracks: unweighted and

¹We do not include a section about local search and MaxSAT because there is a chapter on local search in the handbook.

weighted. The unweighted track combines the industrial and crafted unweighted and unweighted partial MaxSAT categories from previous MaxSAT evaluations. Purely randomly generated instances are not included. The weighted track combines the industrial and crafted weighted and weighted partial MaxSAT categories from previous MaxSAT evaluations. All benchmarks contain soft clauses with different weights. Purely randomly generated instances are not included.

We refer the reader to <https://maxsat-evaluations.github.io/2018/> for additional information and the results of the last edition of the MaxSAT Evaluation.

23.7. Other Contributions to MaxSAT

First of all, we should mention a variety of applications of MaxSAT in a range of real-world domains as diverse as bioinformatics [GL12, MAGL11], circuit design and debugging [SMV⁺07], community detection in complex networks [JMRS17], diagnosis [DG12], FPGA routing [XRS03], planning [ZB12], scheduling [BGSV15], team formation [MNRS17] and time tabling [AN14], among many others.

Other research topics that have appeared in the literature and contain substantial contributions to the field of MaxSAT solving include the definition of clause clause learning schemes in branch-and-bound solvers [AH16, AM06b] that are not yet competitive enough to solve industrial instances, the creation of robust MaxSAT solutions [BBMV13], the definition of efficient encodings from MaxCSP to MaxSAT [ACLM12], the extension of MaxSAT to many-valued logic [ALM17] and the definition of MaxSAT formalisms that deal with blocks of soft clauses instead of individual soft clauses [AM06a, HMM15].

23.8. The MinSAT Problem

Given the success of MaxSAT, the community has started to look into MinSAT. At first sight, one could think that the solving techniques and encodings to be used in MinSAT are very similar to the ones used in MaxSAT and, therefore, that there is no need of investigating MinSAT from a problem solving perspective. However, most of the research conducted so far indicates that they may be quite different, as well as that the performance profile of MaxSAT and MinSAT is also different for several optimization problems represented into these formalisms [ALMZ14, IMM14, LZMS12]. It is also worth mentioning that MinSAT is meaningful for both satisfiable and unsatisfiable instances, whereas MaxSAT is only meaningful for unsatisfiable instances. A closely related problem has been analyzed in [IMPMS13, IMPM16].

The work on MinSAT for solving optimization problems may be divided into the following categories:

- Transformations between MinSAT and MaxSAT: Reductions from MinSAT to partial MaxSAT were defined in [LMQZ10], but these reductions do not generalize to weighted partial MinSAT. This drawback was overcome with the definition of the natural encoding [K12], which was improved in [ZLMA12]. Reductions of weighted partial MinSAT to Group MaxSAT were evaluated in [HMPMS12].

- Encodings from weighted MaxCSP to MinSAT: Efficient encodings were defined in [ALMZ13]. Using the MaxSAT direct encoding [ACLM12], we must add one clause for every no-good, while using the MinSAT direct encoding [ALMZ13], we must instead add one clause for every good. This implies, for instance, that for representing the constraint $X = Y$, we need a number of clauses linear in the domain size in MinSAT, and a quadratic number of clauses in MaxSAT. We are in the opposite situation if we want to represent the constraint $X \neq Y$. So, it seems that MaxSAT and MinSAT could be complementary in some scenarios [ALMZ13].
- Complete logical calculi: MaxSAT resolution is sound for MinSAT but to get completeness the elimination of variables must be defined differently [LM15]. After saturating a variable x , the clauses containing the variable x are ignored in MaxSAT but, in MinSAT, the resulting clauses of eliminating the occurrences of both x and \bar{x} must also be considered in the saturation of the next variable. In this way, after saturating all the variables, the number of empty clauses derived is equal to the maximum number of clauses that can be unsatisfied. In the case of clause tableaux, the clause MaxSAT calculus is unsound for MinSAT because the extension rule does not preserve the maximum number of unsatisfied clauses. A sound and complete clause MinSAT calculus was defined in [LMS16a].
- MinSAT solvers: The only existing branch-and-bound MinSAT solver, MinSatz [LZMS11, LZMS12], is based on MaxSatz and implements upper bounds that exploit clique partition algorithms and MaxSAT technology. There exist two SAT-based MinSAT solvers of this class [ALMZ12, HMPMS12]. They differ with SAT-based MaxSAT solvers in the way of relaxing soft clauses. A local search MinSAT solver was described in [AH15a].

23.9. Conclusions

We have presented an overview about MaxSAT and focused on the solving techniques that have proved to be useful in terms of performance. When we wrote the chapter on MaxSAT for the first edition of this handbook, MaxSAT solving was still an incipient research topic but nowadays can be considered a mature research topic with a variety of applications and also of open problems.

From the perspective of branch-and-bound MaxSAT solvers, the main challenge is to build a solver as competitive as SAT-based MaxSAT solvers on industrial instances. A first step in this direction could be the definition of a powerful clause learning mechanism for soft clauses. From a logical perspective, an interesting research avenue is the study of the proof complexity of logical calculi for MaxSAT to find proof systems more efficient than the proof systems used in SAT solving. From a knowledge representation perspective, an interesting research path is to find clever encodings of combinatorial optimization problems and understand the impact of modeling on the performance of MaxSAT solvers, as well as the definition of richer formalisms like non-clausal MaxSAT.

Chapter 24

Maximum Satisfiability

Fahiem Bacchus, Matti Järvisalo, and Ruben Martins

Maximum satisfiability (MaxSAT) is an optimization version of SAT that is solved by finding an optimal truth assignment instead of just a satisfying one. In MaxSAT the objective function to be optimized is specified by a set of weighted soft clauses: the objective value of a truth assignment is the sum of the weights of the soft clauses it satisfies. In addition, the MaxSAT problem can have hard clauses that the truth assignment must satisfy. Many optimization problems can be naturally encoded into MaxSAT and this, along with significant performance improvements in MaxSAT solvers, has led to MaxSAT being used in a number of different application areas. This chapter provides a detailed overview of the approaches to MaxSAT solving that have in recent years been most successful in solving real-world optimization problems. Further recent developments in MaxSAT research are also overviewed, including encodings, applications, preprocessing, incomplete solving, algorithm portfolios, partitioning-based solving, and parallel solving.

24.1. Introduction

Computational problems that arise from real-world application scenarios often involve constraints that specify the feasible solutions and some notion of cost or goodness associated with the different solutions. Whereas satisfiability (SAT) provides no direct way of distinguishing solutions in terms of their cost or goodness, maximum satisfiability (MaxSAT for short) generalizes SAT with a over the solutions. This cost function is specified by a set of soft clauses with weights: the cost of a solution is the sum of the weights of the soft clauses it fails to satisfy. (Equivalently, the objective value of a solution is the sum of the weights of the soft clauses it satisfies.)

MaxSAT was for most of its history used mainly as a theoretical problem in the analysis of the computational complexity of optimization problems. Within the last decade, however, with the rise of increasingly effective MaxSAT solving techniques and solver implementations, MaxSAT has changed from a theoretical formalism into a viable constraint optimization paradigm. The approach of encoding various NP-hard optimization problems into MaxSAT and then utilizing

MaxSAT solvers has proved to be a viable solution technique capable of efficiently solving problems from a variety of domains. These domains include combinatorics, planning and scheduling, verification, security and software management, data analysis and machine learning, knowledge representation, and bioinformatics, among others. Many problems from these domains have natural propositional encodings on which MaxSAT is particularly effective, often more effective than other constraint optimization paradigms such as integer programming (see, e.g., [BJ17] and the results of [BJM14] in comparison with those of [PFL14]). Section 24.3.2 discusses some of these applications of MaxSAT and provides references to the relevant literature.

A series of MaxSAT evaluations [ALMP08, HLG08, ALMP11, ABJM17, BJM18, BJM19], running yearly since 2006 has supported the development of increasingly robust and efficient MaxSAT solvers containing new algorithmic insights. The evaluations provide a yearly snapshot of the current state of the art in MaxSAT solving, and also provide standard benchmark sets for the scientific evaluation of new algorithmic ideas for MaxSAT. The evaluation series is focused on complete MaxSAT solving, i.e., approaches that provide optimal solutions. Recently, however, the evaluations have also added a track for incomplete solvers, with the motivation of developing approaches which can rapidly find good—though not necessarily optimal—solutions.

Complementing Chapter 23, where various branch-and-bound approaches to MaxSAT solving are described (e.g., [HLO08, LMMP10]), the focus of this chapter is on recent algorithmic advances in MaxSAT solving. In particular, we overview MaxSAT solving approaches that utilize iterative SAT solver calls, namely, the model-improving, the core-guided, and the implicit hitting set approaches to MaxSAT solving, which at the time this chapter was written constitute the main algorithmic approaches for solving large MaxSAT instances arising from real-world domains.

The model-improving approach is based on querying a SAT solver for a solution of lower cost until the solution cost can no longer be improved. Cardinality constraints (Section 24.4.2.1) are used to force the SAT solver to find a lower cost solution. The core-guided and implicit hitting set approaches iteratively query a SAT solver for unsatisfiable cores, which are subsets of soft clauses of which at least one must be falsified by any solution. In the core-guided approaches, these cores are used to construct cardinality constraints that allow the SAT solver to falsify one, but no more than one, soft clause from each core. If the problem remains unsatisfiable, a new core will be found and in the next call the SAT solver will be additionally allowed to falsify one, but no more than one, soft clause of this new core. Eventually, no more cores will be found, i.e., the problem will become satisfiable and the solution returned by the SAT solver will falsify one soft clause from each core. Since every solution must falsify at least one soft clause from every core the returned solution will be optimal.

In the implicit hitting set approach cardinality constraints are not used, which in practice makes the SAT solver calls faster. Rather a minimum-cost hitting set of the accumulated set of cores is computed. The cost of this hitting set provides a lower bound on the cost of optimal solutions, as every solution must incur the cost of at least one soft clause from every core (i.e., it must falsify at least one soft

clause from every core). The SAT solver is then asked to find a solution satisfying all of the soft clauses not in the computed hitting set. If it succeeds that solution must be optimal as it will have a cost equal to the lower bound; and if it does not it will find another core, augmenting the set of cores, and a new hitting set can be computed.

These two approaches rely on assumption-based SAT solving to extract cores when no satisfying solution can be found. Assumption-based SAT solving will be described in Section 24.4.1.2; for further details various aspects of modern SAT solvers we refer the interested reader to Chapter 4.

Beyond overviewing these recent algorithmic advances, we also overview some of the recent successful applications of MaxSAT solving, and briefly discuss some further advances in the field, including preprocessing, parallel solving, and incomplete solving.

In the rest of this chapter, we first formalize the MaxSAT problem. Then using this formalism we discuss some encoding techniques that can be used when one wants to encode different problems into MaxSAT, and give an overview of a range of different application problems that have been solved by encoding to MaxSAT and using MaxSAT solvers (Section 24.3). With this motivation of the usefulness of MaxSAT, we turn to the bulk of the chapter: a presentation of recent algorithmic techniques for solving MaxSAT, preceded by some additional needed background (Section 24.4). Finally, we close the chapter with a discussion of other recent developments (Section 24.5) and a summary and outlook on MaxSAT.

24.2. The MaxSAT Formalism

As with SAT, in MaxSAT we deal exclusively with propositional formulas expressed in conjunctive normal form (CNF): each propositional variable and its negation are **literals**; a clause is a disjunction of literals; and a CNF formula is a conjunction of clauses. Since duplicated disjuncts and conjuncts can be discarded a clause can also be viewed as being a set of literals, and a CNF formula as being a set of clauses.

Given a CNF formula F we use $\text{var}(F)$ to denote the set of propositional variables appearing in F . A truth assignment π for F assigns to a truth value (*true* or *false*) to each propositional variable $p \in \text{var}(F)$. For a literal l , π makes l *true* ($\pi \models l$) if l is the variable p and $\pi(p) = \text{true}$ or if l is $\neg p$ and $\pi(p) = \text{false}$. For a clause c , π satisfies c ($\pi \models c$) if π makes at least one of the literals l in c *true*; and π **satisfies** F (or is a model of F) ($\pi \models F$), if it satisfies every clause of F . Given a set of propositional variables $A \subseteq \text{var}(F)$, and a truth assignment π for F we denote the **restriction** of π to A by $\pi|_A$; $\pi|_A$ is a new truth assignment identical to π but only assigning truth values to the variables of A .

A MaxSAT formula F is a CNF formula that is partitioned into hard and soft clauses: $F = \text{hard}(F) \cup \text{soft}(F)$. The hard clauses must be satisfied, while the soft clauses can be falsified at a cost. In particular, each soft clause $c \in \text{soft}(F)$ has an associated positive integral weight $w(c)$ specifying the cost of falsifying that clause.¹ For example, $F = \{(x, y), (\neg x, r, z), (\neg x)_2, (\neg y)_5\}$ is a

¹It is possible to generalize the framework to accommodate rational valued weights, and

MaxSAT formula where the first two clauses are hard and the third and fourth clauses are soft with weights 2 and 5 respectively. We will use subscripted clauses to indicate that they are soft, where the subscript is the soft clause's weight.

A **feasible solution** of F is a truth assignment to the variables of F , $v r (F)$, that satisfies $h rd(F)$. The cost of a feasible solution π of F is the sum of the weights of the soft clauses it falsifies: $o (\pi, F) = \sum_{\{c|c \in soft(F) \wedge \pi \not\models c\}} w (c)$. When F is clear from the context we often write just $o (\pi)$ to denote $o (\pi, F)$.

An **optimal solution** π of F is a feasible solution with minimum cost: $o (\pi, F) \leq o (\pi', F)$ for all feasible solutions π' of F . An optimal solution could equivalently be defined as a feasible solution *satisfying a maximum weight of soft clauses*. We will also use $o (F)$ to denote the cost of an optimal solution of F , and if H is a set of soft clauses $o (H)$ to denote the sum of the weights of its clauses $\sum_{c \in H} w (c)$.

Definition 1 (The MaxSAT problem). Given a MaxSAT formula F find one of its optimal solutions.

Note that F has feasible solutions if and only if $h rd(F)$ is satisfiable. Thus F will have some optimal solutions if and only if $h rd(F)$ is satisfiable. *In the rest of this chapter, we will assume that $h rd(F)$ is satisfiable.* In practice, one can check the satisfiability of $h rd(F)$ with a SAT solver prior to searching for an optimal solution. In fact, such a check is the first step of many MaxSAT algorithms.

Another useful concept is that of a **core**. In SAT, a core is defined to be an unsatisfiable subset of the input formula. In MaxSAT, since the hard clauses must always be satisfied, it is more useful to define a core as follows.

Definition 2 (MaxSAT core). Given a MaxSAT formula F , any subset K of $o (F)$ such that $K \cup h rd(F)$ is unsatisfiable, is a **core** of F . That is, K is a core if and only if every feasible solution of F falsifies at least one soft clause of K .

Historically, restricted forms of MaxSAT have been defined. In particular, a *partial* MaxSAT formula F is one in which $h rd(F)$ is non-empty and a *unweighted* MaxSAT formula F is one in which all the soft clauses have the same weight (which, without loss of generality, can be assumed to be one). Thus four different types of MaxSAT formulas were traditionally recognized: (1) unweighted MaxSAT, (2) weighted MaxSAT, (3) unweighted partial MaxSAT, and (4) weighted partial MaxSAT. The definition given above corresponds to the most general case (4). In recent years the importance of these distinctions has faded as most MaxSAT solvers can handle the most general input. It is still the case, however, that whether or not the instance is weighted or unweighted has an impact on which algorithms perform better. Hence, the yearly MaxSAT evaluations use different tracks for weighted and unweighted instances.

some MaxSAT solvers (e.g., the implicit hitting set solvers described in Section 24.4.6) can solve problems containing soft clauses with floating point weights.

24.3. Encodings and Applications

Significant performance improvements in MaxSAT algorithms over the years have led to an increasing number of applications of MaxSAT. To provide the reader with a better sense of the practical usefulness of MaxSAT, we first review some of these applications as well as some of the encoding techniques often applied to translate optimization problems into MaxSAT.

24.3.1. Encodings

Boolean optimization problems that can be expressed with linear constraints and a single optimization function are well-suited to be encoded and solved by MaxSAT solvers. However, it can be the case where the problem requires solving a multi-objective optimization function, or that the problem requires soft constraints to be modeled as a group of soft clauses instead of individual soft clauses. In those cases, MaxSAT can still be used with the encodings described in Sections 24.3.1.1 and 24.3.1.2, respectively. Moreover, problems that are originally encoded in different declarative optimization languages and approaches, such as MaxCSP, MinSAT, and pseudo-Boolean constraints can also be translated into MaxSAT, as overviewed in Section 24.3.1.3.

24.3.1.1. Boolean Multilevel Optimization

The class of Boolean optimization problems that can be represented using multi-objective functions with a predefined hierarchy of importance over the objective functions is known as *Boolean multilevel optimization (BMO)* [MAGL11].

Definition 3 (Boolean multilevel optimization). Boolean multilevel optimization (BMO) problems [MAGL11] consist of a set of sets of soft clauses $C = \{C_1, \dots, C_m\}$, where $\{C_1, \dots, C_m\}$ forms a partition of C , and each clause $c \in C_i$ has the same weight w_i . A MaxSAT formula is an instance of BMO if and only if the following condition holds:

$$w_i > \sum_{i+1 \leq j \leq m} w_j |C_j| \quad \text{with } i = 1, \dots, m-1.$$

In words, in BMO problems it is more valuable to satisfy a single soft clause in the set C_i than to falsify all soft clauses in the subsequent sets C_{i+1}, \dots, C_m .

Example 1. Consider the instance

$$F = \{(\neg x_1, x_2), (\neg x_1, x_4), (\neg x_1, \neg x_5), (\neg x_3, x_2, x_4), \\ (\neg x_1)_1, (\neg x_2)_1, (\neg x_3)_1, (\neg x_4)_1, (\neg x_5)_1\}.$$

Assume that instead of all soft clauses having the same priority, the user wants to give priority to satisfying some of the soft clauses over others. For example, say the user wants to solve a multilevel optimization problem where they have three objectives specified by $O_1 = \{(\neg x_1)\}$, $O_2 = \{(\neg x_2)\}$, and $O_3 = \{(\neg x_3), (\neg x_4), (\neg x_5)\}$,

with O_1 being strictly more important than O_2 and O_2 being strictly more important than O_3 . This problem can be solved with MaxSAT by associating suitable weights to each soft clause.

In this example, considering the formula F and the ordered optimization objectives O_1, O_2 and O_3 we would transform F into F^{BMO} by associating all soft clauses in O_3 with the weight 1. All soft clauses in O_2 with the weight equal to the sum of the weights of the soft clauses in O_3 plus 1 ($3 + 1 = 4$). Soft clauses in O_1 will have the weight 8 which corresponds to the sum of the weights of the soft clauses in O_2 and O_3 plus 1 ($3 + 4 + 1 = 8$). The intuition behind these weights is that the cost of falsifying a single soft clause in O_1 is greater than falsifying all soft clauses in O_2 and O_3 . Therefore, these costs capture the lexicographical order between the objective functions: $O_1 > O_2 > O_3$. We arrive at the instance

$$F^{\text{BMO}} = \{(\neg x_1, x_2), (\neg x_1, x_4), (\neg x_1, \neg x_5), (\neg x_3, x_2, x_4), \\ (\neg x_1)_8, (\neg x_2)_4, (\neg x_3)_1, (\neg x_4)_1, (\neg x_5)_1\}.$$

F^{BMO} can be solved using MaxSAT and the optimal solution to this problem corresponds to the optimal solution to the multilevel optimization problem described by the ordered objectives O_1, O_2 and O_3 .

24.3.1.2. Group MaxSAT

Some applications may require achieving more complex soft constraints that can only be represented with a set (or group) of clauses. In this case, the soft constraint is only satisfied if *all* of the clauses used to represent it are satisfied; i.e., the cost of the soft constraint will be incurred if any of its clauses are falsified. These kinds of soft clauses give rise to the *group MaxSAT* problem [HMM15]. In group MaxSAT there are k soft constraints where the i soft constraint is encoded by a group G_i of clauses. The goal in group MaxSAT is to find a solution that satisfies all hard clauses while maximizing the total weight of the satisfied soft constraints.

Group MaxSAT formulas can be transformed into an equivalent MaxSAT formulas by using specific encodings. One of these encodings is known as the \top -encoding [HMM15]. We refer the reader interested in other encodings of group MaxSAT to [HMM15].

Definition 4 (\top -encoding [HMM15]). A group MaxSAT instance F^{G} can be transformed into an equivalent MaxSAT instance F by adding all hard clauses from F^{G} to F . Let the i 'th soft constraint, with weight w_i , be represented by the group of soft clauses $G_i = c_1, \dots, c_k$. For each $c \in G_i$ we add the hard clause $(c \vee r_i)$ to F where r_i is a brand new variable. Finally, for each group G_i , we include the soft clause $(\neg r_i)_{w_i}$ to F .

Example 2. Consider the group MaxSAT instance

$$F^{\text{G}} = \{(\neg x_1, x_2), (\neg x_1, x_5), (\neg x_1, \neg x_4), (\neg x_3, x_2, x_4)\},$$

where

$$G_1 = (\{(\neg x_3), (\neg x_4), (\neg x_5)\})_2,$$

$$G_2 = (\{(\neg x_2), (\neg x_1)\})_3.$$

This formula can be transformed into an equivalent MaxSAT formula F by using the \top -encoding, resulting in

$$F = \{(\neg x_1, x_2), (\neg x_1, x_5), (\neg x_1, \neg x_4), (\neg x_3, x_2, x_4),$$

$$(\neg x_3, r_1), (\neg x_4, r_1), (\neg x_5, r_1), (\neg x_2, r_2), (\neg x_1, r_2)$$

$$(\neg r_1)_2, (\neg r_2)_3\}.$$

Note that the number of soft clauses of the transformed MaxSAT formula corresponds to the number of groups in the original group MaxSAT instance.

24.3.1.3. Encoding other Constraint Optimization Languages to MaxSAT

The algorithmic advances of MaxSAT make it appealing to encode problems from other domains into MaxSAT and solve them with MaxSAT solvers.

For example, other optimization problems such as the maximum constraint satisfaction problem (MaxCSP) [ACLM12] and minimum satisfiability (MinSAT) [ZLMA12, LZMS12] can be reduced to MaxSAT and solved with MaxSAT solvers.

Even decision problems such as SAT can be reduced to Horn MaxSAT by using the dual-rail encoding [IMM17]. This reduction coupled with MaxSAT resolution (Section 24.4.1.1.2) constitutes a proof system that has polynomial-time refutations for pigeonhole formulas. We refer the interested reader to [MIM17] for more examples of reductions of decision and optimization problems into Horn MaxSAT.

A common reduction is to transform a pseudo-Boolean optimization problem to MaxSAT. The interested reader is referred to Chapter 28 for more details on pseudo-Boolean optimization.

Definition 5 (Pseudo-Boolean optimization, PBO). Pseudo-Boolean optimization problems are of the following form:

$$\text{minimize } \sum_{j=1}^n c_j l_j$$

$$\text{subject to } \sum_{j=1}^n a_{ij} l_j \leq b_i \quad \forall i = 1, \dots, m,$$

where $n, m \in \mathbb{N}$ and $a_{ij}, b_i, c_j \in \mathbb{Z}$.

Example 3. Consider the PBO problem instance F^{PBO}

$$\text{minimize } x_1 + x_2 + x_3 + x_4 + x_5$$

$$\text{subject to } \quad \neg x_1 + x_2 \geq 1$$

$$\quad \quad \quad \neg x_1 + x_5 \geq 1$$

$$\quad \quad \quad \neg x_1 + \neg x_4 \geq 1$$

$$\quad \quad \quad \neg x_3 + x_2 + x_4 \geq 1$$

The formula F^{PBO} can be encoded to an equivalent MaxSAT formula F . The constraints are encoded as hard clauses by using appropriate cardinality and pseudo-Boolean encodings 24.4.2.1. The objective function can be encoded as soft clauses: for each literal $c_j x_j$ in the objective function, create a corresponding unit soft clause $(\neg x_j)_{c_j}$.

F^{PBO} is equivalent to the following MaxSAT formula

$$F = \{(\neg x_1, x_2), (\neg x_1, x_5), (\neg x_1, \neg x_4), (\neg x_3, x_2, x_4), \\ (\neg x_3)_1, (\neg x_4)_1, (\neg x_5)_1, (\neg x_2)_1, (\neg x_1)_1\}.$$

Notice that this is the same formula as the one presented in Example 1.

Note, however, that this example has a particularly simple translation to MaxSAT since all of the linear inequalities can be directly represented as clauses. In general, a linear constraint of the form $a_1 x_1 + a_2 x_2 + \dots + a_k x_k \geq t$ would have to be translated to CNF using a pseudo-Boolean constraint encoding (Section 24.4.2.1) which would add multiple clauses to the resultant MaxSAT formula.

24.3.2. Applications

With significant performance improvements in MaxSAT algorithms over the years there has been a corresponding increase in the number and diversity of applications of MaxSAT. Some examples of domains where MaxSAT has been successfully used include planning, scheduling and configuration problems, AI and data analysis problems, combinatorial problems, verification and security, and bioinformatics. We will briefly outline some of these applications and provide references to further details.

24.3.2.1. Planning, Scheduling, and Configuration

Planning problems [ZB12, MBM16] consist of finding a sequence of actions that transform an initial to a final state. These problems can be encoded to MaxSAT to efficiently find solutions that minimize the cost of the actions required to achieve the final state. MaxSAT has also been used to synthesize linear temporal logic (LTL) specifications for robot motion planning and control of autonomous systems in scenarios where specifications may be unrealizable and these can be split into soft and hard specifications [DGT18].

Scheduling problems are widespread and arise in various contexts. MaxSAT has been applied to solving different types of scheduling problems, including course timetabling [DM17, MNRS17, AN14], staff scheduling [DMW17, BGSV15, CHB17], and even wedding seating arrangements [MS17]. The course timetabling problem consists of creating a schedule such that it satisfies various constraints with respect to teachers, rooms, times, lectures and students. These scheduling problems are often solved manually by a school administrator but can be encoded into MaxSAT to lever the algorithmic advances for MaxSAT.

MaxSAT has also been used to solve configuration problems such as finding a pre-production vehicle configuration [MKTR16], solving the package upgradeability problem where the goal is to find new packages to be installed in the current system according to some user preference [ALM09, ABL⁺10b, IJM14], and even for seating arrangements at weddings [MS17].

24.3.2.2. AI and Data Analysis Problems

MaxSAT has been used in a variety of data-oriented AI problems, starting with computing most probable explanations (MPE) [Par02] in Bayesian networks, where the goal is to compute the most likely state of a Bayesian network given observations on a subset of the random variables. MaxSAT has been shown to yield competitive approaches to learning different classes of probabilistic graphical models, including Bayesian network structures with restricted treewidth [BJM14], causal discovery in very generic model spaces [HSJ17], as well as causal structure estimation from time series data [HPJ⁺17]. MaxSAT has also been proposed as an alternative approach to inferring problem-specific cutting planes in a state-of-the-art integer programming approach to Bayesian network structure learning [SMJ15]. Further recent data-oriented applications of MaxSAT include learning explainable decision sets [IPNM18] and interpretable classification rules [MM18], constrained correlation clustering [BJ13, BJ17], and neighborhood-preserving low-dimensional visualization of high-dimensional datasets [BJB⁺14].

Other AI applications, specifically within the area of knowledge representation and reasoning, consist of applying MaxSAT to understand the dynamics of argumentation frameworks [WNJ17, NWJ16a, NWJ16b] and in model-based diagnosis [MJIM15]. Given a model of a system and an input-output observation that is not consistent with the expected behavior, the goal of model-based diagnosis is to identify a subset of components that when removed make the system consistent with the observation. MaxSAT can be used to find the smallest set of components that need to be removed [MJIM15]. In the realm of abstract argumentation, MaxSAT enables efficiently reasoning about different notions of *enforcement*, dealing with smallest changes required to argumentation frameworks in light of knowledge on extensions [WNJ17, NWJ16a] as well as *synthesis* of argumentation frameworks based on negative and positive examples of extensions [NWJ16b].

24.3.2.3. Combinatorial Problems

MaxSAT can also be used to encode and solve many combinatorial problems, such as the Max-Clique problem [LQ10, FLQ⁺14, LJX15] where given a group of vertices, the maximal clique is the largest subset of vertices in which each point is directly connected to every other vertex in the subset.

Other combinatorial problems that have been encoded into MaxSAT include the Steiner tree problem [dOS15], tree-width computation [BJ14] and finding solutions for the maximum quartet consistency problem [MM10].

24.3.2.4. Verification and Security

Another domain with many successful MaxSAT applications is verification and security of software and hardware. For instance, MaxSAT can be used to design and debug circuits [SMV⁺07, CSVMS09, CSMV10, AIMT13, XRS03]. Other examples of applications of MaxSAT to hardware consist in solving the hardware-software partitioning problem which decides during the design phase which parts should be implemented either in hardware or software [TDFDGDJSJ⁺17].

MaxSAT also has many applications in security. For instance, solving the user authorization query problem [WQL09], reconstructing AES key schedule images [LZK16], detecting hardware Trojans [SA18], and maximizing the development assurance level to improve the rigor of the development of software and hardware on aircraft [BDS11]. Another application in security is to find malware in Android applications by maximizing the similarity between a malicious application and the application that is being scanned [FBM⁺17].

MaxSAT has also been used to minimize cascading style sheets (CSS) in order to reduce the size of the code transmitted over the web [HLH19]. Another application is to use MaxSAT for quality of service (QoS) of cloud services where the goal is to minimize the composition of distributed web services while satisfying the user preferences [WJH18, BACF17].

When analyzing software, program analysis tools usually trade precision for scalability and their output often contains undesirable output due to approximations. MaxSAT can be used in a user-guided program analysis setting where the hard clauses capture the soundness of the analysis and soft clauses capture the degrees of approximation and user's preferences [MZNN15a, SZGN17]. Encoding user-guided program analysis into MaxSAT can lead to very large formulas which can be solved by specialized MaxSAT solving algorithms [MZNN15b, ZMNN16].

MaxSAT can also be used for fault localization where the goal is to pinpoint the localization of software bugs [ZWM11, JM11]. In particular, MaxSAT can be used to reduce the error log reported to the programmer and decrease the amount of code that needs to be reviewed. The problem of state-space reduction for non-deterministic visibly pushdown automata can also be encoded into MaxSAT, which can be used to improve the performance of software model-checkers [HST17].

24.3.2.5. Bioinformatics

MaxSAT has applications in many interdisciplinary applications such as bioinformatics. One of these applications is to solve the haplotype inference problem which aims at finding the minimum number of haplotypes which explains a given set of genotypes [GML11, GMLO11].

Other applications within this domain consist of finding generalized Ising models [HKD⁺16], finding the maximum similarity between RNA sequences [Mar17], modeling biological networks representing the interactions between genes [GL12], and even applications in cancer therapy to find faulty areas of the gene regulatory network [LK12].

24.3.2.6. Further Applications

Yet another application of MaxSAT is to improve other constraint solving algorithms. For instance, MaxSAT can be used to restore satisfiability of constraint satisfaction problems (CSPs). By encoding a CSP instance as a MaxSAT instance, one can identify the smallest set of tuples to be removed from the CSP instance to restore satisfiability [LM11]. MaxSAT has also been used to enumerate minimal correction sets (MCS) [MLM13] with the goal of removing a minimal number of clauses such that an unsatisfiable SAT formula becomes satisfiable.

Propagation complete encodings have the property of being able to identify inconsistencies via unit propagation, thus allowing the encoding to be more efficiently solved by SAT solvers. However, this trade-off usually comes at the expense of larger SAT encodings. MaxSAT can be used to compute approximately propagation complete encodings [ER18] which allows conflicts to be detected earlier when using a SAT solver.

24.4. Modern MaxSAT Algorithms

In this section, we provide an overview of the currently most important algorithmic approaches to MaxSAT, focusing on SAT-based approaches: the model-improving approach (based on querying a SAT solver for solutions of increasing quality), the core-guided approach (in its several variants, based on extracting MaxSAT cores and compiling each core into the instance until a satisfying assignment is found), and the implicit hitting set approach (based on accumulating a set of MaxSAT cores and computing a minimum-cost hitting set of the cores until a satisfying assignment for the clauses not in the hitting set is found).

We will not cover branch-and-bound approaches to MaxSAT (e.g., [HLO08, LMMP10]). The interested reader is referred to Chapter 23 for an overview of such approaches. The main feature of the approaches we will present here is that they scale up to much larger problems than branch-and-bound approaches. There do exist small MaxSAT instances with a few hundred variables (e.g., finding largest cuts in random graphs) that branch-and-bound algorithms can solve very quickly (less than ten seconds) while the modern SAT-based MaxSAT algorithms overviewed in this chapter have considerable problem solving (i.e., instances remain unsolved after thousands of seconds). However, branch-and-bound approaches are typically ineffective on instances with more than a thousand variables. Problems from various application areas, including ones described in Section 24.3.2, are usually much larger, typically involving at least ten thousand variables and sometimes as many as millions of variables and clauses.

24.4.1. Background

While details on the MaxSAT formalism were already presented in Section 24.2, in order to properly explain current algorithms for solving MaxSAT we need some further background.

24.4.1.1. Transformations

MaxSAT algorithms rely on certain transformations that can be applied to a MaxSAT formula. There are a number of sound ways to transform a MaxSAT formula F into a new MaxSAT formula F' such that from an optimal solution to F' we can easily obtain an optimal solution for F . Such transformations include simplifying transformations used in preprocessing, and transformations used simply to make it more algorithmically convenient to solve the MaxSAT problem. Preprocessing is discussed in more detail in Section 24.5.1. In this section we present some more basic transformations that are useful for algorithmic convenience (both for MaxSAT solving and for further preprocessing).

24.4.1.1.1. The Blocking Variable Transformation. The blocking variable transformation is used on the input formula by a number of MaxSAT solvers. It transforms an input MaxSAT formula F into an equivalent formula F^b that has only unit soft clauses. Having a single literal ℓ whose truth value encodes the truth value of the soft clause c , allows us to use ℓ as an assumption to the SAT solver (Section 24.4.1.2) and to use ℓ as an input to cardinality constraints used when encoding the cost bound k .

In the F^b transformation, the hard clauses F are unchanged. Each soft clause c_i of F is transformed by adding the negation of a brand new variable b_i ,² adding the resultant extended clause $c_i \vee \neg b_i$ as a new hard clause, and creating a new unit soft clause (b_i) with weight equal to c_i 's weight (c_i 's weight is moved to the new unit soft clause).

Definition 6 (Blocking variable transformation). Given a MaxSAT instance F , F^b is a new MaxSAT instance with:

1. $h\ rd(F^b) = h\ rd(F) \cup \{(c_i \vee \neg b_i) \mid c_i \in o(F)\}$, where each b_i is a new variable called a **blocking** or a **relaxation** variable.
2. $o(F^b) = \{(b_i) \mid b_i \text{ was added in step 1}\}$
3. $w((b_i)) = w(c_i)$ (each new soft clause (b_i) gets the weight of the original $c_i \in o(F)$).

Example 4. If $F = \{(x, \neg y, z), (\neg y, z), (z, y)_{10}, (\neg z)_5\}$, then $F^b = \{(x, \neg y, z), (\neg y, z), (z, y, \neg b_1), (\neg z, \neg b_2), (b_1)_{10}, (b_2)_5\}$.³

F^b has the following useful properties.

1. F^b has only unit soft clauses, so there is a single literal denoting the truth and falsity of each soft clause.
2. If π^b is a feasible solution for F^b then $\pi^b|_{vars(F)}$ is a feasible solution for F with $o(\pi^b, F^b) \geq o(\pi^b|_{vars(F)}, F)$.
3. If π is a feasible solution for F , then we can extend π to π^b , a feasible solution for F^b , with $o(\pi, F) = o(\pi^b, F^b)$.

To illustrate property 2, $\pi^b = \{x, \neg y, z, \neg b_1, \neg b_2\}$ (listing the literals made *true* by π^b) is a feasible solution for F^b from Example 4, and $o(\pi^b, F^b) = 15$. Restricting π^b to $vars(F)$ we obtain $\pi^b|_{vars(F)} = \{x, \neg y, z\}$, which can be seen to be a feasible solution to F with lower cost $o(\pi^b|_{vars(F)}, F) = 5$.

To illustrate property 3, $\pi = \{x, \neg y, z\}$ is a feasible solution of F with $o(\pi, F) = 5$, and we can extend it to be a feasible solution of F^b by setting each b_i to *true* iff $\pi \models c_i$. In this case, we obtain $\pi^b = \{x, \neg y, z, b_1, \neg b_2\}$ with equal cost $o(\pi^b, F^b) = 5$.

Proposition 1. *Properties 2 and 3 hold for the blocking variable transformation.*

²The idea of adding a new variable to a clause so that the new variable encodes the clause's truth value appears in [GW93], but may have been used even earlier.

³For some MaxSAT algorithms it is possible in certain cases to avoid adding a new variable to soft clauses that are already unit [BSJ15b]. This can significantly reduce the number of new variables in the formula F^b making it more efficient to solve.

Proof. To see that property 2 is true, observe the following. If π^b is a feasible solution of F^b it must satisfy all hard clauses of F^b . Hence, π^b satisfies every hard clause of F since $h\text{ rd}(F) \subseteq h\text{ rd}(F^b)$. Since none of the hard clauses of F contain any new b_i variables we also have that $\pi^b|_{\text{vars}(F)}$ satisfies every hard clause of F , and thus $\pi^b|_{\text{vars}(F)}$ is a feasible solution for F . Consider $o(\pi^b|_{\text{vars}(F)}, F)$. This is the sum of the weights of all soft clauses falsified by $\pi^b|_{\text{vars}(F)}$. Let c_i be one of the soft clauses falsified by $\pi^b|_{\text{vars}(F)}$ so that weight $w(c_i)$ is a term in the sum $o(\pi^b|_{\text{vars}(F)}, F)$. Since π^b satisfies the hard clause $(c_i \vee \neg b_i)$ of F^b and $\pi^b|_{\text{vars}(F)}$ falsifies c_i , we must have that $\pi^b \models \neg b_i$. In other words, π^b must falsify the soft clause $(b_i) \in F^b$, which contributes the term $w((b_i)) (= w(c_i))$ to $o(\pi^b, F^b)$. That is, we must have that $o(\pi^b, F^b) \geq o(\pi^b|_{\text{vars}(F)}, F)$.

To see that property 3 is true, let π be a feasible solution for F . We extend π to π^b by setting $\pi^b \models b_i$ if $\pi \models c_i$ and $\pi^b \models \neg b_i$ if $\pi \not\models c_i$. As a result π^b will satisfy all hard clauses of F^b . Also, $o(\pi^b, F^b)$ will include the term $w((b_i))$ if and only if $o(\pi, F)$ includes the term $w(c_i) (= w(b_i))$. Hence $o(\pi, F) = o(\pi^b, F^b)$ \square

Furthermore, properties 2 and 3 imply that the blocking variable transformation MaxSAT equivalence in the following sense.

Proposition 2 (MaxSAT equivalence of F^b). *If π^b is an optimal solution of F^b then $\pi^b|_{\text{vars}(F)}$ is an optimal solution of F .*

Proof. The proposition follows from properties 2 and 3 on the blocking variable transformation. In particular (2) tells us that the cost of an optimal solution to F^b is at least as large as the cost of an optimal solution to F ; and (3) tells us that that is at least as small. \square

This proposition tells us that we can solve a MaxSAT formula F by solving F^b and then simply discarding the truth assignments to the newly introduced variables b_i .

Historically, the idea of adding “relaxation” or “blocking” variables to the soft clauses has been used in all MaxSAT algorithms based on solving a sequence of SAT instances. In the presentation of these algorithms, typically the relaxation variables are introduced at various stages of the algorithm’s execution rather than initially. In practice, however, MaxSAT solvers generally introduce the relaxation variables at the beginning, so as to exploit SAT solving under assumptions to extract cores, or to impose bounds on how many soft clauses can be falsified via cardinality or pseudo-boolean constraints. In general, it is simpler and more uniform to explain these different algorithms as they run in practice—i.e., as they run on F^b rather than as they run on F .

Also typically the positive form of the relaxation variables is added to the clause. So the soft clause $(x, y)_{10}$ would become the hard clause (x, y, b_1) , rather than $(x, y, \neg b_1)$ as we have done here. By adding the negation of the relaxation variable we avoid a potentially confusing polarity flip. In particular, now when b_i is *true* c_i must be satisfied, rather than having $\neg b_i$ imply that c_i must be satisfied.

24.4.1.1.2. Soft Clause Cloning and MaxSAT Resolution. Another transformation that is sometimes used when solving a MaxSAT formula is to split a soft clause c_{m+n} into two soft clauses c_m and c_n . For example, we can replace the single soft clause $(x, \neg y)_{12}$ with the two soft clauses $(x, \neg y)_5$ and $(x, \neg y)_7$. In the literature, this process is called soft clause cloning. It is not difficult to see that the cost of any feasible solution π remains unchanged by soft clause cloning (and hence the optimal solutions are unchanged). This transformation can also be performed in reverse, we can combine the weights of all copies of a soft clause into a single copy. Soft clause cloning is used in many (but not all) MaxSAT algorithms to deal with weighted instances.

Lifting the classical resolution rule to MaxSAT gives rise to a more complex transformation [LH05, BLM07]. The Larrosa and Heras [LH05] transformation is as follows. Given two clauses of the form $(x, A)_{w_1}$ and $(\neg x, B)_{w_2}$ and letting $m = \min(w_1, w_2)$ we can apply a MaxSAT resolution step as follows.

1. Replace the two original clauses $(x, A)_{w_1}$ and $(\neg x, B)_{w_2}$ by their residues:
 $(x, A)_{w_1-m}$ and $(\neg x, B)_{w_2-m}$.
2. Add the resolvent $(A, B)_m$.
3. Add the two compensation clauses $(x, A, \neg B)_m$ and $(\neg x, B, \neg A)_m$.

There are a few things to note. First, any soft clause with weight zero can be removed from the formula—such clauses cannot affect the cost of any feasible solution. Hence, at least one of the residue clauses will vanish. Second, the compensation clauses are not clauses (they contain conjunctions of literals $\neg A$ or $\neg B$). Hence, they have to be converted into a set of clauses, where the size of that set will depend on whether or not new variables are introduced. And third, by treating hard clauses as being soft clauses with infinite weight (e.g., $(x, y) = (x, y)_\infty$), we can apply MaxSAT resolution to combinations of soft and hard clauses.

Since the MaxSAT resolution rule of Larrosa and Heras can generate non-clausal formula it cannot form a proof system. In any proof system for CNF each rule of inference must yield a valid new CNF. Bonet et al. [BLM07] addressed this issue and gave a version of MaxSAT resolution that does yield a new CNF. They also showed that their version of MaxSAT resolution forms a complete proof system: for any MaxSAT instance F there exists a MaxSAT resolution proof that F has optimal cost $o(F)$. MaxSAT resolution has been used as a theoretical underpinning for some MaxSAT algorithms, e.g., PMRes [NB14] and MiniMaxSat [HLO08], but directly implementing MaxSAT resolution to solve MaxSAT does not seem to be practical [MM11].

24.4.1.2. Incremental and Assumption-based SAT Solving for Extracting Cores

An essential technique used in MaxSAT solving is assumption-based SAT solving [ES03] implemented in most modern SAT solvers. When given an input formula F a SAT solver can produce either a satisfying truth assignment or conclude that F is unsatisfiable. Assumption-based SAT solving extends the capacity of the SAT solver by asking it to solve F subject to a set of assumptions A which must be a set of literals. Now the SAT solver must either find a truth assignment satisfying $F \wedge \bigwedge_{\ell \in A} \ell$ (i.e., a truth assignment satisfying F that also makes all of the literals

in A true), or it must conclude that $F \wedge A$ is unsatisfiable. Furthermore, and most critical to MaxSAT solvers, when $F \wedge A$ are unsatisfiable the SAT solver is able to return a clause c such that

1. c contains only negated literals of A , i.e., $A \models \neg c$ (c is a conflict clause over A), and
2. $F \models c$.

The conflict clause c is thus a subset of A that is sufficient to show that no model of F satisfies all of A . In particular any model of F must falsify at least one of the literals of A whose negation is contained in c .

It should be noted that the conflict clause c returned by the SAT solver need not be minimal. That is, there could be another clause $c' \subsetneq c$ satisfying the above two conditions. Hence, if F by itself is unsatisfiable the SAT solver might return any subset of negated literals of A (including possibly the empty clause).

Assumptions can be used to extract cores when the MaxSAT formula contains unit soft clauses (e.g., after the F^b transformation has been applied). In particular, if $(b_1)_{w_1}, \dots, (b_m)_{w_m}$ are the soft clauses of a MaxSAT formula F then using $\{b_1, \dots, b_m\}$ as assumptions in a SAT solve of $h\ rd(F)$ will either result in a model of $h\ rd(F)$ that satisfies all of the soft clauses of F , i.e., a zero-cost model, or it will result in a conflict clause c such that $F \models c$ and $c \subseteq \{\neg b_1, \dots, \neg b_m\}$. That is, the conflict clause c asserts that at least one of the negated b_i literals in it must be true in any feasible model. In other words, c specifies a set of soft clauses at least one of which must be falsified by any feasible model, i.e., a core of F .

Assumptions also play a useful role in *incremental* SAT solving. In many approaches to MaxSAT solving a SAT solver is called on a sequence of problems that are closely related to each other. Each of problems could be solved by invoking a new instance of the SAT solver. However, then information computed during one SAT solver invocation (e.g., learnt clauses) cannot easily be exploited in subsequent solver invocations. The idea of incremental SAT solving is to use only one instance of the SAT solver for all of the problems so that all information computed can be retained for the next problem. In this case, we can monotonically add clauses to the SAT solver or use different sets of assumptions to specify each new problem to be solved. With assumptions we can add or remove certain clauses by adding to those clauses a new literal ℓ . When we assume $\neg \ell$ these clauses become active (added to the problem), and when we assume ℓ these clauses become inactive (removed from the problem).

24.4.2. Approaches based on Sequences of Satisfiability Queries

MaxSAT with weighted soft clauses is known to be in the complexity class FP^{NP} [Pap94]. This means that it can be solved with a polynomial number of calls to an NP-oracle. In particular, a polynomial number of calls to a SAT solver can be used to solve the MaxSAT instance F , with each SAT call determining if F can be satisfied by a feasible solution with cost less than or equal to k , for various values of k . With integer weights, if F can be satisfied with cost k and F cannot be satisfied with cost $k - 1$, then the feasible model achieving cost k must be an optimal solution.

Given the effectiveness of modern SAT solvers, the approach of solving MaxSAT via a sequence of calls to a SAT solver has proved to be both popular and effective. A number of different techniques have been developed for effectively encoding sequences of the following decision problem $\mathcal{D}(F, k)$, for various values of k , into CNF.

Definition 7 (The decision problem $\mathcal{D}(F, k)$). Let $\mathcal{D}(F, k)$ be the decision problem “does a feasible solution of F with cost less than or equal to k exist?”

In particular, we want to encode $\mathcal{D}(F, k)$, into a CNF formula that can be effectively solved by a SAT solver. The key to many of these encoding techniques is the successful exploitation of information returned by the SAT solver when it either determines $\mathcal{D}(F, k)$ to be unsatisfiable or satisfiable. In particular, when $\mathcal{D}(F, k)$ is satisfiable the cost of the model found can be used to determine the next value of k to test; and when the problem is unsatisfiable the returned **core** can be used to add additional constraints to the SAT solver so as to effectively encode $\mathcal{D}(F, k')$ for some value k' larger than k .

MaxSAT solvers using a sequence of SAT queries have been designed in a number of different ways. In this section, we will survey the main MaxSAT algorithms using this approach. First, however we introduce some important features of the CNF encoding of the decision problem “does a feasible solution of F with cost less than or equal to k exist”, since these features affect both the design and effectiveness of the MaxSAT algorithms discussed in this section.

24.4.2.1. Cardinality and Pseudo-Boolean Constraints

Pseudo-Boolean constraints are used to help encode $\mathcal{D}(F, k)$. A pseudo-Boolean constraint over the literals $\{\ell_1, \dots, \ell_m\}$ has the form $a_i \ell_1 + \dots + a_m \ell_m \leq k$ where the a_i and k are integers and the sum is evaluated by regarding $\ell_i = \text{true}$ as 1 and $\ell_i = \text{false}$ as 0.⁴ When all of the a_i are 1, the pseudo-Boolean constraint is called a cardinality constraint. Cardinality constraints limit the number of literals ℓ_i that can be *true*.

There is an extensive literature on different methods for encoding pseudo-Boolean constraints and cardinality constraints, e.g. [War98, FG10, ES06, BB03, Sin05, ANOR09, OLH⁺13, BBR09, MPS14, HMS12, JMM15]. The details of these encodings and their different properties will not be discussed here, but we will point out some key features of these encodings that are particularly relevant to their use in MaxSAT solvers.

The first feature of these encodings is their *size*, i.e., the number of clauses and new variables needed in the CNF encoding. The main parameters influencing size are m the number of literals whose sum is being taken, k the size of the upper bound, and $\max(a_i)$ the greatest coefficient in the sum.

For cardinality constraints the commonly used CNF encodings (e.g., the totalizer encoding [BB03]) the size of the encoding grows as $O(mk)$. So in the worst case when $k = m$ this can be as large as $O(m^2)$. Smaller CNF encodings for cardinality constraints exist. For instance, the modulo totalizer encoding [OLH⁺13]

⁴The other relations ($=$, \geq , $<$, and $>$) can also be represented.

requires $O(m^{\frac{3}{2}})$ clauses, whereas the cardinality network encoding [ANOR09] requires $O(m \log_2(k))$ clauses. However, there are many MaxSAT problems with over 100,000 soft clauses. After the F^b transformation this would yield over 100,000 soft unit clauses. So we can see that naively constructing a cardinality constraint summing all of these literal might require as much as 10^{10} clauses. So MaxSAT solvers must exploit cardinality constraints in more clever ways.

For pseudo-Boolean constraints, the typical encodings are much larger. Some encodings do not necessarily depend on k but rather on m and $\log_2(\max(a_i))$ (the number of bits required to represent the coefficients in binary). There are pseudo-Boolean encodings of size as small as $O(m \log_2(\max(a_i)))$ (linear in m if the size of the coefficients is bounded) [War98], and others that are of larger size $O(m^3 \log_2(m) \log_2(\max(a_i)))$ [BBR09], $O(m^2 \log_2(m) \log_2(\max(a_i)))$ [MPS14]. Other encodings may depend on k (e.g. the sequential weight counter encoding [HMS12]) and have size $O(mk)$, or depend on the number of distinct weights (which is the case for e.g. the generalized totalizer encoding [JMM15]). The tradeoff between these encodings is that the larger encodings achieve better propagation, as we discuss next.

The second relevant feature of these encoding is their propagation power. This is the extent to which unit propagation can find entailed literals. Cardinality constraint encodings typically allow unit propagation to achieve *arc consistency* [Dec03, BB03]. That is, unit propagation on the encoding is able to find all literals entailed by the cardinality constraint. Since SAT solvers learn clauses based on the set of unit propagated literals, this degree of propagation power enhances the effectiveness of the SAT solver. The watchdog encoding [BBR09] was the first polynomial size pseudo-Boolean encoding that maintains arc consistency. Since then, several other polynomial arc consistent encodings have been proposed [MPS14, HMS12]. Encodings that achieve arc consistent are typically very large. Nevertheless, if the encoding is not prohibitively large then it can have better SAT solving performance due to greater propagation power.

Finally, the third relevant feature is whether or not the encoding can be made incremental. That is, given a CNF encoding of $a_i \ell_1 + \dots + a_m \ell_m \leq k$ can we incrementally add additional clauses to encode $a_i \ell_1 + \dots + a_m \ell_m + a_{m+1} \ell_{m+1} \dots a_{m+j} \ell_{m+j} \leq k'$, where we are summing over more literals and $k' \geq k$. For cardinality constraints incrementality was achieved in [MML14], and for pseudo-Boolean constraints [MJML14a, PRB18] reported on incremental ways of changing the left-hand size k to k' . In both cases making these encodings incremental yielded significant speedups for the underlying MaxSAT solver.

A critical element supporting incremental SAT solving (Section 24.4.1.2) is that some cardinality constraint encodings (e.g., the totalizer encoding [BB03]) include a set of “output” variables that encode the sum of the input literals in unary. That is, the encoding has a set of “output” variables o_i such that for any i , o_i is *true* if and only if the input literals sum to at least i . This allows using incremental SAT solving when changes are made to the the left-hand side of the constraint simply by making different assumptions. For example, given the totalizer encoding of the cardinality constraint $\sum_{j=1}^m \ell_j \leq k$ we can incrementally impose the constraint $\sum_{j=1}^m \ell_j < i$ for any $i \leq k$, by simply assuming $\neg o_i$ during the SAT call.

Figure 24.1: Structure of CNF for solving $\mathcal{D}(F, k)$. Note some blocking variable inputs to the cardinality layer might be passed directly through to the outputs (i.e., used directly as assumption literals).

24.4.3. General Structure of CNF Encodings of $\mathcal{D}(F, k)$

Figure 24.1 shows the general structure of the CNF formulas typically used for encoding the decision problem $\mathcal{D}(F, k)$. As already mentioned, the MaxSAT algorithms discussed in this section are all based on solving a sequence of $\mathcal{D}(F, k)$ decision problems for various values of k using a SAT solver. The encoding typically used consists of the hard clauses of the blocking variable transformation, $hard(F^b)$, conjoined with clauses of a cardinality layer. The clauses of the cardinality layer encode various cardinality constraints (or pseudo-Boolean Constraints) over the *blocking* variables of F^b , and sometimes over other internal variables of the cardinality layer.

The soft clauses of F^b are all of the form (b_i) , i.e., positive instances of the newly introduced blocking variables. Typically, the cardinality layer imposes constraints on which and how many of the literals $\neg b_i$ can be *true*. That is, it imposes constraints on the set of soft clauses of F^b that the SAT solver is allowed to falsify. In addition, various literals from the cardinality layer (including perhaps some of blocking variables) can be assumed to be *true* in assumption-based SAT solving.

The SAT solver, for which all clauses are of course hard, has all of the clauses of $hard(F^b)$. Hence, all satisfying models found by the SAT solver must be feasible models of F when restricted to $var(F)$. (Since these models are feasible solutions of F^b this follows from the properties of F^b described in Section 24.4.1.1.1). Furthermore, the SAT solver must find a model that satisfies all of the clauses of the cardinality layer and makes its current set of assumptions *true*. Of course, if no such model exists the SAT solver can return a conflict clause over its assumptions, as described in Section 24.4.1.2.

24.4.4. Model-Improving Algorithms

The first MaxSAT algorithm we present is the model-improving Linear SAT/UNSAT (LSU) algorithm. LSU follows almost directly from a proof that MaxSAT is in the complexity class FP^{NP} . That is, it uses a SAT solver to solve the sequence of decision problems $\mathcal{D}(F, k_0), \mathcal{D}(F, k_1), \dots, \mathcal{D}(F, k_u)$, where $k_0 = \infty$ (i.e., find a feasible solution irrespective of cost), k_i is the cost of the model found when solving $\mathcal{D}(F, k_{i-1})$ minus one, and $\mathcal{D}(F, k_u)$ is the first decision problem in the sequence that was unsatisfiable (UNSAT). The feasible solution returned by

Algorithm 1: Linear SAT/UNSAT algorithm for MaxSAT [BP10]

```

1 LSU( $F$ )
2  $F^b = \text{bv\_transform}(F)$ ;  $\text{card\_layer} = \{\}$ ;  $\text{Blits} = \{-b_i \mid (b_i) \in \text{soft}(F^b)\}$ 
3  $\text{bestmodel} = \{\}$ ;  $\text{cost} = \infty$ ;  $\text{sat?} = \text{true}$ 
4 while  $\text{sat?}$  do
    | /* SAT solver returns boolean SAT/UNSAT status */
    | /* if SAT returns  $\pi$ , the model found */
5    $(\text{sat?}, \pi) = \text{SATSolve}(\text{hard}(F^b) \cup \text{card\_layer})$ 
6   if  $\text{sat?}$  then
7     |  $\text{bestmodel} = \pi$ 
8     |  $\text{cost} = \text{cost}(\pi)$ 
9     |  $\text{card\_layer} = \text{CNF}(\sum_{b_i \in \text{Blits}} \text{wt}((b_i)) \times -b_i < \text{cost})$ 
10  else
11  | return  $(\text{bestmodel}, \text{cost})$ 

```

the last satisfiable instance $\mathcal{D}(F, k_{u-1})$ when restricted to the variables of F is an optimal solution of F .

Algorithm 1 gives the details. First any feasible model π is found (line 5) with card_layer equal to the empty set of clauses. Then using either a cardinality (when $w((b_i)) = 1$ for all i) or pseudo-Boolean constraint (when the soft clauses have varying weights) in the cardinality layer (line 9), the SAT solver is asked to find a feasible solution with cost strictly less than $\text{cost}(\pi)$.⁵ This is repeated until the SAT solver returns UNSAT, in which case the last feasible solution returned is an optimal solution.

The approach of solving a sequence of decision problems $\mathcal{D}(F, k_i)$ with decreasing bounds k_i has a long history. The earliest reported use of this approach in SAT solving appears to be [ARMS02]. The approach was also used in the Minisat+ solver described in [ES06], and in the Sat4j MaxSAT solver [BP10] where the name LSU was first used and an algorithm similar to Algorithm 1 was presented. These three systems actually found optimal models with respect to pseudo-Boolean objective functions. However, pseudo-Boolean objective functions can easily represent MaxSAT when all of the soft clauses are unit (as they are in the transformed formula F^b).

This approach continues to be used in the QMaxSAT [KZFH12] and Pacose solvers (described in [BJM18]). QMaxSAT includes a number of different cardinality and pseudo-Boolean encodings, and carefully chooses which encoding to use based on the characteristics of the input problem. Pacose builds on QMaxSAT by implementing a dynamic construction of one of its pseudo-Boolean encodings [PRB18].

Recently, the LSU algorithm has seen increasing use in incomplete MaxSAT solving in which the aim is to return the lowest-cost feasible solution within a given time bound. As can be seen from Algorithm 1 its chief benefit in this context is that each completed call to the SAT solver returns an improved solution. Hence, at any point the best model found so far can be returned.

Overall, however, the downside of this algorithm is that the cardinality or

⁵Finding a low cost initial feasible model can potentially reduce the size of the cardinality constraint encoding (see Section 24.4.2.1).

pseudo-Boolean constraint needs to be over m literals, where m is the number of soft clauses. As pointed out in Section 24.4.2.1, this can lead to very large encodings when the MaxSAT formula has tens or hundreds of thousands of soft clauses. Hence, solving the resulting SAT problem can become infeasible.

24.4.5. Core-Guided Algorithms

In contrast to LSU, core-guided algorithms work from UNSAT to SAT. That is, they solve a sequence of decision problems $\mathcal{D}(F, k_i)$ where k_i is increasing ($k_i > k_{i-1}$). When k_i is less than the cost of an optimal solution, $\mathcal{D}(F, k_i)$ will be unsatisfiable. Essentially, core-guided algorithms increase k_i until the current $\mathcal{D}(F, k_i)$ is satisfiable, but do not do this as explicitly as done in the LSU approach.

As with LSU these algorithms utilize information from the SAT solver returned from each UNSAT result, to construct the next decision problem to solve. The key insight, originally coming from Fu and Malik [FM06] is that cores can be extracted from the SAT solver when $\mathcal{D}(F, k)$ is unsatisfiable. Every feasible solution must falsify at least one soft clause of every core. Hence, the cores provide us information about the subset of soft clauses that the SAT solver can consider for falsification when solving $\mathcal{D}(F, k)$.

Empirically, many MaxSAT instances have optimal solutions falsifying very few soft clauses (relative to the total number of soft clauses). Hence MaxSAT cores often contain only a small subset of the soft clauses. So instead of having large cardinality constraints over all of the soft clauses, core-based algorithms can often utilize much smaller cardinality constraints over only those soft clauses appearing in the found cores, as these are the only ones that the SAT solver needs to consider falsifying. The other soft clauses can be required to be satisfied by using assumptions, rather than via cardinality constraints.

24.4.5.1. Fu-Malik

Fu and Malik presented the first MaxSAT algorithm exploiting cores [FM06]. Algorithm 2 gives the details. This algorithm only works on unweighted MaxSAT instances (i.e., all soft clauses have weight 1).

All blocking variables are always assumed to be *true* (line 2 and 5). Their main role is simply to allow the SAT solver to extract cores via its assumption mechanism. In the initial call, `card_layer` is empty. Hence, the initial call is asking the SAT solver to find a feasible model satisfying all soft clauses (line 5). In particular, every soft clause c_i of F has been encoded in F^b as the hard clause $(c_i \vee \neg b_i)$. Hence, when we assume b_i this clause is reduced to c_i , and the SAT solver must satisfy it.

Unless there is a zero-cost feasible solution, this call will result in the SAT solver declaring unsatisfiability. Furthermore, the SAT solver will also identify a subset of negated assumptions forming a core, κ . That is, at least one of the literals $\neg b_i$ in κ must be *true*. The algorithm then modifies the hard clause corresponding to each of the soft clauses in the core; for $\neg b_i$ this is the hard clause $(c_i \vee \neg b_i)$. It adds a brand new relaxation variable r_i^{cost} to each such clause by modifying the c_i part of the clause (line 8). (Note that “cost” is always incremented in the loop, line 10, so different variables are added in each iteration).

Algorithm 2: Fu-Malik algorithm for unweighted MaxSAT [FM06]

```

1 FuMalik( $F$ )
2  $F^b = \text{bv\_transform}(F)$ ;  $\text{card\_layer} = \{\}$ ;  $\text{assumptions} = \{b_i \mid (b_i) \in \text{soft}(F^b)\}$ 
3  $F' \text{ hard}(F^b)$ ;  $\text{cost} = \text{ ; sat?} = \text{false}$ 
4 while not sat? do
    /* SAT solver takes as input the CNF to solve and a set of literals to assume */
    /* Returns boolean SAT/UNSAT status */
    /* If SAT returns  $\pi$ , the model found */
    /* If UNSAT returns  $\kappa$ , a core (subset of negated assumptions). */
5 ( $\text{sat?}, \pi, \kappa$ ) = SATSolve ( $F' \cup \text{card\_layer}$ ,  $\text{assumptions}$ )
6 if not sat? then
7     for  $\neg b_i \in \kappa$  do
8          $c_i \quad c_i \vee r_i^{\text{cost}}$ 
            /* Modifying  $c_i$  modifies the clause  $(c_i \vee b_i) \in F'$  */
            /* Each  $r_i^{\text{cost}}$  is a brand new variable. */
9          $\text{card\_layer} = \text{card\_layer} \cup \text{CN} \left( \sum_{\{i \mid \neg b_i \in \kappa\}} r_i^{\text{cost}} \right)$ 
10         $\text{cost} = \text{cost} + 1$ 
11 else
12 return ( $\pi|_{\text{vars}(F)}$ ,  $\text{cost}$ )

```

Finally, it adds a cardinality constraint asserting that one and only one of the newly added relaxation variables can be made *true*. Making r_i^{cost} *true* immediately satisfies (or relaxes) the clause $(c_i \vee r_i^{\text{cost}} \vee \neg b_i)$, allowing the SAT solver to set the assumption b_i to *true* with impunity.

This algorithm does not quite follow the general structure described in Section 24.4.3. In particular, each new call to the SAT solver involves changing $\text{hard}(F^b)$. Since the change involves adding brand new variables to existing clauses (line 8), it is not easy to use the SAT solver incrementally in this algorithm.

Example 5. Consider $F = \{(x, \neg y), (y, z), (y, \neg z), (\neg x)_1, (\neg y)_1\}$. In this formula both x and y are forced, and thus both soft clauses must be falsified. Any feasible solution has cost 2, and thus all feasible solutions are optimal solutions.

$F^b = \{(x, \neg y), (y, z), (y, \neg z), (\neg x, \neg b_1), (\neg y, \neg b_2), (b_1)_1, (b_2)_1\}$. The first iteration of the main loop of Algorithm 2 would call the SAT solver on the CNF $\{(x, \neg y), (y, z), (y, \neg z), (\neg x, \neg b_1), (\neg y, \neg b_2)\}$ with the assumptions $\{b_1, b_2\}$. A possible core is $\kappa = \{\neg b_1, \neg b_2\}$. (Note that the cores returned by the SAT solver do not have to be minimal.)

The second iteration would then be a call to the SAT solver on the CNF $\{(x, \neg y), (y, z), (y, \neg z), (\neg x, \mathbf{r}_1^0, \neg b_1), (\neg y, \mathbf{r}_2^0, \neg b_2)\} \cup \text{CNF}(r_1^0 + r_2^0 = 1)$ with the same assumptions $\{b_1, b_2\}$. Again $\kappa = \{\neg b_1, \neg b_2\}$ is a possible core.

The third iteration would then be a call to the SAT solver on the CNF $\{(x, \neg y), (y, z), (y, \neg z), (\neg x, \mathbf{r}_1^0, \mathbf{r}_1^1, \neg b_1), (\neg y, \mathbf{r}_2^0, \mathbf{r}_2^1, \neg b_2)\} \cup \text{CNF}(r_1^0 + r_2^0 = 1) \cup \text{CNF}(r_1^1 + r_2^1 = 1)$ with the same assumptions $\{b_1, b_2\}$. This time the formula is satisfiable. For example, the truth assignment $\{x, y, z, r_1^0, r_2^1, \neg r_2^0, \neg r_1^1, b_1, b_2\}$ satisfies all of the clauses. At this point $\text{cost} = 2$.

Each core yields a subset of soft clauses of which at least one must be falsified. Adding the relaxation variables and the cardinality constraint gives the SAT

Algorithm 3: WPM1/WMSU1 algorithm for MaxSAT [ABL09, MMP09]

```

1 WPM1/WMSU1( $F$ )
2  $F^b = \text{bv\_transform}(F)$ ;  $\text{card\_layer} = \{\}$ ;  $\text{assumptions} = \{b_i \mid (b_i) \in \text{soft}(F^b)\}$ 
3  $F' = \text{hard}(F^b)$ ;  $\text{cost} = 0$ ;  $\text{iter} = 0$ ;  $\text{sat?} = \text{false}$ 
4  $m = \max\{i \mid b_i \in \text{assumptions}\} + 1$ 
5 while not sat? do
6   /* SAT solver interface is the same as in Algorithm 2 */
7    $(\text{sat?}, \pi, \kappa) = \text{SATSolve}(F' \cup \text{card\_layer}, \text{assumptions})$ 
8   if not sat? then
9      $wt_{\min} = \min_{\{b_i \mid \neg b_i \in \kappa\}} wt((b_i))$ 
10     $\text{cost} = \text{cost} + wt_{\min}$ 
11    for  $\neg b_i \in \kappa$  do
12      if  $wt((b_i)) > wt_{\min}$  then
13        /* Add new copy of clause  $c_i$  with new blocking variable  $b_m$  */
14         $c_m = c_i$ ;  $m = m + 1$ ;  $F' = F' \cup \{(c_m \vee \neg b_m)\}$ 
15         $\text{assumptions} = \text{assumptions} \cup \{b_m\}$ 
16         $wt((b_m)) = wt((b_i)) - wt_{\min}$  /* New copy gets residual weight */
17         $wt((b_i)) = wt_{\min}$  /* Old copy gets weight  $wt_{\min}$  */
18         $c_i = c_i \vee r_i^{\text{iter}}$  /* Add new relaxation variable to old copy */
19        /* Modifies clause  $(c_i \vee \neg b_i) \in F'$  */
20     $\text{card\_layer} = \text{card\_layer} \cup \text{CN}(\sum_{\{i \mid \neg b_i \in \kappa\}} r_i^{\text{iter}})$ 
21     $\text{iter} = \text{iter} + 1$ 
22  else
23    return  $(\pi|_{\text{vars}(F)}, \text{cost})$ 

```

solver the freedom to falsify one (and only one) of these soft clauses by setting its relaxation variable to *true*. Each iteration finds a core subject to all of the previously derived relaxations. That is, at least one clause from the i 'th core κ_i must be falsified even when we falsify a soft clause from each previously derived core. Hence, at stage k we have proved that the optimal cost is at least k . Note that the cores allow us to restrict the set of soft clauses that need to be considered for falsification. That is, only those soft clauses appearing in the found cores need be considered for falsification. This makes the size of the cardinality constraint encodings much smaller.

The example shows that one feature of this algorithm is that it can add multiple relaxation variables to the same clause if that clause appears in more than one core. This is a by-product of using an “= 1” cardinality constraint. In the example, we need to use one relaxation variable from each cardinality constraint in order to satisfy the two clauses $(\neg x, \neg b_1, \mathbf{r}_1^0, \mathbf{r}_1^1)$ and $(\neg y, \neg b_2, \mathbf{r}_2^0, \mathbf{r}_2^1)$; we cannot use two relaxation variables from the same cardinality constraint. These multiple relaxation variables in the soft clause can be a source of significant inefficiency as they introduce symmetries that can slow the SAT solver down [ABL13].

24.4.5.2. WPM1/WMSU1—Fu-Malik for Weighted MaxSAT

A restriction of the Fu-Malik algorithm is that it only works with unweighted MaxSAT instances. Soft clause cloning is a technique [ABL09, MMP09] that allows many unweighted algorithms to be extended to the general weighted case.

This technique was first used in the WPM1 [ABL09] and WMSU1 [MMP09] algorithms which appeared concurrently and independently in 2009. Both algorithms are essentially identical and extend Fu-Malik to deal with weighted soft clauses. Details are presented as Algorithm 3.

When a new core κ is found after we have already found and relaxed some previous cores, we know that at least one of the soft clauses in κ must be falsified. If these soft clauses have different weights, all that can be concluded is that the lower bound on the cost of an optimal solution must be incremented by $w_{\min} = \min_{\{-b_i \in \kappa\}} w((b_i))$, i.e., by the minimum weight among the soft clauses in κ . Clause cloning takes place at this stage, converting κ into a core containing clauses of weight w_{\min} by splitting every clause in κ into two copies: one with weight w_{\min} and one with the residual weight. The copies with the residual weight are added to the set of soft clauses, while the copies with weight w_{\min} are processed as an unweighted core.

In Algorithm 3 we again use the blocking variables introduced into F^b as assumptions so that we can extract cores. In processing each core we add a new relaxation variable to the hard clause corresponding to each of the soft clauses in the core (line 16). And for those soft clauses with weight greater than the minimum weight in the core (w_{\min}), we create a new copy of the clause (line 12), give it a brand new blocking variable b_m , and add it to the formula F' (line 12). The old soft clause (b_i) , whose hard clause $(c_i \vee r_i^{\text{iter}} \vee \neg b_i)$ contains the new relaxation variable, gets weight w_{\min} . The new soft clause (b_m) , whose hard clause $(c_m \vee \neg b_m)$ is a copy of the original clause with a new blocking variable, gets the remaining weight $w((b_i)) - w_{\min}$ (line 14). Note that, as in Algorithm 2, the unit soft clauses of F^b , including the new soft clause (b_m) , only appear in the set of assumptions. So we also need to add b_m to the set of assumptions (line 13). This means that the SAT solver is not allowed to falsify the original soft clause c_i until this clause has appeared in cores whose sum of w_{\min} weights is equal to $w(c_i)$. Only at that point will all copies of c_i have a relaxation variable allowing the SAT solver to falsify c_i . Furthermore, to falsify c_i the SAT solver will have to use a relaxation variable from each copy (by setting that variable to *true*). This will then “use up” all of the cardinality constraints c_i appeared in. That is, once c_i is *false*, all of the cardinality constraints it appears in will have one relaxation variable set, and will thus disallow any other relaxation variable in the constraint from being used.

Example 6. Consider

$$\begin{aligned} F &= \{(\neg x, \neg q), (\neg y, \neg q), (\neg z, \neg q), (x)_1, (y)_1, (z)_1, (q)_2\}, \\ F^b &= \{(\neg x, \neg q), (\neg y, \neg q), (\neg z, \neg q), (x, \neg b_1), (y, \neg b_2), (z, \neg b_3), (q, \neg b_4), \\ &\quad w((b_1)) = w((b_2)) = w((b_3)) = 1, w((b_4)) = 2\}. \end{aligned}$$

On this input, Algorithm 3 could perform the following sequence of iterations (different iterations are possible depending on what cores are returned by the SAT solver).

1. Core $\kappa_1 = \{-b_1, \neg b_4\}$, then $w_{\min} = 1$, $\text{cost} = 0 + w_{\min} = 1$, and

$$F' = \{(x, \neg q), (y, \neg q), (z, \neg q), (x, \mathbf{r}_1^0, \neg b_1), (y, \neg b_2), (z, \neg b_3), \\ \mathbf{r}_4^0, \neg b_4), (\mathbf{q}, \neg \mathbf{b}_5)\} \cup \mathbf{CNF}(\mathbf{r}_1^0 + \mathbf{r}_4^0 = 1), \\ \text{assumptions} = \{b_1, b_2, b_3, b_4, \mathbf{b}_5\}, \\ w((b_1)) = w((b_2)) = w((b_3)) = 1, \mathbf{wt}((\mathbf{b}_4)) = 1, \mathbf{wt}((\mathbf{b}_5)) = 1.$$

2. Core $\kappa_2 = \{-b_1, \neg b_2, \neg b_4, \neg b_5\}$, then $w_{\min} = 1$, $\text{cost} = 1 + w_{\min} = 2$, and

$$F' = \{(x, \neg q), (y, \neg q), (z, \neg q), (x, r_1^0, \mathbf{r}_1^1, \neg b_1), (y, \mathbf{r}_2^1, \neg b_2), (z, \neg b_3), \\ (q, r_4^0, \mathbf{r}_4^1, \neg b_4), (\mathbf{q}, \mathbf{r}_5^1, \neg \mathbf{b}_5)\} \\ \cup \mathbf{CNF}(r_1^0 + r_4^0 = 1) \cup \mathbf{CNF}(\mathbf{r}_1^1 + \mathbf{r}_2^1 + \mathbf{r}_4^1 + \mathbf{r}_5^1 = 1), \\ \text{assumptions and weights unchanged.}$$

3. Now the formula is satisfied by the truth assignment $\pi = \{x, y, z, \neg q, r_4^0, r_5^1, \neg r_1^0, \neg r_1^1, \neg r_2^1, \neg r_4^1, b_1, b_2, b_3, b_4, b_5\}$, and $\pi|_{\text{vars}(F)} = \{x, y, z, \neg q\}$ is an optimal solution for F .

Fu-Malik and its weighted version are mostly of historical interest as the first application of cores and clause cloning, respectively. To date no one has developed implementations of these algorithms that perform as efficiently as more recent algorithms. It is of course always possible that new insight could make these algorithms competitive.

24.4.5.3. MSU3 for Unweighted MaxSAT

MSU3 [MP07] is a much simpler algorithm than Fu-Malik (Section 24.4.5.1), and, when implemented with incremental SAT solving [MJML14b], it has proved to be much more efficient. In fact, at the time this chapter was written, the implementation of MSU3 in the Open-WBO system [MML14] was one of the most effective solvers for the unweighted MaxSAT problem. MSU3, like the LSU algorithm (Section 24.4.4) and unlike the Fu-Malik algorithm, uses a simple encoding that transparently captures the decision problem $\mathcal{D}(F, k)$. Like Fu-Malik, MSU3 starts with $k = 0$ and increases k until $\mathcal{D}(F, k)$ becomes SAT exploiting the cores found for each UNSAT decision problem instance $\mathcal{D}(F, k)$. In particular, in the unweighted case, $\mathcal{D}(F, k)$ is asking the SAT solver to find a feasible solution that falsifies at most k soft clauses. The SAT solver need not consider all soft clauses for falsification. Rather, it needs to consider only those soft clauses that have appeared in one of the cores obtained from the previous SAT solver calls. This makes the cardinality constraint used in the encoding of $\mathcal{D}(F, k)$ much smaller and easier for the SAT solver to handle.

Algorithm 4 gives the details. It starts with an empty `card_layer` and assumptions that force all soft clauses to be satisfied (line 2). Hence, the SAT solver is being asked to find a feasible solution with zero cost. Unless a solution is found, the SAT solver will return a core specifying a set of soft clauses one of which must be falsified. The literals b_i forcing the satisfaction of these soft clauses (b_i) are then removed from the assumptions (line 9), and added to the cardinality constraint (line 8). Finally, the cost is incremented and a new cardinality constraint is constructed specifying that at most this new “cost” of soft clauses can be falsified.

Algorithm 4: MSU3 algorithm for unweighted MaxSAT [MP07]

```

1 MSU3( $F$ )
2  $F^b = \text{bv\_transform}(F)$ ;  $\text{card\_layer} = \{\}$ ;  $\text{assumptions} = \{b_i \mid (b_i) \in \text{soft}(F^b)\}$ 
3  $\text{inCard} = \{\}$ 
4  $F' = \text{hard}(F^b)$ ;  $\text{cost} = 0$ ;  $\text{sat?} = \text{false}$ 
5 while not sat? do
6     /* SAT solver interface is the same as in Algorithm 2 */
7      $(\text{sat?}, \pi, \kappa) = \text{SATSolve}(F' \cup \text{card\_layer}, \text{assumptions})$ 
8     if not sat? then
9          $\text{inCard} = \text{inCard} \cup \kappa$ 
10         $\text{assumptions} = \text{assumptions} \setminus \{b_i \mid \neg b_i \in \kappa\}$ 
11         $\text{cost} = \text{cost} + 1$ 
12         $\text{card\_layer} = \text{CN}(\sum_{\neg b_i \in \text{inCard}} \neg b_i \leq \text{cost})$ 
13    else
14        return  $(\pi|_{\text{vars}(F)}, \text{cost})$ 

```

Note that the initial cardinality constraint is only over the soft clauses that have appeared in the found core κ . In subsequent iterations, the core κ will specify a subset of soft clauses one of which must be falsified *even though the cardinality constraint already allowed some number of soft clauses to be falsified*. Hence, the bound on the cardinality constraint is always incremented by one, and it is always over the soft clauses in the union of the cores that have been found so far. Note also that by removing the literal b_i from the assumptions, we no longer require the SAT solver to satisfy the soft clause (b_i) . However, by adding $\neg b_i$ to the cardinality constraint we still require the SAT solver to not falsify more than *cost* of these soft clauses. Note also that κ can be empty. In this case, the SAT solver has proved that the current bound on the number of soft clauses that can be falsified in the current cardinality constraint is too low. In this case, the only change to card_layer will be to increase the right-hand side bound “cost”.

If we consider the formula being solved by the SAT solver on line 6, we see that only card_layer changes between SAT solver invocations. Furthermore, card_layer changes in two ways: (a) the right-hand side cost bound is incremented, and (b) potentially additional literals are added to the left-hand side sum. Martins et al. [MJML14b] show how, using a totalizer encoding of the cardinality constraint [BB03], both changes can be made by only adding new clauses to the SAT solver and by changing the assumed totalizer output variable to change the right-hand side bound (Section 24.4.2.1). Hence, the same SAT solver instance can be used throughout the algorithm giving rise to significant performance improvements over non-incremental implementations.

24.4.5.3.1. The PM2 Algorithm. Algorithm 4 (MSU3) uses a single cardinality constraint over all of the soft clauses that have appeared in some core. However, in some cases, this cardinality constraint can be decomposed into smaller cardinality constraints each over a disjoint set of soft clauses. This is the insight used in the PM2 algorithm [ABL09, ABL13]. In particular, PM2 operates just like MSU3 except that in each iteration card_layer will contain a set of cardinality constraints rather than just one larger cardinality constraint.

Consider the following sequence of cores (discovered by the SAT solver in this order): $\kappa_1 = \{\neg b_1, \neg b_2, \neg b_3\}$, $\kappa_2 = \{\neg b_4, \neg b_5, \neg b_6\}$, $\kappa_3 = \{\neg b_7, \neg b_8\}$, $\kappa_4 = \{\neg b_1, \neg b_6\}$. MSU3 would construct the following sequence of cardinality constraints (setting `card_layer` to the i 'th constraint in the i 'th iteration):

- (1) $\neg b_1 + \neg b_2 + \neg b_3 \leq 1$,
- (2) $\neg b_1 + \dots + \neg b_6 \leq 2$,
- (3) $\neg b_1 + \dots + \neg b_8 \leq 3$,
- (4) $\neg b_1 + \dots + \neg b_8 \leq 4$.

However, the first three cores are over disjoint sets of soft clauses. PM2 would instead use a set of cardinality constraints in `card_layer` during each iteration:

- (1) $\neg b_1 + \dots + \neg b_3 \leq 1$,
- (2) $\neg b_1 + \neg b_2 + \neg b_3 \leq 1$ **and** $\neg b_4 + \neg b_5 + \neg b_6 \leq 1$,
- (3) $\neg b_1 + \neg b_2 + \neg b_3 \leq 1$ **and** $\neg b_4 + \neg b_5 + \neg b_6 \leq 1$ **and** $\neg b_7 + b_8 \leq 1$.

However, κ_4 is over soft clauses contained in κ_1 and κ_2 . So as to ensure that its cardinality constraints are each over disjoint sets of soft clauses, PM2 would now merge the soft clauses in κ_1 , κ_2 and κ_4 and construct one cardinality constraint over the union of their soft clauses with a bound of 3 (since 3 cores have been discovered over this subset of soft clauses). Hence, at iteration 4, PM2 would use the following set of cardinality constraints in `card_layer`: (4) $\neg b_1 + \dots + \neg b_6 \leq 3$ **and** $\neg b_7 + \neg b_8 \leq 1$.

By splitting up the cores into multiple cardinality constraints PM2 is potentially giving the SAT solver an easier problem to solve. In particular, there are fewer settings of the b_i variables satisfying the two cardinality constraints $\neg b_1 + \dots + \neg b_6 \leq 3$ **and** $\neg b_7 + \neg b_8 \leq 1$ than there are settings satisfying the single cardinality constraint $\neg b_1 + \dots + \neg b_8 \leq 4$.

PM2 also added \geq cardinality constraints (At-Least) to the SAT solver. However, these constraints are logically redundant—the SAT solver has already inferred that at least this number of soft clauses must be falsified. Potentially, these At-Least constraints might slow down the SAT solver.

24.4.5.4. OLL for Weighted MaxSAT

Another algorithm that is very efficient for MaxSAT is the OLL algorithm. OLL is originally an algorithm for optimization in Answer Set Programming [AKMS12] and was adapted for MaxSAT by Morgado et al. [MDM14]. The OLL MaxSAT algorithm was most recently (at the time this chapter was written) implemented in the RC2 solver.

The key idea of OLL is to utilize what are called “soft cardinality constraints.” Consider an unweighted instance for which a core $\kappa = \{\neg b_1, \dots, \neg b_n\}$ has been found (i.e., for each $\neg b_i \in \kappa$, (b_i) is a soft clause with $w((b_i)) = 1$). The formula can be relaxed by removing the b_i from the assumptions and adding a cardinality constraint $\sum_{\neg b_i \in \kappa} \neg b_i < j$. This allows the SAT solver to falsify up to $j-1$ of these soft clauses. Now define new summation output variables o_j for $j = 1, \dots, n-1$ such that o_j is *true* if and only if $\sum_{\neg b_i \in \kappa} \neg b_i \geq j$. That is, o_j is *true* if at least j of the soft clauses $(b_1), \dots, (b_n)$ are falsified; and *false* if at most $j-1$ are falsified.

Algorithm 5: OLL algorithm for MaxSAT [MDM14]

```

1  OLL( $F$ )
2   $F^b = \text{bv\_transform}(F)$ ;  $\text{card\_layer} = \{\}$ ;  $\text{assumptions} = \{b_i \mid (b_i) \in \text{soft}(F^b)\}$ 
3   $F' = \text{hard}(F^b)$ ;  $\text{cost} = \ ; \text{iter} = 0$ ;  $\text{sat?} = \text{false}$ 
4  while not sat? do
    /* SAT solver interface is the same as in Algorithm 2 */
5     $(\text{sat?}, \pi, \kappa) = \text{SATSolve}(F' \cup \text{card\_layer}, \text{assumptions})$ 
6    if not sat? then
7       $wt_{\min} = \min_{\{\ell \mid \ell \in \kappa\}} wt((-\ell))$ 
8       $\text{cost} = \text{cost} + wt_{\min}$ 
9      for  $\ell \in \kappa$  do /*  $(-\ell)$  is a soft clause */
10       |  $wt((-\ell)) - wt_{\min}$ 
11       | if  $wt((-\ell))$  then
12         |  $\text{assumptions} = \text{assumptions} \setminus \{-\ell\}$ 
13       for  $o_j^i \in \kappa$  do /* Summation output variables */
14         | if  $wt((-\neg o_j^i)) \wedge o_{j+1}^i$  exists then
15           | /*  $i$ 'th summation has another output variable */
16           |  $\text{assumptions} = \text{assumptions} \cup \{-o_{j+1}^i\}$ 
17         /* Encode clauses that make output variables equal to value of sum */
18          $\text{card\_layer} = \text{card\_layer} \cup \text{CN}(\sum_{\ell \in \kappa} \ell \geq j \equiv o_j^{\text{iter}} \text{ for } o_2^{\text{iter}}, \dots, o_{|\kappa|}^{\text{iter}})$ 
19         for  $j = 1, \dots, |\kappa|$  do
20           |  $wt((-\neg o_j^{\text{iter}})) - wt_{\min}$ 
21           |  $\text{assumptions} = \text{assumptions} \cup \{-o_j^{\text{iter}}\}$ 
22           |  $\text{iter} = \text{iter} + 1$ 
23     else
24       return  $(\pi|_{\text{vars}(F)}, \text{cost})$ 

```

We will refer to the o_j as being *output* variables of the cardinality constraint, and the literals being summed (the left-hand side) as the *input* variables.

Instead of adding the cardinality constraint $\sum_{-b_i \in \kappa} -b_i < j$, we can add the clauses specifying that for each output variable o_j the equivalence $o_j \equiv \sum_{-b_i \in \kappa} -b_j \geq j$ holds, and call the SAT solver under the assumption $\neg o_j$ (Section 24.4.2.1). This technique is used by [MJML14b] to make MSU3 incremental. However, the use of soft cardinality constraints takes this idea further. Instead of treating the literals $\neg o_j$ as hard assumptions, we can regard them to be new soft clauses $(\neg o_j)_1$. Since $o_j \rightarrow o_{j-1}$, we observe that any truth assignment falsifying the soft clause $(\neg o_j)_1$ must also falsify the j soft clauses $\{(\neg o_1)_1, \dots, (\neg o_j)_1\}$. Hence any feasible solution falsifying $(\neg o_j)_1$ incurs cost j , and this is exactly the same as the costs incurred by falsifying j of the original soft clauses (b_i) (o_j is *true* implies j of the $-b_i$ are *true*). That is, replacing the soft clauses $(b_i)_1$ by the soft clauses $(\neg o_j)_1$ corresponding to the sums of the $-b_i$ is a cost-preserving transformation of the MaxSAT formula.

The main advantage of treating the $(\neg o_i)$ as new soft clauses is that cores can now be found over these variables. For example, the SAT solver could compute a core $\kappa = \{-b_2, -b_4, o_2^2\}$ where $(b_2)_1$ and $(b_4)_1$ are soft clauses of F^b , and o_2^2 is the 2nd output of the second cardinality constraint. This core asserts that either one of $(b_2)_1$ or $(b_4)_1$ must be falsified *or* more than two soft clause inputs of the second cardinality constraint must be falsified. This is clearly a more general

and potentially more powerful type of core than cores strictly over the original soft clauses (b_i). Furthermore, the outputs of one cardinality constraint (the right-hand side variables) can end up being used as the inputs (the left-hand side literals) to additional cardinality constraints, building up new output variables representing quite complicated constraints on the set of original soft clauses that can be falsified.

Algorithm 5 gives the details of the weighted case.⁶ One main feature of this algorithm is that the totalizer encoding [BB03] of cardinality constraints already provides the summation output variables o_i used on line 16 (see Section 24.4.2.1).⁷ Another feature of the algorithm is that through its use of assumptions it can perform clause cloning without having to actually duplicate the clauses as was needed in WPM1/WMSU1 (Section 24.4.5.2); this is described below.

The algorithm starts as normal with an empty `card_layer` and assumptions that force the satisfaction of all soft clauses. Whenever a core is found, the minimum weight over the soft clauses in the core is subtracted from the weight of every soft clause in the core. Note that with summation output literals $\neg o_j^i$ being assumed (lines 15 and 19) the core can contain either negated blocking variables $\neg b_i$ or positive output variables o_j^i . In both cases the corresponding soft clause contains the negation, (b_i) or ($\neg o_j^i$). Line 10 reduces the weight of these soft clauses by w_{\min} . If the weight drops to zero, then that particular soft clause has been fully absorbed into the `card_layer` (i.e., its weight has been fully accounted for in the cost of the cores found so far). In that case we can remove it from the assumptions; otherwise, we continue to assume it but now with reduced weight.

The summation output variables appearing in the core require special treatment if their weight drops to zero. If the weight of o_j^i drops to zero, the i -th cardinality constraint has had j of its inputs made *true*. This corresponds to j soft clauses being falsified, and the weight of these j falsifications has been fully absorbed into `card_layer`. Now we must disallow any further falsifications by assuming $\neg o_{j+1}^i$ (line 15). If further falsifications are needed, the SAT solver will subsequently generate cores containing o_{j+1}^i ; eventually the weight of a $(j+1)$ 'th falsification, i.e., $w(\neg o_{j+1}^i)$, will be absorbed into the `card_layer` and we will then assume o_{j+2}^i . Note that each of the soft clauses ($\neg o_j^i$) has a weight equal to the minimum weight of the soft clauses in the i 'th core (line 18). This is in general different from w_{\min} of the $iter$ 'th core currently being processed. If all of the summation output variables have been absorbed (i.e., there is no o_{j+1}^i output variable) then no further assumptions need be added to the SAT solver—the possible falsification of all of the soft clause inputs to this cardinality constraint has been fully accounted for by the algorithm.

After updating the weights of the soft clauses a new cardinality constraint is generated over the literals in the core (line 16) with a corresponding new set of summation output variables o_j^{iter} . We do not need o_1^{iter} because we know that at

⁶The original publication [MDM14] did not detail the general weighted case, so this algorithm is based on the RC2 implementation.

⁷Algorithms that use the cardinality constraint CN $(\sum_{-b_i \in \text{inCard}} \neg b_i \leq \text{cost})$ with a specific bound, such as MSU3, often use the totalizer encoding that also supplies these summation output variables o_i . To impose the bound of $\leq \text{cost}$, these algorithms add $\neg o_{\text{cost}+1}$ to the set of SAT solver assumptions.

least one of the literals in κ must be *true*, κ specifies a conflict clause satisfied by all feasible solutions (see Section 24.4.1.2), and so o_1^{iter} is already *true*. These new summation output variables will count up how many literals $\neg\ell$ of κ are *true*, and thus how many of the corresponding soft clauses (ℓ) are *false*. Since each of the summation output variables gets weight w_{\min} (line 18), each input clause (ℓ) contributes w_{\min} if falsified. This is how clause cloning is implemented. If the soft clause (ℓ) (for $\neg\ell \in \kappa$) has weight $w(\ell) > w_{\min}$ we will have ℓ as an assumption with new weight $w(\ell) - w_{\min}$, and ℓ as an input to the cardinality constraint with weight w_{\min} . These two uses of the literal ℓ correspond to the two clause copies used in WPM1, and there is no longer a need to add clause copies to the SAT solver.⁸

There are a number of options with respect to assuming the new output variables. In Algorithm 5 the assumptions contain at most one output literal from each cardinality constraint at any time: initially we add $\neg o_2^i$ (line 19), and whenever $w(\neg o_j^i)$ drops to zero we remove it and add the next output literal $\neg o_{j+1}^i$. However, since $\neg o_j^i \rightarrow \neg o_{j+1}^i$ (equivalently $o_{j+1}^i \rightarrow o_j^i$) it is logically sound to assume all of the output literals $\neg o_j^i$ at once [ADR15]. In the RC2 implementation (see [BJM18]) only $w(\neg o_2^{\text{iter}})$ is initialized to w_{\min} (as in line 18). Then, whenever weight is removed from $(\neg o_j^i)$, an equivalent weight is added to $(\neg o_{j+1}^i)$. Thus by the time $(\neg o_2^{\text{iter}})$ has had its weight reduced to zero, $(\neg o_3^{\text{iter}})$ will have had a total of w_{\min} weight added to it. That is, instead of starting $(\neg o_3^{\text{iter}})$ with weight w_{\min} as is done on line 18, weight w_{\min} is moved to this soft clause incrementally. Hence, by the time $(\neg o_j^i), \dots, (\neg o_2^i)$ all have weight zero, $w_{\min} \cdot j$ weight must have been accumulated into `card_layer`.

With multiple output literals o_j^i in the assumptions, the cores (which are not minimal) can contain multiple output literals from the same cardinality constraint. Furthermore, the weight of o_j^i might become zero even when o_{j-1}^i still has positive weight. Hence, solvers such as RC2 might remove o_j^i from the assumptions when its weight gets reduced to zero, and then add it back in when weight is later shifted in from o_{j-1}^i . The impact of this on the efficiency of the algorithm has not been reported to date.

Finally, it can be noted that the cardinality constraint built on line 16 of Algorithm 5 need not be built all at once. Instead, solvers like RC2 build this cardinality constraint incrementally, adding output variables o_j^{iter} only as these are needed.

24.4.5.5. Other Soft Cardinality Constraint Algorithms

Besides OLL other published algorithms have used the notion of dynamically creating new soft clauses representing summations or disjunctions of the original soft clauses. These include, e.g., PMRes [NB14], Maxino [ADR15], and WPM3 [ADG15], all of which have very good performance. We briefly describe their main features, leaving the interested reader to consult the references for more detailed information.

⁸This can yield a significant improvement in efficiency when the core contains hundreds or thousands of soft clauses.

All of these algorithms use the same main loop as Algorithm 5 except that they process cores differently. That is, initially all soft clauses are assumed to be *true* and `card_layer` is empty. Then, for every core κ that is found, w_{\min} is determined and subtracted from every soft clause in κ (line 10). If the remaining weight is greater than zero, a “copy” of the soft clause is left in the assumptions; otherwise, the clause is removed (line 12). This leaves κ with soft clauses all with the same weight w_{\min} .

After this, the core is processed, updating `card_layer` and assumptions. In Algorithm 5 this is done on lines 13 to 19. It is this processing and these lines that are changed by the different algorithms we discuss here.

First, it is useful to describe the properties processing a core must satisfy. Core processing has to update the formula so that the SAT solver is now allowed to falsify *one* of the weight w_{\min} soft clauses in κ : w_{\min} has been added to cost (line 8) so the cost of a single falsification has already been accounted for. Furthermore, the update must preserve the condition that if a truth assignment falsifies j soft clauses of κ , then that truth assignment must incur a cost of $(j - 1) \cdot w_{\min}$ in the new formula.

In OLL this is accomplished by defining the summation output variables o_j^{iter} for $j = 2$ to $|\kappa|$ with totalizer clauses (added to `card_layer`) ensuring that $o_j^{\text{iter}} \equiv \sum_{\ell \in \kappa} \ell \geq j$. Then the soft clauses $(\neg o_j^{\text{iter}})_{w_{\min}}$ are added by adding $\neg o_j^{\text{iter}}$ to the assumptions and setting $w((\neg o_j^{\text{iter}})) = w_{\min}$ (line 18). These soft clauses are added incrementally to the assumptions (line 15), with initially only $\neg o_2^{\text{iter}}$ in the assumptions (line 19). Thus, since $\neg o_1^{\text{iter}}$ is never assumed nor even defined, the SAT solver is allowed to falsify any single soft clause in κ . Furthermore, if a truth assignment falsifies j soft clauses in κ , the variables $o_2^{\text{iter}}, \dots, o_j^{\text{iter}}$ will all be made *true*, and thus $j - 1$ soft clauses $(\neg o_2^{\text{iter}})_{w_{\min}}, \dots, (\neg o_j^{\text{iter}})_{w_{\min}}$ will be falsified incurring cost $(j - 1) \cdot w_{\min}$.

PMRes. The PMRes algorithm processes cores differently. In particular, PMRes does not use summation output variables. Instead it operates as follows. Let $\kappa = \{\neg \ell_1, \dots, \neg \ell_m\}$ and $w = w_{\min}$. Thus the soft clauses are $(\ell_1)_w, \dots, (\ell_m)_w$. PMRes will define $m - 1$ variables d_2, \dots, d_m such that $d_i \equiv \ell_i \vee (\ell_1 \wedge \dots \wedge \ell_{i-1})$, adding the clauses defining this equivalence to `card_layer` ([NB14] presents a compact way of encoding these equivalences). That is, each d_i is *true* if either the soft clause $(\ell_i)_w$ is satisfied or if all prior soft clauses in the sequence $(\ell_1)_w, \dots, (\ell_{i-1})_w$ are satisfied. It will then add the soft clauses $(d_2)_w, \dots, (d_m)_w$ by adding d_2, \dots, d_m to the assumptions and setting $w((d_1)) = w, \dots, w((d_m)) = w$.

In the new formula, the SAT solver is now allowed to falsify any single soft clause in κ . If exactly one $(\ell_i)_w$ is falsified, then all of the d_j assumptions will be *true*: for $j \neq i$, ℓ_j is *true*, making d_j *true*, and for $j = i$, the conjunction $(\ell_1 \wedge \dots \wedge \ell_{i-1})$ is *true*, making d_j *true*. Furthermore, if a truth assignment falsifies j of the soft clauses $(\ell_i)_w$, then it will make d_i *true* for all i corresponding to satisfied soft clauses; it will make d_i *true* for i equal to the index of the first falsified soft since all previous soft clauses are satisfied; and it will make d_i *false* for i equal to the index of all $j - 1$ subsequent falsified soft clauses, since in this case all previous soft clauses are not satisfied. Hence, the truth assignment will falsify exactly $j - 1$ of the soft clauses $(d_i)_w$ in the new formula incurring cost $(j - 1) \cdot w_{\min}$.

PMRes has proved to be a very effective algorithm, with the Eva solver implementing it was one of the best performers in the 2014 MaxSAT evaluation. An open issue with PMRes is that the order of the soft clauses in κ has an influence on the algorithm's performance. Why this is the case is not well understood. A better understanding of this issue might lead to improved ordering schemes and better performance.

Maxino. The Maxino algorithm uses summation output variables to define the new soft clauses like OLL. Its main innovation is to use a simple technique to partition the core κ into a sequence of smaller subsets that are pairwise disjoint and whose union is κ . The algorithm then constructs a sequence of cardinality constraints, each cardinality constraint summing the falsified soft clauses of one partition. It links the cardinality constraints together by including the 1 output (the output variable indicating that the sum of the inputs is ≥ 1) from the previous cardinality constraint as an input of the subsequent cardinality constraint.

Each cardinality constraint allows at most one of its inputs to be *true* (at most one of its corresponding soft clauses to be *false*). In particular, its outputs indicating that the sum is ≥ 2 , ≥ 3 , ..., are all assumed to be *false* and each is given weight w_{\min} (i.e., the negation of these output variables become new soft clauses as in OLL⁹). Its 1 output indicating that the sum is ≥ 1 is not made into a soft clause, instead the 1 output is fed into the subsequent cardinality constraint.

With these new assumptions and clauses capturing the new sequence of cardinality constraints, the SAT solver is now allowed to falsify any single soft clause in κ . Say that the single falsified soft clause is an input to the i 'th cardinality constraint in the sequence of cardinality constraints. The first to $i(-1)$ 'th cardinality constraints will all have only *false* inputs and thus will set all of their outputs to *false*, satisfying the assumptions. The i 'th cardinality constraint has one *true* input, the input corresponding to the falsified soft clause, and will set its 1 output to *true* and all other outputs to *false*. This again satisfies all of the assumptions since the 1-output has not been added to the assumptions. The $(i+1)$ 'th cardinality constraint will have a *true* input, the input corresponding to the 1 output of the i 'th cardinality constraint, and will set its 1 output to *true* and all other outputs to *false*. Again this will satisfy all of the assumptions since the 1 output has not been added to the assumptions. This pattern will continue for the subsequent cardinality constraints and all assumptions will be satisfied.

Furthermore, if j soft clauses in κ are falsified by some truth assignment, then the sequence of cardinality constraints will have j *true* input variables. The first cardinality constraint in the sequence with $i > 0$ *true* inputs, will set its i , $i - 1$, ..., 1 outputs to *true* incurring cost $(i - 1) \cdot w_{\min}$: the 1 output is not a soft clause and hence does not incur any cost while the other outputs all falsify soft clauses with weight w_{\min} . Every subsequent cardinality constraint with k *true* input variables will also get an additional *true* input variable from the previous cardinality constraint's 1 output. Thus, it will set its $k + 1$, k , ..., 1 outputs to *true*

⁹However, all output variables are assumed to be *false*, whereas in OLL only the \geq output is assumed to be *false*. As already explained, OLL incrementally assumes the output variables of the cardinality constraint whereas Maxino assumes them all at once.

incurring cost $k \cdot w_{\min}$: again the 1 output does not incur any cost. Summing over all the cardinality constraints it can be seen that a total cost of $(j-1) \cdot w_{\min}$ will be incurred.

The interested reader may consult [ADR15] for further details. However, we note that in [ADR15] the totalizer encoding is presented in a non-standard way. In particular, for a totalizer with inputs ℓ_1, \dots, ℓ_n and outputs $o_i \equiv \sum_{j=1}^n \ell_j \geq i$ ($1 \leq i \leq n$), [ADR15] uses the non-standard but equivalent encoding $\text{CNF}(\neg \ell_1 + \dots + \neg \ell_n + o_1 + \dots + o_n \geq n)$ conjoined with $\bigwedge_{i=1}^n o_i \rightarrow o_i$. That is, if k inputs ℓ_i are *true* (i.e. at most $k-n$ of the $\neg \ell_i$ are *true*), then at least k outputs must be *true* with the *true* outputs clustered at the lowest indices.

Maxino is another very effective algorithm being one of the best performing algorithms in the 2018 MaxSAT evaluation. An open issue with Maxino is understanding more precisely how partitioning the core into smaller subsets helps the solver, and how this clustering should be done in order to maximize solver performance.

WPM3. The WPM3 algorithm, like Maxino and OLL, uses summation output variables to define the new soft clauses, but it differs in some ways. First, the cardinality constraints it uses are always summations of falsified input soft clauses. The new “meta” soft clauses arising from the output of previous cardinality constraints are not used as inputs to new cardinality constraints as in Maxino, OLL, and PMRes. Second, WPM3 utilizes a sub-optimization step to find the best bound for each core.

When processing a new core κ , WPM, like OLL, distinguishes between the soft clauses that are input soft clauses and those that are output variables of previously constructed cardinality constraints. In particular, if $o_i^j \in \kappa$ is the i 'th output of the j 'th cardinality constraint ($(\neg o_i^j)$ is a soft clause), then WPM3 replaces o_i^j with the union of the inputs of the j 'th cardinality constraint. Since this replacement is done before the new cardinality constraint over the literals in the core is constructed, every cardinality constraint will have only input soft clauses as input (i.e., literals indicating the falsification of some input soft clause). After building this larger core κ , WPM3 constructs a new cardinality constraint C with the literals in κ as inputs and a corresponding set of output variables o_i^C counting the number of falsified soft clauses in κ .

Now instead of assuming the 2 output of the new cardinality constraint C to limit the number of falsified soft clauses to one, WPM3 does a sub-optimization to determine if this limit must be higher. This can be done in various ways, but WPM3 applies the LSU (Algorithm 1) over the subproblem consisting of $h \text{ rd}(F_b)$ along with only the soft clauses that are inputs to C . Say that this sub-optimization concludes that k of the soft clause inputs of C must be falsified. Then WPM3 will add the output $\neg o_{k+1}^C$ to the set of assumptions with weight w_{\min} and will add $(k-1) \cdot w_{\min}$ to the cost. In other words, after concluding that k soft clauses inputs to C must be falsified, WPM3 will construct a problem in which the SAT solver can falsify no more than k of these soft clauses without incurring an additional cost.

24.4.5.5.1. Remarks. The algorithms mentioned in this section, all of which use the technique of adding new soft clauses defined in terms of previous soft clauses, seem to have similar levels of excellent performance. It is not clear if any single approach is generally the best. In particular, much of the demonstrated performance differences seem to arise from the quality of implementation and additional techniques used in the implementation. We close this section by mentioning some of the key techniques used to improve the base algorithm.

An important technique for all core-guided algorithms is weight stratification [ABL09]. This is the technique of partitioning the soft clauses into k sets so that the soft clauses in set i have higher weight than those in set $i - 1$. Then the problem is solved ignoring all soft clauses except those in the k 'th set. Once a solution is found for these higher-weight soft clauses, the $k - 1$ 'th set of soft clauses is added and the problem solved again. This is repeated until the problem has been solved with all soft clauses.

The reason this technique is useful for core-guided algorithms is that it generates cores with higher minimum weight. This moves the cost towards the optimum more rapidly and reduces the amount of clause cloning that needs to occur. In particular, even with clause cloning optimized to be simply reusing a literal (as described earlier), excessive cloning will still slow the solver down by forcing it to generate more cores. For example, if an instance contains a single soft clause of weight 100 that must be falsified in any optimal solution, along with many other soft clauses of weight 1, then the solver would have to generate at least 100 cores if each of these cores has w_{\min} of 1. One hundred such cores would be required to reduce the weight 100 soft clause down to weight zero: before its weight is reduced to zero it remains in the assumptions and must continue to be satisfied by the SAT solver. Furthermore, every core generated augments the complexity of `card_layer`, which starts to slow the SAT solver down. Even with stratification, however, core-guided algorithms become significantly less efficient as the number of distinct soft clause weights increases.

The WPM3 technique of finding an optimal lower bound for each cardinality constraint via a sub-optimization also seems to be quite effective. For example, RC2 implementation of OLL (see [BJM18]) employed this technique (its “`exhaust_core`” method). As pointed out earlier, each added cardinality constraint slows down the SAT solver. The sub-optimization technique allows the solver to increase the cost towards the optimum without adding additional cardinality constraints; optimization is done by using the output variables of the already added cardinality constraint as SAT solver assumptions (recall Section 24.4.5.5).

The final technique that we will mention here is that of core minimization. There are a number of algorithms for reducing the size of a core. For example, one simple technique is as follows. Given a core $\kappa = \{\ell_1, \dots, \ell_n\}$, we can ask the SAT solver if it can satisfy $\neg\ell_1, \dots, \neg\ell_{n-1}$ using assumptions. In the negative case, the SAT solver it will provide a new core that must be a strict subset of κ . In the positive case, the test can be performed leaving out a different literal ℓ_i , $i \neq n$. Depending on the size of κ and the complexity of the current SAT formula (which is growing as we process more cores and add more cardinality constraints), this technique can be effective in reducing the size of the core after which the reduced core can be processed. Core reduction if applied judiciously

can speed up the solver.

Besides the algorithms already mentioned, it should also be noted that a number of other core-guided MaxSAT algorithms have been proposed, e.g., [IMM⁺14, MHM12, MM08, ABL10a]. These algorithms have mostly been subsumed by the algorithms discussed, but some ideas and insights might still be available by examining these earlier works more carefully.

24.4.6. The Implicit Hitting Set Approach

Implicit hitting set (IHS) MaxSAT solvers [DB11, DB13a, DB13b, Dav13, SBJ16] instantiate the implicit hitting set paradigm [DCB10, Kar10] in the context of MaxSAT. In particular, similarly to the purely SAT-based core-guided approach, IHS solvers extract cores in an iterative fashion. However, in contrast to the core-guided approach, in the IHS approach hitting sets over the iteratively accumulated set of cores are computed. If a minimum-cost hitting set (MCHS)¹⁰ of the accumulated cores, when removed from the input formula, makes the formula satisfiable, then any satisfying truth assignment must be an optimal solution [DB11]. In contrast to solvers implementing the purely SAT-based core-guided approach, IHS solvers do not transform the input instance using core compilation steps; rather, the input MaxSAT instance is not altered during search. Each SAT solver call is made on the original hard clauses together with a subset of the original soft clauses (selected through the use of assumptions). Thus the MaxSAT instance does not get larger in size as the search progresses. As a result, the cores found during search remain relatively small compared to the core-guided approaches (consisting of no more than a few hundred clauses on current typical MaxSAT benchmarks).

To obtain a MCHS, current IHS solvers for MaxSAT have employed integer programming (IP) solvers on the following MCHS IP formulation:

$$\begin{aligned}
 & \text{minimize} && \sum_{(b_i) \in \text{soft}(F^b)} w((b_i)) \cdot -b_i \\
 & \text{subject to} && \sum_{-b_i \in \kappa} -b_i \geq 1 && \forall \kappa \in \mathcal{K}, \\
 & && -b_i \in \{0, 1\} && \forall (b_i) \in o(F^b),
 \end{aligned}$$

where \mathcal{K} is the accumulated set of cores, the b_i are the blocking variables for the input soft clauses c_i created by the blocking variable transformation (Section 24.4.1.1.1), and $-b_i = 1$ when b_i is *false* and c_i is falsified.¹¹ In the original

¹⁰Given a set of cores, a hitting set of the cores is a set of soft clauses that includes a soft clause from each core. A hitting set is optimal (of minimum cost) iff the sum of the weights of the soft clauses in it is smallest among all hitting sets of the set of cores.

¹¹Other techniques for computing minimum-cost hitting sets besides using IP solvers can be used. These include branch-and-bound methods [Kle11] and SAT based methods, e.g., [IPLM15]. In certain contexts these methods can be quite effective, e.g., when recomputing a minimum-cost hitting set after adding a single new set. However, these alternatives to IP solvers either cannot handle the weighted case or are not very efficient on the weighted case. In addition, IP solvers support adding other types of constraints that can be extracted from the input formula [DB13a], and bounding techniques that can be used to harden some of the soft clauses [BHJS17]; both of these ideas can yield significant efficiency improvements.

Algorithm 6: IHS algorithm for MaxSAT [DB13b]

```

1 IHS( $F$ )
2  $F^b = \text{bv\_transform}(F)$ ;  $F'$    $\text{hard}(F^b)$ ;  $\mathcal{K} = \{\}$ ;  $HS = \{\}$ 
  /* Initialize upper and lower bounds ( $UB$  and  $LB$ ).  $LB$  is initialized to zero.  $UB$  is
   initialized to a feasible solution. A feasible solution must exist since by assumption
    $\text{hard}(F)$  is satisfiable. Remember the solution yielding the  $UB$  cost. SAT solver
   interface is the same as in Algorithm 2 */
3 ( $\text{sat?}$ ,  $\pi$ ,  $\kappa$ ) = SATSolve ( $F'$ ,  $\{\}$ )
4  $UB = \text{cost}(\pi)$ ;  $LB = 0$ ;  $\text{best\_sol} = \pi$ 
5 while true do
6   ( $\text{sat?}$ ,  $\pi$ ,  $\kappa$ ) = SATSolve ( $F'$ ,  $\{b_i \mid (b_i) \in (\text{soft}(F^b) \setminus HS)\}$ )
7   if not  $\text{sat?}$  then
8      $\mathcal{K} = \mathcal{K} \cup \{\kappa\}$ 
9     ( $HS$ ,  $MCHS?$ ) = ComputeHittingSet( $\mathcal{K}$ )
10    if  $MCHS?$  then
11       $LB = a(LB, \text{cost}(HS))$ 
12      if  $LB \geq UB$  then
13        return ( $\text{best\_sol}$ ,  $\text{cost}(\text{best\_sol})$ )
14    else
15      if  $\text{cost}(\pi) < UB$  then
16         $UB = \text{cost}(\pi)$ 
17         $\text{best\_sol} = \pi$ 
18        if  $LB \geq UB$  then
19          return ( $\text{best\_sol}$ ,  $\text{cost}(\text{best\_sol})$ )

```

IHS algorithm for MaxSAT [DB11] each iteration of the algorithm involved computing a MCHS of the current set of cores \mathcal{K} (which is initially empty) and then testing the satisfiability of $\text{hard}(F^b)$ subject to the assumptions $\{b_i \mid (b_i) \in (\text{soft}(F^b) \setminus HS)\}$. That is, a feasible solution satisfying all soft clauses except those in the MCHS must be found. If this formula is satisfiable, the set must hit *all* cores of the instance [Rei87], and the optimality of implies the optimality of the solution [DB11], terminating the MaxSAT search.

One benefit of the IHS approach is the possibility of tightly integrating upper and lower bound information into search. In fact, starting with [DB13b], more recent versions of IHS MaxSAT solvers have used a different approach that is better cast as an algorithm computing an upper and lower bound and stopping when these two bounds meet. This more modern version of the IHS algorithm is shown in Algorithm 6.

The algorithm starts by applying the blocking variable transformation and initializing the set of cores \mathcal{K} and the hitting set to be empty. It also initializes the lower bound (LB) to be zero and finds a feasible solution whose cost is used to initialize the upper bound (UB). Note that by calling the SAT solver with an empty set of assumptions (line 3) the SAT solver is free to falsify any of the soft clauses. Hence, this call will return SAT if any feasible solution exists, and since by assumption the input set of hard clauses, $\text{hard}(F)$ are satisfiable, this call must return SAT (Section 24.4.1.1.1). The feasible solution is stored in `best_sol` so that an optimal solution can be returned on termination.

Then the main loop is entered where the SAT solver is asked to find a solution satisfying all soft clauses except those in the current hitting set (line 6). If the

solver reports unsatisfiability, the found core κ is added to the set of cores \mathcal{K} , and a new hitting set is computed. If that hitting set is an MCHS, the lower bound can be updated to be the maximum of its previous value and the cost of the MCHS (line 11). In particular, every truth assignment π must falsify at least one soft clause in every core. Thus the set of soft clauses falsified by π forms a hitting set of \mathcal{K} . The cost of π is equal to the sum of the weights of these falsified clauses; that is, it is equal to the cost of the hitting set it generates. Thus $o(\pi)$ must be at least as high as the cost of any MCHS. Since this is true for all truth assignments including the optimal solutions when \mathcal{K} is an MCHS, its cost must be a valid lower bound on $o(F)$.

On the other hand, if the SAT solver returns a satisfying truth assignment, we can check the cost of the returned solution π and update the upper bound if we have found a new lower cost solution. In both cases when either the lower or upper bound is updated we check if the bounds now meet. If they do, we return `best_sol`, since π has now been proven to be an optimal solution.

ComputeHittingSet. The one part of Algorithm 6 that is incompletely specified is how `ComputeHittingSet` works. This subroutine must satisfy two properties: (a) it must return a hitting set of \mathcal{K} , and (b) it must always eventually return an MCHS of \mathcal{K} . That is, `ComputeHittingSet` is free to compute and return non-optimal hitting sets (in which case MCHS? is returned as *false*), but there must always exist a future call that will compute and return an MCHS. In fact, the ability to postpone computing MCHS (which is a computationally hard problem) has been shown to be essential for the effectiveness of the IHS approach [DB13b].

It can be shown that as long as `ComputeHittingSet` satisfies these two properties, Algorithm 6 will eventually terminate returning an optimal solution [BHJS17]. Nevertheless, there is still considerable flexibility in how `ComputeHittingSet` works, and although effective implementations have been found, deep insight has not yet been achieved into how to implement this function optimally. However, Saikko [Sai15] did provide useful empirical evidence about different techniques.

In current IHS solvers (MaxHS and LMHS [BJM18]) the following techniques are used to compute hitting sets.

1. The entire new core κ is added to the previously computed hitting set H . Clearly, if H was a hitting set of all previous cores in \mathcal{K} , $H \cup \kappa$ will be a hitting set of $\mathcal{K} \cup \{\kappa\}$. Typically, this technique is used immediately after any other more expensive technique for computing a hitting set is employed, and it is used until the hitting set becomes so large that the SAT solver returns SAT. Saikko [Sai15] showed that employed in this way this technique is empirically effective.
2. A greedy algorithm can be used to compute a new hitting set. The standard greedy heuristic, where the soft clause that hits the most cores for the least weight is continually selected until all cores are hit, is typically used.
3. The IP solver can be used to compute a hitting set but it can be stopped as soon as it finds a feasible solution with a cost lower than the current upper bound. This technique can help limit the time consumed by the IP

solver.

4. Finally the IP solver is used when it is time to compute an MCHS

These techniques are listed in order of increasing computational cost. ComputeHittingSet implementations typically try to repeat the least expensive technique as many times as they can before moving on to a more expensive technique, with the aim of reducing the time required to accumulate a set of cores capable of raising the lower bound. In particular, when the hitting set returned by a technique immediately yields a solution, there is no longer any point in repeating that technique—no more cores can be found using it until some other cores have been found by other techniques. This “repeat the cheapest until nothing new can be computed” method has proved to be quite effective in practice, but other more sophisticated policies might well be even more effective.

Other Techniques. A number of additional techniques are employed by IHS solvers to speed up the algorithm. Here we mention some of the most important ones.

Seeding is the technique of examining the input MaxSAT instance to determine if any constraints can immediately be added to the IP solver. This technique is quite effective and is more fully described in [DB13a].

Core minimization (Section 24.4.5.5.1) is very effective for IHS solvers [DB13a] and is standardly employed. However, as with its use in core-guided algorithms, the resources expended on core minimization must be limited. For example, it would be too expensive to compute the smallest core. Nevertheless, core minimization tends to be easier to perform in IHS solvers than in core-guided solvers. As already mentioned, the cores in IHS solvers tend to be smaller to begin with, and since cardinality constraints are not being added to the formula the SAT solver calls used during minimization are more efficient. In IHS solvers, minimizing the cores results in tighter constraints for the IP solver, allowing it to raise the lower bound with fewer cores.

The final technique that we will mention here is the IP technique of *reduced cost fixing*. IP solvers standardly work by iteratively solving linear (LP) relaxations of the input IP and then refining those relaxations with cuts or by branching. In the context of IHS, the LP relaxation of the minimum-cost hitting set IP provides a lower bound on the value of the MCHS, which in turn is a lower bound on the cost of an optimal solution to the MaxSAT problem. Hence, as proposed in [BHJS17], the LP can be used to obtain a *reduced cost* for every soft clause by computing the reduced costs of the IP variables $-b_i$. This allows the solver to make use of the standard IP technique of reduced cost fixing [Wol98, DFJ54, CJP83, NW99]. Intuitively, the reduced cost of a soft clause specifies a minimum increase in the cost of the LP relaxation that would arise from falsifying (respectively, satisfying) a soft clause which was satisfied (respectively, falsified) in a computed optimal LP solution. If this cost increase makes the lower bound provided by the LP relaxation greater than the current best known MaxSAT upper bound, the clause (i.e., its blocking variable) can be fixed to its status as prescribed by the LP solution. Fixing the values of blocking variables subsequently simplifies both the minimum-cost hitting set computations as well as the SAT solver calls. This use of a proven IP technique to improve IHS solvers

is made possible by their hybrid use of both SAT and IP solvers. Potentially, other ideas from the rich field of IP solving could be discovered to be useful.

24.4.7. Solving MaxSAT Directly via Integer Programming

In addition to developing SAT-based approaches to MaxSAT, integer programming systems can be used to directly solve MaxSAT instances using the standard encoding of MaxSAT to integer programming [GW93]. In more detail, starting with the blocking variable transformation F^b , an IP 0/1 variable x can be defined for each propositional variable x with $\neg x$ translated as $(1 - x)$. Then every clause can be translated into a ≥ 1 linear constraint, and the objective function can be defined to be the minimization of $\sum_{(b_i) \in \text{soft}(F^b)} w((b_i)) \cdot \neg b_i$. As shown in [AG13, DB13a], IP solvers can be quite effective on some MaxSAT instances using this standard IP encoding of MaxSAT. However, in general, their performance is not competitive with MaxSAT-specific algorithms on most instances.

24.5. Further Developments

Finally, we overview further recent developments in MaxSAT solving involving preprocessing, practical incomplete algorithms, algorithm portfolios, partitioning-based, and parallel approaches to MaxSAT solving.

24.5.1. Preprocessing

Preprocessing techniques for SAT provide significant performance improvements to SAT solving, and preprocessing is today a standard part of the SAT solving workflow (see also Chapter 9). In comparison, progress on MaxSAT preprocessing is more recent and preprocessing less routinely applied.

Nevertheless, essentially all major SAT preprocessing techniques can be naturally lifted to MaxSAT. The key to SAT-based preprocessing for MaxSAT is in introducing first blocking variables through the F^b transformation (cf. Section 24.4.1.1.1), turning each soft clause c into the hard clause $c \vee \neg b_C$. The clauses of $h \text{ rd}(F^b)$ resulting from this transformation can then be preprocessed using an SAT preprocessing with one minor but—in terms of correctness for MaxSAT—very important restriction: the elimination of the blocking variables by resolving on the variables (e.g., through bounded variable elimination) must be disallowed, in order to preserve the unsatisfiable core structure of the instance [BJM13, BMM13]. By lifting the notions of resolution asymmetric tautologies [JHB12] from SAT to MaxSAT, a generic proof of correctness for natural MaxSAT liftings of SAT preprocessing techniques was recently provided [BJ19].

An optimal solution to the original MaxSAT instance can then be obtained from any optimal solution to the instance after applying SAT preprocessing by applying the generic solution reconstruction technique for SAT preprocessing [JHB12] in linear time with respect to the number of preprocessing steps made.

After applying SAT preprocessing the clauses can contain more than one

blocking variable, and a blocking variable can occur in multiple clauses.¹² Hence the bijective mapping between blocking variables and soft clauses is lost after SAT preprocessing. For coupling SAT preprocessing with core-guided and IHS MaxSAT approaches, this is not problematic, but nevertheless requires attention. The blocking variables introduced before preprocessing can be directly used as blocking variables by the MaxSAT algorithms which employ blocking variables, instead of performing another F^b transformation step after preprocessing [BSJ15a].

Variables that can be directly used as blocking variables can also be detected from input MaxSAT instances and reused as assumptions throughout the MaxSAT solving process, thereby limiting the number of new variables added by the F^b transformation step, as proposed in [BSJ15b] under the notion of *group detection*. Group detection refers to detecting auxiliary variables introduced by MaxSAT encodings of more high-level finite-domain constraints. In more detail, assume that a set of clauses $\text{CNF}(\mathcal{C}) = \{C_1, \dots, C_k\}$ is a conjunctive normal form encoding of a finite-domain constraint \mathcal{C} . Now assume that \mathcal{C} is a soft constraint, with an associated weight $W_{\mathcal{C}}$. On the level of *group MaxSAT* [HMM15] this soft constraint can be represented as the soft group $\{C_1, \dots, C_k\}$ with weight $W_{\mathcal{C}}$. For employing a standard MaxSAT solver, a natural way of encoding such a group-level MaxSAT representation is to introduce a single blocking variable $b_{\mathcal{C}}$ and add it to each of the clauses C_1, \dots, C_k , thereby obtaining the hard clauses $C_1 \vee \neg b_{\mathcal{C}}, \dots, C_k \vee \neg b_{\mathcal{C}}$ together with the soft clause $b_{\mathcal{C}}$ with weight $W_{\mathcal{C}}$. With this intuition, group detection refers to pattern matching in a MaxSAT instance literals that are directly re-usable as blocking variables. In particular, a literal l is re-usable as a blocking variable if the literal $\neg l$ only appears in the hard clauses of the MaxSAT instance. This captures the auxiliary variables arising from the already-described general approach of encoding high-level soft constraints in MaxSAT. In practice, in [BSJ15b] the authors showed that in the industrial and crafted benchmark instances of MaxSAT Evaluation 2014, variables re-usable directly as blocking variables were found in a majority of the instances using group detection, most often in significant numbers.

The impact of SAT preprocessing on the efficiency of MaxSAT algorithms in practice has been to date less studied, although some theoretical evidence on its potential is available; see e.g. [BMM13, KBSJ17]. However, it has been shown that, theoretically, SAT preprocessing has no effect on the best-case number of iterations of core-guided MaxSAT algorithms [BJ16], which suggests that its impact may mainly be in making the individual SAT solver calls within core-guided MaxSAT algorithms simpler.

Beyond SAT preprocessing, native MaxSAT-specific preprocessing techniques have also been proposed. A limited form of variable saturation in the context of MaxSAT resolution was proposed as a MaxSAT preprocessing technique in [ALM08]. More recently, the MaxPre MaxSAT preprocessor [KBSJ17] introduced several further preprocessing techniques native to MaxSAT, including label matching, binary core removal, and generalized form of subsumed label elimina-

¹²In this context, blocking variables are sometimes referred to as *labels*, following the *labeled CNF* framework [BM12] that explicitly distinguishes between the blocking variables and original clauses of each clause.

tion [BSJ16], the last of which allows for removing blocking variables (labels) in the following sense: A blocking variable b is subsumed by a set of blocking variables $\{b_1, \dots, b_k\}$ if one of b_1, \dots, b_k occurs in a clause whenever b occurs in the clause, and $\sum_{i=1}^k w(b_i) \leq w(b)$. For $k = 1$, this gives the original proposed definition of subsumed label elimination [BSJ16], while in general the conditions correspond to the NP-complete hitting set problem. In practice, an approximate version of the generalized form of subsumed label elimination can be computed using a classical $\ln(n)$ -approximation algorithm for the hitting set problem.

In terms of implementations of MaxSAT preprocessing, the SAT preprocessor Coprocessor [Man12] supports SAT preprocessing techniques for MaxSAT instances, while the MaxPre preprocessor [KBSJ17] offers combinations of SAT preprocessing and native MaxSAT preprocessing techniques.

24.5.2. Incomplete Algorithms for MaxSAT

Incomplete MaxSAT solving can primarily be divided into two categories: (i) local search MaxSAT solvers and (ii) approximation algorithms based on iterative calls to SAT solvers that may not guarantee optimality.

24.5.2.1. Local Search for MaxSAT

Local search solvers start by finding a random assignment to the MaxSAT formula. Since this assignment is unlikely to satisfy all clauses, they choose a clause that is unsatisfied and flip the assignment of a variable occurring in that clause. When compared to local search solvers for SAT, local search solvers for MaxSAT face additional challenges since they must find an assignment that satisfies all hard clauses while trying to maximize the sum of the weights of satisfied soft clauses. To overcome this challenge, local MaxSAT solvers distinguish between soft and hard clauses and apply weighting schemes that favor satisfying hard clauses [CLTS14, LCW⁺15, CJS15, CLLS16, LCSH17, LC18]. For more details on local search SAT solvers, we refer the interested reader to Chapter 6.

24.5.2.2. Model-Improving Approximation

Model-improving approximation algorithms do not guarantee the optimality of the final solution. An example of this approach is an enumeration of minimal correction subsets (MCSes) [MHJ⁺13, MPM15]. An MCS of an unsatisfiable set of clauses is a minimal subset that, if removed, makes the formula satisfiable. There has been a recent trend of using approximation approaches for incomplete MaxSAT. For instance, an approach based on bit-vector optimization was proposed for unweighted incomplete MaxSAT with promising results [Nad18].

LINSBPS [DS18] is an incomplete MaxSAT solver based on model-improving algorithms. For weighted instances, they simplify the weights of the formula and see it in *low resolution*, i.e., with all their weights divided by a large value. Since they use integer division, the weights of some soft clauses are set to zero, effectively removing them. Whenever the solver terminates with an “optimal” solution to the simplified formula, the resolution is increased by decreasing the divisor value. Additionally, they use solution-based saving [AG17, DCS18] to guide the search towards the best solution found so far.

OPEN-WBO-INC [JKMR18] is another incomplete MaxSAT solver based on model-improving algorithms. For weighted instances, this solver also simplifies the weights of the formula by clustering them into k different weights. An alternative approach also employed by this solver is to consider a weighted instance as a multilevel optimization problem (even though it may not satisfy the BMO condition described in Section 24.3.1.1). This alternative approach reduces the solving of a weighted instance to solving a sequence of unweighted instances, which significantly improves the performance of model-improving algorithms and quickly converges to a final solution which corresponds to an upper bound on the optimal value of the original formula.

24.5.3. Algorithm Portfolios

Given the diversity of MaxSAT algorithms (some of which were overviewed in Section 24.4), a meta approach that aims at taking advantage of this diversity is to build an oracle to predict the most suitable MaxSAT algorithm for a particular instance. Inspired by the success of SATzilla [XHH08] and other algorithm portfolios for SAT solving, Matos et al. [MPLM08] proposed the first algorithm portfolio for MaxSAT by employing linear regression using three kinds of features [NLH⁺04]: problem size features, balance features and local search probe features.

ISAC+ [AMS14] is another algorithm portfolio approach that extends the instance-specific algorithm configuration (ISAC [KMST10]) by clustering the benchmarks and tuning the parameters of existing solvers on each cluster. ISAC does not use regression-based analysis but instead computes a representative feature vector that captures properties of a particular instance in order to identify clusters of similar instances. A single solver is selected for each group based on the characteristics of those benchmarks. Given a new instance, its features are computed and it is assigned to the closest cluster and solved by the respective solver. The features used by ISAC+ consider the percentage of clauses that are soft, and the statistics of the distribution of weights (average, minimum, maximum, standard deviation). The remaining 32 features are a subset of the features used by SATZilla that are specific to SAT instances and are applied to MaxSAT instances by considering all soft clauses as hard. ISAC+ differs from ISAC since it also applies an algorithm selector to choose the best parameters of existing solvers for each cluster. Using a portfolio of different MaxSAT solvers, allowed ISAC+ to be one of the best approaches for MaxSAT in the 2013-2015 MaxSAT Evaluations.

24.5.4. Parallel Solving

Nowadays, extra computational power is no longer coming from higher processor frequencies but rather from adding additional processors. Distributed systems are also becoming more predominant and cheaper. For instance, it is not uncommon to deploy distributed tools to web services such as Amazon Web Services. Even though parallel approaches for MaxSAT are not as predominant as in SAT solving, there are a few parallel MaxSAT solvers that can take advantage of these new architectures. These parallel solvers can be mainly categorized into two classes: (i) portfolio approaches, and (ii) search space splitting.

24.5.4.1. Portfolio Approaches

Portfolio approaches are not restricted to sequential solving and can be extended to a parallel setting where different strategies are run in parallel. These different strategies can be based on different MaxSAT algorithms (e.g., model-improving algorithms, core-guided algorithms, implicit hitting set algorithms) or by using different settings of a given algorithm (e.g., changing the encoding for cardinality or pseudo-Boolean constraints). An example of a portfolio solver is PWBO [MML11] which allocates half of the workers to use model-improving algorithms, and the other half core-guided algorithms. To further increase diversity between workers using the same algorithm, PWBO translates cardinality and pseudo-Boolean constraints with different encodings [MML11].

The portfolio approaches for parallel MaxSAT solving are closely related to portfolio approaches for parallel SAT solving. The main difference consists on how diversity is employed. Both approaches perform clause sharing where learned clauses between different workers are exchanged to further prune the search space and boost the performance of the parallel solver.

Portfolio approaches are better suited for multicore approaches since diversity does not usually scale and clause sharing is more efficient when performed in shared memory.

24.5.4.2. Search Space Splitting

Another approach for parallel MaxSAT solving is to split the original problem into subproblems such that each worker solves a smaller formula that is hopefully easier to solve. The two main approaches to divide the search space is to (i) perform interval splitting or (ii) split the search space with guiding paths.

The optimal solution value of a MaxSAT problem is bounded between 0 and the sum of the weights of the soft clauses. Therefore one way of splitting the search space is to divide this interval and have different workers searching on different bounds in order to narrow the search interval and converge to an optimal solution. This approach is employed in a version of PWBO [MML12].

The search space can also be viewed as a binary tree, where each node corresponds to a variable and each of its edges corresponds to an assignment to that variable. The search space can then be split by using different paths in the tree (called guiding paths) to split the search into sub-trees and assign each of them to a different worker. There are many ways of generating guiding paths. One of the most successful approaches has been using lookahead solvers [vdTHB12] to split the search tree. This strategy has been used in a distributed MaxSAT solver [TLM16].

One of the advantages of this approach is that it is easier to split the search space into many workers and therefore can be more suitable for a distributed setting. However, since some of the sub-trees may be much easier to solve than others, it is necessary to have a dynamic load balancing scheme that continuously splits the search space and keeps all workers busy.

24.5.5. Partitioning-based MaxSAT

Divide-and-conquer techniques are not restricted to parallel MaxSAT solving and can also be applied to sequential MaxSAT solving. For instance, partitioning-based MaxSAT has been successfully used to improve the performance of core-based algorithms [MML13, NMJ⁺15].

Core-based algorithms rely on unsatisfiable cores returned by the SAT solver. Usually, core-based algorithms perform better when small cores are found early. However, this is not necessarily the case, since these unsatisfiable cores are not guaranteed to be minimal, and there are no guarantees that smaller cores will be found first. The order in which cores are enumerated can have a large impact on the performance of MaxSAT algorithms.

Similarly to SAT instances, MaxSAT instances can also be represented using graphs. For instance, a MaxSAT instance can be represented by either the variable incidence graph (VIG) or the clause variable incidence graph (CVIG) [MML13]. In the VIG representation, vertices correspond to the variables of the problem, and edges correspond to clauses where both variables occur. In the CVIG representation, vertices correspond to both variables and clauses and there is an edge between the vertices that represent the variables and the clauses where they occur. One can also use the resolution rule to construct a graph where vertices are clauses and edges correspond to clauses that can be resolved with each other (RES) [NMJ⁺15].

Partitioning-based MaxSAT uses graph partition techniques to split the formula into disjoint subsets (e.g., using a modularity clustering approach [GN02]). By decomposing the MaxSAT instance into disjoint subformulas, the SAT solver is forced to find unsatisfiable cores on a subset of the formula. If such unsatisfiable cores exist, then they may be much smaller than if the entire MaxSAT instance was given to the SAT solver. The RES representation [NMJ⁺15] is implemented on top of the Open-WBO system [MML14] using the MSU3 algorithm and has been shown to be particularly effective for unweighted MaxSAT.

24.6. Summary

Advances in practical aspects of maximum satisfiability within the last 10-15 years have established MaxSAT as a general-purpose Boolean constraint optimization paradigm. The improvements have come in increasing numbers both in terms of domain-specific MaxSAT encodings of various hard optimization problems to novel algorithmic techniques and their efficient implementations in general-purpose MaxSAT solvers. In terms of algorithmic advances, the advent of SAT-based approaches to practical MaxSAT solving in its different forms is arguably at the center of this success. To this end, we have here aimed at covering central research advances on practical aspects of MaxSAT within the last 10 years, with a strong focus on the three main SAT-based approaches to MaxSAT solving: the model-improving, core-guided, and the implicit hitting set approach. Beyond further improvements to these algorithmic approaches to MaxSAT, there are plenty of avenues for further research on MaxSAT in terms of novel applications of the

technology, as well as further advances in the recent research directions on incomplete and parallel approaches to MaxSAT solving.

Chapter 25

Model Counting

Carla P. Gomes, Ashish Sabharwal, and Bart Selman

Propositional model counting or #SAT is the problem of computing the number of models for a given propositional formula, i.e., the number of distinct truth assignments to variables for which the formula evaluates to TRUE. For a propositional formula F , we will use $\#F$ to denote the model count of F . This problem is also referred to as the solution counting problem for SAT. It generalizes SAT and is the canonical #P-complete problem. There has been significant theoretical work trying to characterize the worst-case complexity of counting problems, with some surprising results such as model counting being hard even for some polynomial-time solvable problems like 2-SAT.

The model counting problem presents fascinating challenges for practitioners and poses several new research questions. Efficient algorithms for this problem will have a significant impact on many application areas that are inherently beyond SAT ('beyond' under standard complexity theoretic assumptions), such as bounded-length adversarial and contingency planning, and probabilistic reasoning. For example, various probabilistic inference problems, such as Bayesian net reasoning, can be effectively translated into model counting problems [cf. BDP03, Dar05, LMP01, Par02, Rot96, SBK05b]. Another application is in the study of hard combinatorial problems, such as combinatorial designs, where the number of solutions provides further insights into the problem. Even finding a single solution can be a challenge for such problems; counting the number of solutions is much harder. Not surprisingly, the largest formulas we can solve for the model counting problem with state-of-the-art model counters are orders of magnitude smaller than the formulas we can solve with the best SAT solvers. Generally speaking, current exact counting methods can tackle problems with a couple of hundred variables, while approximate counting methods push this to around 1,000 variables.

#SAT can be solved, in principle and to an extent in practice, by extending the two most successful frameworks for SAT algorithms, namely, DPLL and local search. However, there are some interesting issues and choices that arise when extending SAT-based techniques to this harder problem. In general, solving #SAT requires the solver to, in a sense, be cognizant of all solutions in the search space, thereby reducing the effectiveness and relevance of commonly used SAT heuristics designed to quickly narrow down the search to a single solution. The resulting

scalability challenge has drawn many satisfiability researchers to this problem, and to the related problem of sampling solutions uniformly at random.

We will divide practical model counting techniques we consider into two main categories: *exact counting* and *approximate counting*, discussed in Sections 25.2 and 25.3, respectively. Within exact counting, we will distinguish between methods based on *DPLL-style* exhaustive search (Section 25.2.1) and those based on “knowledge compilation” or conversion of the formula into certain *normal forms* (Section 25.2.2). Within approximate counting, we will distinguish between methods that provide fast *estimates without any guarantees* (Section 25.3.1) and methods that provide lower or upper *bounds with a correctness guarantee*, often in a probabilistic sense and also in a statistical sense (Section 25.3.2).

We would like to note that there are several other directions of research related to model counting that we will not cover here. For example, Nishimura et al. [NRS06] explore the concept of “backdoors” for #SAT, and show how the vertex cover problem can be used to identify small such backdoors based on so-called cluster formulas. Bacchus et al. [BDP03] consider structural restrictions on the formula and propose an algorithm for #SAT whose complexity is polynomial in n (the number of variables) and exponential in the “branch-width” of the underlying constraint graph. Gottlob et al. [GSS02] provide a similar result in terms of “tree-width”. Fischer et al. [FMR08] extend this to a similar result in terms of “cluster-width” (which is never more than tree-width, and sometimes smaller). There is also complexity theoretic work on this problem by the theoretical computer science community. While we do provide a flavor of this work (Section 25.1), our focus will mostly be on techniques that are available in the form of implemented and tested model counters.

25.1. Computational Complexity of Model Counting

We begin with a relatively brief discussion of the theoretical foundations of the model counting problem. The reader is referred to standard complexity texts [cf. Pap94] for a more detailed treatment of the subject.

Given any problem in the class NP, say SAT or CLIQUE, one can formulate the corresponding *counting problem*, asking *how many solutions exist* for a given instance? More formally, given a polynomial-time decidable relation Q ,¹ the corresponding counting problem asks: given x as input, how many y ’s are there such that $(x, y) \in Q$? For example, if Q is the relation “ y is a truth assignment that satisfies the propositional expression x ” then the counting problem for Q is the propositional model counting problem, #SAT. Similarly, if Q is the relation “ y is a clique in the graph x ” then the counting problem for Q is #CLIQUE. The complexity class #P (pronounced “number P” or “sharp P”) consists of all counting problems associated with such polynomial-time decidable relations. Note that the corresponding problem in NP asks: given x , *does there exist a y such that $(x, y) \in Q$?*

The notion of *completeness* for #P is defined essentially in the usual way, with a slight difference in the kind of reduction used. A problem A is #P-complete if

¹Technically, Q must also be polynomially balanced, that is, for each x , the only possible y ’s with $(x, y) \in Q$ satisfy $|y| \leq |x|^k$ for a constant k .

(1) A is in $\#P$, and (2) for every problem B in $\#P$, there exists a polynomial-time *counting reduction* from B to A . A counting reduction is an extension of the reductions one often encounters between NP-complete decision problems, and applies to function computation problems. There are two parts to a counting reduction from B to A : a polynomial-time computable function R that maps an instance z of B to an instance $R(z)$ of A , and a polynomial-time computable function S that recovers from the count N of $R(z)$ the count $S(N)$ of z . In effect, given an algorithm for the counting problem A , the relations R and S together give us a recipe for converting that algorithm into one for the counting problem B with only a polynomial overhead.

Conveniently, many of the known reductions between NP-complete problems are already *parsimonious*, that is, they preserve the number of solutions during the translation. Therefore, these reductions can be directly taken to be the R part of a counting reduction, with the trivial identity function serving as the S part, thus providing an easy path to proving $\#P$ -completeness. In fact, one can construct a parsimonious version of the Cook-Levin construction, thereby showing that $\#SAT$ is a canonical $\#P$ -complete problem. As it turns out, the solution counting variants of all six basic NP-complete problems listed by Garey and Johnson [GJ79], and of many more NP-complete problems, are known to be $\#P$ -complete.²

In his seminal paper, Valiant [Val79] proved that, quite surprisingly, the solution counting variants of polynomial-time solvable problems can also be $\#P$ -complete. Such problems, in the class P , include 2-SAT, Horn-SAT, DNF-SAT, bipartite matching, etc. What Valiant showed is that the problem PERM of computing the *permanent* of a 0-1 matrix, which is equivalent to counting the number of perfect matchings in a bipartite graph or $\#BIP$ -MATCHING, is $\#P$ -complete. On the other hand, the corresponding search problem of computing a *single* perfect matching in a bipartite graph can be solved in deterministic polynomial time using, e.g., a network flow algorithm. Therefore, unless $P=NP$, there does not exist a *parsimonious* reduction from SAT to BIP-MATCHING; such a reduction would allow one to solve any SAT instance in polynomial time by translating it to a BIP-MATCHING instance and checking for the existence of a perfect matching in the corresponding bipartite graph. Valiant instead argued that there is a smart way to *indirectly* recover the answer to a $\#SAT$ instance from the answer to the corresponding PERM (or $\#BIP$ -MATCHING) instance, using a non-identity polynomial-time function S in the above notation of counting reductions.

Putting counting problems in the traditional complexity hierarchy of decision problems, Toda [Tod89] showed that $\#SAT$ being $\#P$ -complete implies that it is no easier than solving a quantified Boolean formula (QBF) with a constant number (independent of n , the number of variables) of “there exist” and “forall” quantification levels in its variables. For a discussion of the QBF problem, see Part 2, Chapters 29-31 of this Handbook. Formally, Toda considered the decision problem class $P^{\#P}$ consisting of polynomial-time decision computations with “free” access to $\#P$ queries, and compared this with k -QBF, the subset of QBF instances that have exactly k quantifier alternations, and the infinite polynomial

²Note that a problem being NP-complete does not automatically make its solution counting variant $\#P$ -complete; one must demonstrate a polynomial time *counting* reduction.

hierarchy $\text{PH} = \bigcup_{k=1}^{\infty} k\text{-QBF}$.³ Combining his result with the relatively easy fact that counting problems can be solved in polynomial space, we have $\#\text{P}$ placed as follows in the worst-case complexity hierarchy:

$$\text{P} \subseteq \text{NP} \subseteq \text{PH} \subseteq \text{P}\#\text{P} \subseteq \text{PSPACE}$$

where PSPACE is the class of problems solvable in polynomial space, with QBF being the canonical PSPACE -complete problem. As a comparison, notice that SAT can be thought of as a QBF with exactly one level of “there exist” quantification for all its variables, and is thus a subset of 1-QBF . While the best known deterministic algorithms for SAT , $\#\text{SAT}$, and QBF all run in worst-case exponential time, it is widely believed—by theoreticians and practitioners alike—that $\#\text{SAT}$ and QBF are significantly harder to solve than SAT .

While $\#\text{P}$ is a class of function problems (rather than decision problems, for which the usual complexity classes like P and NP are defined), there does exist a natural variant of it called PP (for “probabilistic polynomial time”) which is a class of essentially equally hard decision problems. For a polynomial-time decidable relation Q , the corresponding PP problem asks: given x , is $(x, y) \in Q$ for *more than half* the y ’s? The class PP is known to contain both NP and co-NP , and is quite powerful. The proof of Toda’s theorem mentioned earlier in fact relies on the equality $\text{P}^{\text{PP}} = \text{P}\#\text{P}$ observed by Angluin [Ang80]. One can clearly answer the PP query for a problem given the answer to the corresponding $\#\text{P}$ query. The other direction is a little less obvious, and uses the fact that PP has the power to provide the “most significant bit” of the answer to the $\#\text{P}$ query and it is possible to obtain all bits of this answer by repeatedly querying the PP oracle on appropriately modified problem instances.

We close this section with a note that Karp and Luby [KL85] gave a Markov Chain Monte Carlo (MCMC) search based fully polynomial-time randomized approximation scheme (FPRAS) for the DNF-SAT model counting problem, and Karp et al. [KLM89] later improved its running time to yield the following: for any $\epsilon, \delta \in (0, 1)$, there exists a randomized algorithm that given F computes an ϵ -approximation to $\#\text{F}$ with correctness probability $1 - \delta$ in time $O(|F| \cdot 1/\epsilon^2 \cdot \ln(1/\delta))$, where $|F|$ denotes the size of F .

25.2. Exact Model Counting

We now move on to a discussion of some of the practical implementations of exact model counting methods which, upon termination, output the true model count of the input formula. The “model counters” we consider are CDP by Birnbaum and Lozinskii [BL99], ReIsat by Bayardo Jr. and Pehoushek [BP00], Cachet by Sang et al. [SBB⁺04], sharpSAT by Thurley [Thu06], and c2d by Darwiche [Dar04].

³For simplicity, we use $k\text{-QBF}$ to represent not only a subset of QBF formulas but also the complexity class of alternating Turing machines with k alternations, for which solving these formulas forms the canonical complete problem.

25.2.1. DPLL-Based Model Counters

Not surprisingly, the earliest practical approach for counting models is based on an extension of systematic DPLL-style SAT solvers. The idea, formalized early by Birnbaum and Lozinskii [BL99] in their model counter CDP, is to directly explore the complete search tree for an n -variable formula as in the usual DPLL search, pruning unsatisfiable branches based on falsified clauses and declaring a branch to be satisfied when all clauses have at least one TRUE literal. However, unlike the usual DPLL, when a branch is declared satisfied and the partial truth assignment at that point has t fixed variables (fixed either through the branching heuristic or by unit propagation), we associate 2^{n-t} solutions with this branch corresponding to the partial assignment being extended by all possible settings of the $n - t$ yet unset variables, backtrack to the last decision variable that can be flipped, flip that variable, and continue exploring the remaining search space. The model count for the formula is finally computed as the sum of such 2^{n-t} counts obtained over all satisfied branches. Although all practical implementations of DPLL have an iterative form, it is illustrative to consider CDP in a recursive manner, written here as Algorithm 25.1, where $\#F$ is computed as the sum of $\#F|_x$ and $\#F|_{\neg x}$ for a branch variable x , with the discussion above reflected in the two base cases of this recursion.

Algorithm 25.1: CDP ($F, 0$)

Input : A CNF formula F over n variables; a parameter t initially set to 0
Output : $\#F$, the model count of F
begin
 UnitPropagate(F)
 if F has an empty clause **then return** 0
 if all clauses of F are satisfied **then return** 2^{n-t}
 $x \leftarrow$ SelectBranchVariable(F)
 return CDP($F|_x, t + 1$) + CDP($F|_{\neg x}, t + 1$)
end

An interesting technical detail is that many of the modern implementations of DPLL do *not* maintain data structures that would allow one to easily check whether or not all clauses have been satisfied by the current partial assignment. In general, DPLL-style SAT solvers often do not explicitly keep track of the number of unsatisfied clauses. They only keep track of the number of assigned variables, and declare success when all variables have been assigned values and no clause is violated. Keeping track of the number of unsatisfied clauses is considered unnecessary because once a partial assignment happens to satisfy all clauses, further branching immediately sets all remaining variables to arbitrary values and obtains a complete satisfying assignment; complete satisfying assignments are indeed what many applications of SAT seek. DPLL-based model counters, on the other hand, do maintain this added information about how many clauses are currently satisfied and infer the corresponding 2^{n-t} counts. Having to enumerate each of the 2^{n-t} complete satisfying assignments instead would make the technique impractical.

Obtaining partial counts: As discussed above, a basic DPLL-based model counter works by using appropriate multiplication factors and continuing the search after a single solution is found. An advantage of this approach is that the model count is computed in an incremental fashion: if the algorithm runs out of a pre-specified time limit, it can still output a correct *lower bound* on the true model count, based on the part of the search space it has already explored. This can be useful in many applications, and has been the motivation for some new randomized techniques that provide fast lower bounds with probabilistic correctness guarantees (to be discussed in Section 25.3.2). In fact, a DPLL-based model counter can, in principle, also output a correct *upper bound* at any time: 2^n minus the sum of the 2^{n-t} style counts of un-satisfying assignments contained in all unsatisfiable branches explored till that point. Unfortunately, this is often not very useful in practice because the number of solutions of problems of interest is typically much smaller than the size of the search space. As a simple example, in a formula with 1000 variables and 2^{200} solutions, after having explored, say, a $1/16$ fraction of the search space, it is reasonable to expect the model counter to have seen roughly $2^{200}/16 = 2^{196}$ solutions (which would be a fairly good lower bound on the model count) while one would expect to have seen roughly $(2^{1000} - 2^{200})/16$ un-satisfying assignments (yielding a poor naïve upper bound of $2^{1000} - (2^{1000} - 2^{200})/16$, which is at least as large as 2^{999}). We will discuss a more promising, statistical upper bounding technique towards the end of this chapter.

Component analysis: Consider the constraint graph G of a CNF formula F . The vertices of G are the variables of F and there is an edge between two vertices if the corresponding variables appear together in some clause of F . Suppose G can be partitioned into disjoint components G_1, G_2, \dots, G_k where there is no edge connecting a vertex in one component to a vertex in another component, i.e., the variables of F corresponding to vertices in two different components do not appear together in any clause. Let F_1, F_2, \dots, F_k be the sub-formulas of F corresponding to the k components of G and restricted to the variables that appear in the corresponding component. Since the components are disjoint, it follows that every clause of F appears in a unique component, the sub-problems captured by the components are independent, and, most pertinent to this chapter, that $\#F = \#F_1 \times \#F_2 \times \dots \times \#F_k$. Thus, $\#F$ can be evaluated by identifying disjoint components of F , computing the model count of each component, and multiplying the results together.

This idea is implemented in one of the first effective exact model counters for SAT, called `ReIsat` [BP00], which extends a previously introduced DPLL-based SAT solver by the same name [BS97]. Components are identified dynamically as the underlying DPLL procedure attempts to extend a partial assignment. With each new extension, several clauses may be satisfied so that the constraint graph simplifies dynamically depending on the actual value assignment to variables. While such dynamic detection and exploitation of components has often been observed to be too costly for pure satisfiability testing,⁴ it certainly pays off well for the harder task of model counting. Note that for the correctness of the

⁴Only recently have SAT solvers begun to efficiently exploit partial component caching schemes [PD07].

method, all we need is that the components are disjoint. However, the components detected by `ReIsat` are, in fact, the *connected* components of the constraint graph of F , indicating that the full power of this technique is being utilized. One of the heuristic *optimizations* used in `ReIsat` is to attempt the most constrained sub-problems first. Another trick is to first check the satisfiability of every component, before attempting to count any. `ReIsat` also solves sub-problems in an interleaved fashion, dynamically jumping to another sub-problem if the current one turns out to be less constrained than initially estimated, resulting in a best-first search of the developing component tree. Finally, the component structure of the formula is determined lazily while backtracking, instead of eagerly before branch selection. This does not affect the search space explored but often reduces the component detection overhead for unsatisfiable branches.

Bayardo Jr. and Schrag [BS97] demonstrated through `ReIsat` that applying these ideas significantly improves performance over basic CDP, obtaining exact counts for several problems from graph coloring, planning, and circuit synthesis/analysis domains that could not be counted earlier. They also observed, quite interestingly, that the *peak of hardness* of model counting for random 3-SAT instances occurs at a very different clause-to-variable ratio than the peak of hardness of solving such formulas. These instances were found to be the hardest for model counting at a ratio of $\alpha \approx 1.5$, compared to $\alpha \approx 4.26$ which marks the peak of hardness for SAT solvers as well as the (empirical) point of phase transition in such formulas from being mostly satisfiable to mostly unsatisfiable. Bailey et al. [BDK07] followed up on this observation and provided further analytical and empirical results on the hardness peak and the corresponding phase transition of the decision variants of random counting problems.

Caching: As one descends the search tree of a DPLL-based model counter, setting variables and simplifying the formula, one may encounter sub-formulas that have appeared in an earlier branch of the search tree. If this happens, it would clearly be beneficial to be able to efficiently recognize this fact, and instead of re-computing the model count of the sub-formula from scratch, somehow “remember” the count computed for it earlier. This is, in principle, similar to the clause learning techniques used commonly in today’s SAT solvers, except that for the purposes of model counting, it is no longer possible to succinctly express the key knowledge learned from each previous sub-formula as a single “conflict clause” that, for SAT, quite effectively captures the “reason” for that sub-formula being unsatisfiable. For model counting, one must also store, in some form, a signature of the full satisfiable sub-formulas encountered earlier, along with their computed model counts. This is the essence of *formula caching* systems [BDP03, BIPS03, ML98]. While formula caching is theoretically appealing even for SAT, being more powerful than clause learning [BIPS03], its overhead is much more likely to be offset when applied to harder problems like #SAT.

Bacchus et al. [BDP03] considered three variants of caching schemes: simple caching (a.k.a. formula caching), component caching, and linear-space caching. They showed that of these, *component caching* holds the greatest promise, being theoretically competitive with (and sometimes substantially better than) some of the best known methods for Bayesian inference. Putting these ideas into prac-

tice, Sang et al. [SBB⁺04] created the model counter **Cachet**, which ingeniously combined component caching with traditional clause learning within the setup of model counting.⁵ **Cachet** is built upon the well-known SAT solver **zChaff** [MMZ⁺01]. It turns out that combining component caching and clause learning in a naïve way leads to subtle issues that would normally permit one to only compute a lower bound on the model count. This problem is taken care of in **Cachet** using so-called *sibling pruning*, which prevents the undesirable interaction between cached components and clause learning from spreading.

Taking these ideas further, Sang et al. [SBK05a] considered the efficiency of various heuristics used in SAT solvers, but now in the context of model counting with component caching. They looked at component selection strategies, variable selection branching heuristics, randomization, backtracking schemes, and cross-component implications. In particular, they showed that model counting works better with a variant of the conflict graph based branching heuristic employed by **zChaff**, namely VSIDS (variable state independent decaying sum). This variant is termed VSADS, for variable state *aware* decaying sum, which linearly interpolates between the original VSIDS score and a more traditional formula-dependent score based on the number of occurrences of each variable.

Improved caching and more reasoning at each node: An important concern in implementing formula caching or component caching in practice is the space requirement. While these concerns are already present even for clause learning techniques employed routinely by SAT solvers and have led to the development of periodic clause deletion mechanisms, the problem is clearly more severe when complete sub-formulas are cached. **sharpSAT** [Thu06] uses several ideas that let components be stored more succinctly. For example, all clauses of any component stored by **sharpSAT** have at least two unassigned literals (unit propagation takes care of any active clauses with only one unassigned literal), and it does not explicitly store any binary clauses of the original formula in the component signature (binary clauses belonging to the component have both literals unassigned and can thus be easily reconstructed from the set of variables associated with the component). Further, it only stores (1) the indices of the variables in the component and (2) the indices of the original clauses that belong to that component, rather than storing full clauses or the learned conflict clauses. This can, in principle, prohibit some components from being identified as identical when they would be identified as identical by **Cachet**, which stores full clauses. Nonetheless, these techniques together are shown to reduce the storage requirement by an order of magnitude or more compared to **Cachet**, and to often increase efficiency.

sharpSAT also uses a “look ahead” technique known in the SAT community as the *failed literal* rule (the author refers to it as *implicit BCP*). Here every so often one identifies a set of candidate variables for each of which the failed literal test is applied: if setting x to TRUE makes the current formula unsatisfiable, then assert $x = \text{FALSE}$ and simplify; otherwise, if setting x to FALSE makes the current formula unsatisfiable, then assert $x = \text{TRUE}$ and simplify. The technique is shown to pay off well while model counting several difficult instances.

⁵Note that clause learning and decomposition into components were already implemented in the model counter **RelSAT**, but no caching.

Davies and Bacchus [DB07] have shown that employing more reasoning at each node of the DPLL search tree can significantly speed-up the model counting process.⁶ Specifically, they use hyper-binary resolution and equality reduction in addition to unit propagation, which simplifies the formula and often results in more efficient component detection and caching, and sometimes even stronger component division.

25.2.2. Counting Using Knowledge Compilation

A different approach for exact model counting is to convert or *compile* the given CNF formula into another logical form from which the count can be deduced easily, i.e., in time polynomial in the size of the formula in the new logical form. For example, in principle, one could convert the formula into a binary decision diagram or BDD [Bry86] and then “read off” the solution count by traversing the BDD from the leaf labeled “1” to the root. One advantage of this methodology is that once resources have been spent on compiling the formula into this new form, several complex queries can potentially be answered fairly quickly, often with a linear time traversal with simple book keeping. For instance, with BDDs, one can easily answer queries about satisfiability, being a tautology, logical equivalence to another formula, number of solutions, etc.

A knowledge compilation alternative was introduced by Darwiche [Dar04] in a compiler called *c2d*, which converts the given CNF formula into *deterministic, decomposable negation normal form* or d-DNNF. The DNNF form [Dar01, DM02] is a strict superset of ordered BDDs (in the sense that an ordered BDD can be converted in linear time into DNNF), and often more succinct. While a BDD is structurally quite different from a CNF style representation of a Boolean function,⁷ the negation normal form or NNF underlying d-DNNF is very much like CNF. Informally, one can think of a CNF formula as a 4-layer directed acyclic graph, with the root node labeled with AND or \wedge , pointing to all nodes in the next layer corresponding to clauses and labeled with OR or \vee , and each clause node pointing either directly or through a layer-3 node labeled NOT or \neg to nodes labeled with variable names, one for each variable; this represents the conjunction of disjunctions that defines CNF. In contrast, an NNF formula is defined by a rooted directed acyclic graph in which there is no restriction on the depth, each non-leaf node is labeled with either \wedge or \vee , each leaf node is labeled with either a variable or its negation, and the leaf nodes only have incoming edges (as before). Thus, unlike CNF, one may have several levels of alternations between \wedge and \vee nodes, but all negations are pushed down all the way to the leaf nodes. There are, in general, twice as many leaf nodes as variables.

In order to exploit NNF for model counting, one must add two features to it, decomposability and determinism:

- i. *Decomposability* says that for the children A_1, A_2, \dots, A_s of a node A^{AND} labeled \wedge , the variables appearing in each pair of the A_i 's must be disjoint, i.e., the logical expression at an AND-node can be decomposed into disjoint

⁶In SAT solving, this extra reasoning was earlier observed to not be cost effective.

⁷A BDD is more akin to the search space of a DPLL-style process, with nodes corresponding to branching on a variable by fixing it to TRUE or FALSE.

components corresponding to its children. For model counting, this translates into $\#f^{\text{AND}} = \#f_1 \times \#f_2 \times \dots \times \#f_s$, where f^{AND} and f_i denote the Boolean functions captured by A^{AND} and A_i , respectively.

- ii. In a similar manner, *determinism* says that the children B_1, B_2, \dots, B_t of a node B^{OR} labeled \vee do not have any common solutions, i.e., the logical conjunction of the Boolean functions represented by any two children of an OR-node is inconsistent. For model counting, this translates into $\#f^{\text{OR}} = \#f_1 + \#f_2 + \dots + \#f_s$, where f^{OR} and f_i denote the Boolean functions captured by B^{OR} and B_i , respectively.

The above properties suggest a simple model counting algorithm which computes $\#F$ from a d-DNNF representation of F , by performing a topological traversal of the underlying acyclic graph starting from the leaf nodes. Specifically, each leaf node is assigned a count of 1, the count of each \wedge node is computed as the product of the counts of its children, and the count of each \vee node is computed as the sum of the counts of its children. The count associated with the root of the graph is reported as the model count of F .

In the simplified d-DNNF form generated by `c2d`, every \vee node has exactly two children, and the node has as its secondary label the identifier of a variable that is guaranteed to appear as `TRUE` in all solutions captured by one child and as `FALSE` in all solutions captured by the other child. `c2d` can also be asked to compile the formula into a *smoothed* form, where each child of an \vee node has the same number of variables.

Inside `c2d`, the compilation of the given CNF formula F into d-DNNF is done by first constructing a decomposition tree or *dtree* for F , which is a binary tree whose leaves are tagged with the clauses of F and each of whose non-leaf vertices has a set of variables, called the *separator*, associated with it. The separator is simply the set of variables that are shared by the left and right branches of the node, the motivation being that once these variables have been assigned truth values, the two resulting sub-trees will have disjoint sets of variables. `c2d` uses an exhaustive version of the DPLL procedure to construct the dtree and compile it to d-DNNF, by ensuring that the separator variables for each node are either instantiated to various possible values (and combined using \vee nodes) or no longer shared between the two subtrees (perhaps because of variable instantiations higher up in the dtree or from the resulting unit-propagation simplifications). Once the separator variables are instantiated, the resulting components become disjoint and are therefore combined using \wedge nodes.

`c2d` has been demonstrated to be quite competitive on several classes of formulas, and sometimes more efficient than DPLL-based exact counters like `Cachet` and `ReIsat` even for obtaining a single overall model count. For applications that make several counting-related queries on a single formula (such as “marginal probability” computation or identifying “backbone variables” in the solution set), this knowledge compilation approach has a clear “re-use” advantage over traditional DPLL-based counters. This approach is currently being explored also for computing connected clusters in the solution space of a formula.

25.3. Approximate Model Counting

Most exact counting methods, especially those based on DPLL search, essentially attack a #P-complete problem head on—by exhaustively exploring the raw combinatorial search space. Consequently, these algorithms often have difficulty scaling up to larger problem sizes. For example, perhaps it is too much to expect a fast algorithm to be able to precisely distinguish between a formula having 10^{70} and $10^{70} + 1$ solutions. Many applications of model counting may not even care about such relatively tiny distinctions; it may suffice to provide rough “ball park” estimates, as long as the method is quick and the user has some confidence in its correctness. We should point out that problems with a higher solution count are not necessarily harder to determine the model count of. In fact, counters like **ReIsat** can compute the true model count of highly under-constrained problems with many “don’t care” variables and a lot of models by exploiting big clusters in the solution space. The model counting problem is instead much harder for more intricate combinatorial problems in which the solutions are spread much more finely throughout the combinatorial space.

With an abundance of difficult to count instances, scalability requirements shifted the focus on efficiency, and several techniques for fairly quickly estimating the model count have been proposed. With such estimates, one must consider two aspects: the *quality of the estimate* and the *correctness confidence* associated with the reported estimate. For example, by simply finding one solution of a formula F with a SAT solver, one can easily proclaim with high (100%) confidence that F has at least one solution—a correct lower bound on the model count. However, if F in reality has, say, 10^{15} solutions, this high confidence estimate is of very poor quality. On the other extreme, a technique may report an estimate much closer to the true count of 10^{15} , but may be completely unable to provide any correctness confidence, making one wonder how good the reported estimate actually is. We would ideally like to have some control on both the quality of the reported estimate as well as the correctness confidence associated with it. The quality may come as an empirical support for a technique in terms of it often being fairly close to the true count, while the correctness confidence may be provided in terms of convergence to the true count in the limit or as a probabilistic (or even statistical) guarantee on the reported estimate being a correct lower or upper bound. We have already mentioned in Section 25.1 one such randomized algorithm with strong theoretical guarantees, namely, the FPRAS scheme of Karp and Luby [KL85]. We discuss in the remainder of this section some approaches that have been implemented and evaluated more extensively.

25.3.1. Estimation Without Guarantees

Using sampling for estimates: Wei and Selman [WS05] introduced a local search based method that uses Markov Chain Monte Carlo (MCMC) sampling to compute an approximation of the true model count of a given formula. Their model counter, **ApproxCount**, is able to solve several instances quite accurately, while scaling much better than exact model counters as problem size increases.

ApproxCount exploits the fact that if one can sample (near-)uniformly from the set of solutions of a formula F , then one can compute a good estimate of

the number of solutions of F .⁸ The basic idea goes back to Jerrum, Valiant, and Vazirani [JVV86]. Consider a Boolean formula F with M satisfying assignments. Assuming we could sample these satisfying assignments uniformly at random, we can estimate the fraction of all models that have a variable x set to TRUE, M^+ , by taking the ratio of the number of models in the sample that have x set to TRUE over the total sample size. This fraction will converge, with increasing sample size, to the true fraction of models with x set positively, namely, $\gamma = M^+/M$. (For now, assume that $\gamma > 0$.) It follows immediately that $M = (1/\gamma)M^+$. We will call $1/\gamma$ the “multiplier” (> 0). We have thus reduced the problem of counting the models of F to counting the models of a simpler formula, $F^+ = F|_{x=\text{TRUE}}$; the model count of F is simply $1/\gamma$ times the model count of F^+ . We can recursively repeat the process, leading to a series of multipliers, until all variables are assigned truth values or—more practically—until the residual formula becomes small enough for us to count its models with an exact model counter. For robustness, one usually sets the selected variable to the truth value that occurs more often in the sample, thereby keeping intact a majority of the solutions in the residual formula and recursively counting them. This also avoids the problem of having $\gamma = 0$ and therefore an infinite multiplier. Note that the more frequently occurring truth value gives a multiplier $1/\gamma$ of at most 2, so that the estimated count grows relatively slowly as variables are assigned values.

In **ApproxCount**, the above strategy is made practical by using an efficient solution sampling method called **SampleSat** [WES04], which is an extension of the well-known local search SAT solver **Walksat** [SKC96]. Efficiency and accuracy considerations typically suggest that we obtain 20-100 samples per variable setting and after all but 100-300 variables have been set, give the residual formula to an exact model counter like **ReIsat** or **Cachet**.

Compared to exact model counters, **ApproxCount** is extremely fast and has been shown to provide very good estimates for solution counts. Unfortunately, there are no guarantees on the uniformity of the samples from **SampleSat**. It uses Markov Chain Monte Carlo (MCMC) methods [Mad02, MRR⁺53, KGV83], which often have exponential (and thus impractical) mixing times for intricate combinatorial problems. In fact, the main drawback of Jerrum et al.’s counting strategy is that for it to work well one needs uniform (or near-uniform) sampling, which is a very hard problem in itself. Moreover, biased sampling can lead to arbitrarily bad under- or over-estimates of the true count. Although the counts obtained from **ApproxCount** can be surprisingly close to the true model counts, one also observes cases where the method significantly over-estimates or under-estimates.

Interestingly, the inherent strength of most state-of-the-art SAT solvers comes actually from the ability to quickly narrow down to a certain portion of the search space the solver is designed to handle best. Such solvers therefore sample solutions in a highly non-uniform manner, making them seemingly ill-suited for model counting, unless one forces the solver to explore the full combinatorial space. An

⁸Note that a different approach, in principle, would be to estimate the *density* of solutions in the space of all 2^n truth assignments for an n -variable formula, and extrapolate that to the number of solutions. This would require sampling all truth assignments uniformly and computing how often a sampled assignment is a solution. This is unlikely to be effective in formulas of interest, which have very sparse solution spaces, and is not what **ApproxCount** does.

intriguing question (which will be addressed in Section 25.3.2) is whether there is a way around this apparent limitation of the use of state-of-the-art SAT solvers for model counting.

Using importance sampling: Gogate and Dechter [GD07] proposed a model counting technique called **SampleMinisat**, which is based on sampling from the so-called backtrack-free search space of a Boolean formula through **SampleSearch** [GD06]. They use an importance re-sampling method at the base. Suppose we wanted to sample all solutions of F uniformly at random. We can think of these solutions sitting at the leaves of a DPLL search tree for F . Suppose this search tree has been made backtrack-free, i.e., all branches that do not lead to any solution have been pruned away. (Of course, this is likely to be impractical to achieve perfectly in practice in reasonably large and complex solution spaces without spending an exponential amount of time constructing the complete tree, but we will attempt to approximate this property.) In this backtrack-free search space, define a random process that starts at the root and at every branch chooses to follow either child with equal probability. This yields a probability distribution on all satisfying assignments of F (which are the leaves of this backtrack-free search tree), assigning a probability of 2^{-d} to a solution if there are d branching choices in the tree from the root to the corresponding leaf. In order to sample not from this particular “backtrack-free” distribution but from the *uniform* distribution over all solutions, one can use the importance sampling technique [Rub81], which works as follows. First sample k solutions from the backtrack-free distribution, then assign a new probability to each sampled solution which is proportional to the inverse of its original probability in the backtrack-free distribution (i.e., proportional to 2^d), and finally sample one solution from this new distribution. As k increases, this process, if it could be made practical, provably converges to sampling solutions uniformly at random.

SampleMinisat builds upon this idea, using DPLL-based SAT solvers to construct the backtrack-free search space, either completely or to an approximation. A simple modification of the above uniform sampling method can be used to instead estimate the *number* of solutions (i.e., the number of leaves in the backtrack-free search space) of F . The process is embedded inside a DPLL-based solver, which keeps track of which branches of the search tree have already been shown to be unsatisfiable. As more of the search tree is explored to generate samples, more branches are identified as unsatisfiable, and one gets closer to achieving the exact backtrack-free distribution. In the limit, as the number of solution samples increases to infinity, the entire search tree is explored and all unsatisfiable branches tagged, yielding the true backtrack-free search space. Thus, this process in the limit converges to purely uniform solutions and an accurate estimate of the number of solutions. Experiments with **SampleMinisat** show that it can provide very good estimates of the solution count when the formula is within the reach of DPLL-based methods. In contrast, **ApproxCount** works well when the formula is more suitable for local search techniques like **Walksat**.

Gogate and Dechter [GD07] show how this process, when using the exact backtrack-free search space (as opposed to its approximation), can also be used to provide lower bounds on the model count with probabilistic correctness guarantees following the framework of **SampleCount**, which we discuss next.

25.3.2. Lower and Upper Bounds With Guarantees

Using sampling for estimates with guarantees: Building upon `ApproxCount`, Gomes et al. [GHSS07a] showed that, somewhat surprisingly, using sampling with a modified, randomized strategy, one can get provable *lower bounds* on the total model count, with high confidence (probabilistic) correctness guarantees, *without any requirement on the quality of the sampling process*. They provide a formal analysis of the approach, implement it as the model counter `SampleCount`, and experimentally demonstrate that it provides very good lower bounds—with high confidence and within minutes—on the model counts of many problems which are completely out of reach of the best exact counting methods. The key feature of `SampleCount` is that the correctness of the bound reported by it holds even when the sampling method used is arbitrarily bad; only the quality of the bound may deteriorate (i.e., the bound may get farther away from the true count on the lower side). Thus, the strategy remains sound even when a heuristic-based practical solution sampling method is used instead of a true uniform sampler.

The idea is the following. Instead of using the solution sampler to select the variable setting and to compute a multiplier, let us use the sampler only as a heuristic to determine *in what order* to set the variables. In particular, we will use the sampler to select a variable whose positive and negative setting occurs most balanced in our set of samples (ties are broken randomly). Note that such a variable will have the highest possible multiplier (closest to 2) in the `ApproxCount` setting discussed above. Informally, setting the most balanced variable will divide the solution space most evenly (compared to setting one of the other variables). Of course, our sampler may be heavily biased and we therefore cannot really rely on the observed ratio between positive and negative settings of a variable. Interestingly, we can simply set the variable to a randomly selected truth value and use the multiplier 2. This strategy will still give—in expectation—the true model count. A simple example shows why this is so. Consider the formula F used in the discussion in Section 25.3.1 and assume x occurs most balanced in our sample. Let the model count of F^+ be $2M/3$ and of F^- be $M/3$. If we decide with probability $1/2$ to set x to `TRUE`, we obtain a total model count of $2 \times 2M/3$, i.e., too high; but, with probability $1/2$, we will set x to `FALSE`, obtaining a total count of $2 \times M/3$, i.e., too low. Together, these imply an expected (average) count of exactly M .

Technically, the *expected total model count* is correct because of the linearity of expectation. However, we also see that we may have significant *variance* between specific counts, especially since we are setting a series of variables in a row (obtaining a sequence of multipliers of 2), until we have a simplified formula that can be counted exactly. In fact, in practice, the distribution of the estimated total count (over different runs) is often heavy-tailed [KSTW06]. To mitigate the fluctuations between runs, we use our samples to select the “best” variables to set next. Clearly, a good heuristic would be to set such “balanced” variables first. We use `SampleSat` to get guidance on finding such balanced variables. The random value setting of the selected variable leads to an expected model count that is equal to the actual model count of the formula. Gomes et al. [GHSS07a] show how this property can be exploited using Markov’s inequality to obtain lower

bounds on the total model count with predefined confidence guarantees. These guarantees can be made arbitrarily strong by repeated iterations of the process.

What if all variable are found to be not so balanced? E.g., suppose the most balanced variable x is TRUE in 70% of the sampled solutions and FALSE in the remaining 30%. While one could still set x to TRUE or FALSE with probability $1/2$ each as discussed above and still maintain a correct count in expectation, Kroc et al. [KSS08] discuss how one might reduce the resulting variance by instead using a *biased coin* with probability $p = 0.7$ of Heads, setting x to TRUE with probability 0.7, and scaling up the resulting count by $1/0.7$ if x was set to TRUE and by $1/0.3$ if x was set to FALSE. If the samples are uniform, this process provably reduces the variance, compared to using an unbiased coin with $p = 0.5$.

The effectiveness of `SampleCount` is further boosted by using variable “equivalence” when no single variable appears sufficiently balanced in the sampled solutions. For instance, if variables x_1 and x_2 occur with the same polarity (either both TRUE or both FALSE) in nearly half the sampled solutions and with a different polarity in the remaining, we randomly replace x_2 with either x_1 or $\neg x_1$, and simplify. This turns out to have the same simplification effect as setting a single variable, but is more advantageous when no single variable is well balanced.

Using XOR-streamlining: `MBound` [GSS06] is a very different method for model counting, which interestingly uses any complete SAT solver “as is” in order to compute an estimate of the model count of the given formula. It follows immediately that the more efficient the SAT solver used, the more powerful this counting strategy becomes. `MBound` is inspired by work on so-called “streamlining constraints” [GS04], in which additional, non-redundant constraints are added to the original problem to increase constraint propagation and to focus the search on a small part of the subspace, (hopefully) still containing solutions. This technique was earlier shown to be successful in solving very hard combinatorial design problems, with carefully created, domain-specific streamlining constraints. In contrast, `MBound` uses a domain-independent streamlining process, where the streamlining constraints are constructed purely at random.

The central idea of the approach is to use a special type of randomly chosen constrains, namely XOR or parity constraints on the original variables of the problem. Such constraints require that an *odd* number of the involved variables be set to TRUE. (This requirement can be translated into the usual CNF form by using additional variables [Tse68], and can also be modified into requiring that an *even* number of variables be TRUE by adding the constant 1 to the set of involved variables.)

`MBound` works in a very simple fashion: repeatedly add a number s of purely random XOR constraints to the formula as additional CNF clauses, feed the resulting streamlined formula to a state-of-the-art complete SAT solver without any modification, and record whether or not the streamlined formula is still satisfiable. At a very high level, each random XOR constraint will cut the solution space of satisfying assignments approximately in half. As a result, intuitively speaking, if after the addition of s XOR constraints the formula is still satisfiable, the original formula must have at least of the order of 2^s models. More rigorously, it can be shown that if we perform t experiments of adding s random XOR constraints and our formula remains satisfiable in each case, then with probability at least

$1 - 2^{-\alpha t}$, our original formula will have at least $2^{s-\alpha}$ satisfying assignments for any $\alpha > 0$, thereby obtaining a lower bound on the model count with a probabilistic correctness guarantee. The confidence expression $1 - 2^{-\alpha t}$ says that by repeatedly doing more experiments (by increasing t) or by weakening the claimed bound of $2^{s-\alpha}$ (by increasing α), one can arbitrarily boost the confidence in the lower bound count reported by this method.

The method generalizes to the case where some streamlined formulas are found to be satisfiable and some are not. Similar results can also be derived for obtaining an upper bound on the model count, although the variance-based analysis in this case requires that the added XOR constraints involve as many as $n/2$ variables on average, which often decreases the efficiency of SAT solvers on the streamlined formula.⁹ The efficiency of the method can be further boosted by employing a *hybrid* strategy: instead of feeding the streamlined formula to a SAT solver, feed it to an exact model counter. If the exact model counter finds M solutions to the streamlined formula, the estimate of the total model count of the original formula is taken to be $2^{s-\alpha} \times M$, again with a formal correctness probability attached to statistics over this estimate over several iterations; the minimum, maximum, and average values over several iterations result in different associated correctness confidence.

A surprising feature of this approach is that it does not depend at all on how the solutions are distributed throughout the search space. It relies on the very special properties of random parity constraints, which in effect provide a good hash function, randomly dividing the solutions into two near-equal sets. Such constraints were earlier used by Valiant and Vazirani [VV86] in a randomized reduction from SAT to the related problem UniqueSAT (a “promise problem” where the input is guaranteed to have either 0 or 1 solution, never 2 or more), showing that UniqueSAT is essentially as hard as SAT. Stockmeyer [Sto85] had also used similar ideas under a theoretical setting. The key to converting this approach into a state-of-the-art model counter was the relatively recent observation that very short XOR constraints—the only ones that are practically feasible with modern constraint solvers—can provide a fairly accurate estimate of the model count on a variety of domains of interest [GSS06, GHSS07b].

Exploiting Belief Propagation methods: Kroc et al. [KSS08] showed how one can use probabilistic reasoning methods for model counting. Their algorithm, called **BPCount**, builds upon the lower bounding framework of **SampleCount**. However, instead of using several solution samples for heuristic guidance—which can often be time consuming—they use a probabilistic reasoning approach called Belief Propagation or BP. A description of BP methods in any reasonable detail is beyond the scope of this chapter; we refer the reader to standard texts on this subject [e.g. Pea88] as well as to Part 2, Chapter 22 of this Handbook. In essence, BP is a general “message passing” procedure for probabilistic reasoning, and is often described in terms of a set of mutually recursive equations which are solved in an iterative manner. On SAT instances, BP works by passing likelihood

⁹It was later demonstrated empirically [GHSS07b] that for several problem domains, significantly shorter XOR constraints are effectively as good as XOR constraints of length $n/2$ (“full length”) in terms of the key property needed for the accuracy of this method: low *variance* in the solution count estimate over several runs of **MBound**.

information between variables and clauses in an iterative fashion until a fixed point is reached. From this fixed point, statistical information about the solution space of the formula can be easily computed. This statistical information is provably exact when the constraint graph underlying the formula has a tree-like structure, and is often reasonably accurate (empirically) even when the constraint graph has cycles [cf. MWJ99].

For our purposes, BP, in principle, provides *precisely* the information deduced from solution samples in **SampleCount**, namely, an estimate of the *marginal probability* of each variable being TRUE or FALSE when all solutions are sampled uniformly at random. Thus, **BPCount** works exactly like **SampleCount** and provides the same probabilistic correctness guarantees, but is often orders of magnitude faster on several problem domains because running BP on the formula is often much faster than obtaining several solution samples through **SampleSat**. A challenge in this approach is that the standard mutually recursive BP equations don't even converge to any fixed point on many practical formulas of interest. To address this issue, Kroc et al. [KSS08] employ a *message-damping* variant of BP whose convergence behavior can be controlled by a continuously varying parameter. They also use *safety checks* in order to avoid fatal mistakes when setting variables (i.e., to avoid inadvertently making the formula unsatisfiable).

We note that the model count of a formula can, in fact, also be estimated directly from just one fixed point run of the BP equations, by computing the value of so-called partition function [YFW05]. However, the count estimated this way is often highly inaccurate on structured loopy formulas. **BPCount**, on the other hand, makes a much more robust use of the information provided by BP.

Statistical upper bounds: In a different direction, Kroc et al. [KSS08] propose a second method, called **MiniCount**, for providing *upper bounds* on the model counts of formulas. This method exploits the power of modern DPLL-based SAT solvers, which are extremely good at finding single solutions to Boolean formulas through backtrack search. The problem of computing upper bounds on the model count had so far eluded solution because of the asymmetry (discussed earlier in the partial counts sub-section of Section 25.2.1) which manifests itself in at least two inter-related forms: the set of solutions of interesting n variable formulas typically forms a minuscule fraction of the full space of 2^n truth assignments, and the application of Markov's inequality as in the lower bound analysis of **SampleCount** does not yield interesting upper bounds. As noted earlier, this asymmetry also makes upper bounds provided by partial runs of exact model counters often not very useful. To address this issue, Kroc et al. [KSS08] develop a *statistical framework* which lets one compute upper bounds under certain statistical assumptions, which are independently validated.

Specifically, they describe how the SAT solver **MiniSat** [ES05], with two minor modifications—randomizing whether the chosen variable is set to TRUE or to FALSE, and disabling restarts—can be used to estimate the total number of solutions. The number d of branching decisions (not counting unit propagations and failed branches) made by **MiniSat** before reaching a solution, is the main quantity of interest: when the choice between setting a variable to TRUE or to

FALSE is randomized,¹⁰ the number d is provably not any lower, in expectation, than \log_2 of the true model count. This provides a strategy for obtaining upper bounds on the model count, only if one could efficiently estimate the expected value, $\mathbb{E}[d]$, of the number of such branching decisions. A natural way to estimate $\mathbb{E}[d]$ is to perform multiple runs of the randomized solver, and compute the average of d over these runs. However, if the formula has many “easy” solutions (found with a low value of d) and many “hard” solutions (requiring large d), the limited number of runs one can perform in a reasonable amount of time may be insufficient to hit many of the “hard” solutions, yielding too low of an estimate for $\mathbb{E}[d]$ and thus an incorrect upper bound on the model count.

Interestingly, they show that for many families of formulas, d has a distribution that is very close to the normal distribution; in other words, the estimate 2^d of the upper bound on the number of solutions is log-normally distributed. Now, under the assumption that d is indeed normally distributed, estimating $\mathbb{E}[d]$ for an upper bound on the model count becomes easier: when sampling various values of d through multiple runs of the solver, one need not necessarily encounter both low and high values of d in order to correctly estimate $\mathbb{E}[d]$. Instead, even with only below-average samples of d , the assumption of normality lets one rely on standard statistical tests and conservative computations to obtain a statistical upper bound on $\mathbb{E}[d]$ within any specified confidence interval. We refer the reader to the full paper for details. Experimentally, `MiniCount` is shown to provide good upper bounds on the solution counts of formulas from many domains, often within seconds and fairly close to the true counts (if known) or separately computed lower bounds.

25.4. Conclusion

With SAT solving establishing its mark as one of the most successful automated reasoning technologies, the model counting problem for SAT has begun to see a surge of activity in the last few years. One thing that has been clear from the outset is that model counting is a much harder problem. Nonetheless, thanks to its broader scope and applicability than SAT solving, it has led to a range of new ideas and approaches—from DPLL-based methods to local search sampling estimates to knowledge compilation to novel randomized streamlining methods. Practitioners working on model counting have discovered that many interesting techniques that were too costly for SAT solving are not only cost effective for model counting but crucial for scaling practical model counters to reasonably large instances. The variety of tools for model counting is already rich, and growing. While we have made significant progress, at least two key challenges remain open: how do we push the limits of scalability of model counters even further, and how do we extend techniques to do model counting for *weighted* satisfiability problems?¹¹ While exact model counters are often able to also solve

¹⁰`MiniSat` by default always sets variables to FALSE.

¹¹In weighted model counting, each variable x has a weight $p(x) \in [0, 1]$ when set to TRUE and a weight $1 - p(x)$ when set to FALSE. The weight of a truth assignment is the product of the weights of its literals. The weighted model count of a formula is the sum of the weights of its satisfying assignments.

the weighted version of the problem at no extra cost, much work needs to be done to adapt the more scalable approximate methods to handle weighted model counting.

Chapter 26

Approximate Model Counting

Supratik Chakraborty, Kuldeep S. Meel, and Moshe Y. Vardi

26.1. Introduction

Model counting, or counting the solutions to a set of constraints, is a fundamental computational problem with applications in diverse areas spanning probabilistic inference, network reliability estimation, statistical physics, explainable AI, security vulnerability analysis, and the like [Rot96, DH07, XCD12, ABB15, DOMPV17, LSS17, BEH⁺18, ZQRZ18, NSM⁺19, BSS⁺19]. While exact counting is known to be computationally hard (see Chapter 25 for more details on exact counting), a large class of applications can benefit even if approximate model counts are available. Approximate counting algorithms have therefore been studied in great depth by both theoreticians and practitioners. In this chapter, we discuss some of the key ideas behind modern approximate model counters for propositional constraints.

We begin with some notation and terminology. Let φ be a propositional formula. We use $|\varphi|$ to denote the size of φ presented as a string to a Turing machine, and call the set of all variables in φ the *support* of φ , or $\text{Sup}(\varphi)$. Following standard terminology, a variable or its negation is called a *literal*, a *clause* is a disjunction of literals, and a *cube* is a conjunction of literals. We say φ is in *conjunctive normal form* (CNF) if it is a conjunction of clauses. Similarly, we say φ is in *disjunctive normal form* (DNF) if it is a disjunction of cubes. A satisfying assignment, solution, or model of φ is an assignment of truth values to all variables in $\text{Sup}(\varphi)$ such that φ evaluates to True. We use $\text{Sol}(\varphi)$ to denote the set of all models of φ . The *model counting* problem asks: *Given φ , find $|\text{Sol}(\varphi)|$.*

26.1.1. A historical perspective

Approximate model counting techniques, at least for CNF formulas, have mostly evolved hand-in-hand with techniques for exact model counting, except in the last decade or so, when a few innovations triggered a large body of work in the broad area of approximate counting and sampling. The real value-addition of approximate counters has always been in cases that lie beyond the reach of exact counters, given computational resource constraints. Scalability has therefore been

a key consideration throughout the history of the development of approximate model counters. It was widely believed until recently (circa 2006) that this scalability can be achieved only by weakening or sacrificing approximation guarantees. As a consequence, most applications used approximate counting techniques with weak or no guarantees at all. An example of such usage is that of Monte Carlo estimators for model counting where the number of Monte Carlo steps is truncated heuristically before the theory-mandated mixing of states happen [WS05]. Fortunately, work done over the last decade has convincingly demonstrated that by striking a fine balance between theoretical and practical considerations, it is indeed possible to design approximate model counters that provide strong guarantees while also scaling to problem instances that are orders of magnitude larger than what was possible earlier. To get a sense of where we stand in 2019, state-of-the-art approximate model counters can solve problem instances with half a million propositional variables in less than 2 hours on a single high-end computing node, yielding estimates that are provably within a factor of 1.8 of the true count with at least 99% confidence [SM19].

Some of the key theoretical results pertaining to approximate counting were already known as early as the mid 1980s [Sto83, JVV86]. In a seminal paper [Sto83], Stockmeyer used universal hash functions [CW77] to solve the approximate counting problem using polynomially many NP oracle calls. While theoretically elegant, the proposed technique suffered from the requirement of a prohibitively large number of invocations of NP oracle to perform symbolic reasoning on formulas with very large numbers of variables. Jerrum, Valiant, and Vazirani demonstrated inter-reducibility of approximate counting and almost-uniform sampling in [JVV86]. Almost a decade later, Bellare, Goldreich, and Petrank reported an almost uniform generator of models using hash-functions of high degree of universality [BGP00]. Technically, this could be used to approximately count models using Jerrum et al.'s result [JVV86]. Unfortunately, our attempt in this direction [CMV13a] showed that this approach did not scale beyond formulas with more than 20 propositional variables. The major stumbling block was the requirement of inverting a hash function with a high degree of universality.

After a long period of relatively incremental improvements in approximate counting techniques, in 2006, Gomes, Sabharwal and Selman [GSS06] reported a parameterized approximate counting algorithm that used random parity constraints as universal hash functions and harnessed the power of a state-of-the-art CNF satisfiability solver in the backend. They showed that if the right combination of parameters was chosen by the user (this is not always easy), this approach could solve problems much larger than what was possible earlier, and yet provide guarantees on the quality of the estimate. Subsequently, this work was developed further in [GHSS07b, GHSS07a]. In 2013, two independent papers [CMV13b, EGSS13b] reported highly scalable approximate counting algorithms in two different settings, guaranteeing $(1 + \varepsilon)$ -factor approximation with confidence at least $1 - \delta$ for any user-provided values of ε and δ . The dependence on the user to provide the right combination of parameters was removed in these algorithms and their implementations benefitted from the then newly-proposed SAT solver *CryptoMiniSat* that could handle parity constraints natively [SNC09].

Since then, there has been a large body of work in this area, as detailed later in the chapter.

Interestingly, the history of development of approximate model counters for DNF formulas followed a different trajectory. As early as 1983, Karp and Luby showed that it is possible to approximate the model count of DNF formulas efficiently and with strong guarantees using Monte Carlo sampling [KL83]. While there have been several follow-up works that built and improved on this algorithm, the success of these techniques could not be lifted to the case of CNF formulas due to key steps that exploit the fact that the input formula is in DNF. Monte Carlo techniques have dominated the landscape of approximate counters for DNF formulas since Karp and Luby’s early work. It is only recently that an alternative approach using universal hash functions has been found to achieve the same guarantees and the same asymptotic time complexity [CMV16, MSV17, MSV19] as the best-known Monte Carlo algorithm. As observed, however, in [MSV19], the empirically observed runtime of approximate DNF counting algorithms is much more nuanced and hard to predict.

26.1.2. An overview of the complexity landscape

Exact model counting, and even some variants of approximate counting are computationally hard in a formal sense. To appreciate this better, we review a few concepts from complexity theory. The reader is assumed to be familiar with the notions of Turing machines, as well as the complexity classes P , NP , $coNP$ and their generalization to the polynomial hierarchy (PH). A detailed exposition on these can be found in [AB09]. Given an instance of a problem in NP , the corresponding counting problem asks how many accepting paths exist in the non-deterministic Turing machine that solves the problem. The complexity class $\#P$ is defined to be the set of counting problems associated with all decision problems in NP . Toda showed that a single invocation of a $\#P$ -oracle suffices to solve every problem in the polynomial hierarchy efficiently [Tod89]. Formally, $PH \subseteq P^{\#P}$, where $\mathcal{C}_1^{\mathcal{C}_2}$ denotes the class of problems that can be solved by a Turing machine for a problem in \mathcal{C}_1 when equipped with an oracle for a complete problem in \mathcal{C}_2 . A consequence of Toda’s theorem is that problems in $\#P$ (viz. exact model counting) are likely much harder than those in PH.

A *probabilistic Turing machine* is a non-deterministic Turing machine with specially designated “coin-tossing” states. When the machine reaches one of these states, it can choose between alternative transitions based on a probability distribution of coin tosses. For our purposes, the probability distribution is assumed to be uniform. Computing with probabilistic Turing machines gives rise to probabilistic complexity classes like RP , BPP etc. The reader is referred to [AB09] for more details on these classes. In a functional problem like model counting, for every input x , we seek an answer $f(x) \in \mathbb{N}$ of size polynomial in $|x|$. A *fully polynomial randomized approximation scheme* (FPRAS) for such a problem is a probabilistic Turing machine that takes as input x and a parameter $\varepsilon (> 0)$. It then generates an estimate c that lies within $f(x) \cdot (1 + \varepsilon)^{-1}$ and $f(x) \cdot (1 + \varepsilon)$ with probability strictly greater than $\frac{1}{2}$, while taking time polynomial in $|x|$ and $\frac{1}{\varepsilon}$. Given an FPRAS for a functional problem, the probability of generating an estimate outside the tolerance window can be reduced below any desired confidence

threshold δ ($0 < \delta \leq 1$) by running the FPRAS $\mathcal{O}(\log \frac{1}{\delta})$ times independently and by choosing the median estimate.

Valiant showed that exact model counting is $\#\text{P}$ -complete for both CNF and DNF formulas [Val79]. Therefore, it is unlikely that any efficient algorithm exists for exact model counting. This has motivated significant research on different variants of approximate model counting over the past four decades. To have a unified view of these variants, we introduce some notation. Let Z be a random variable with a specified probability distribution. Let $\bowtie \in \{=, \leq, <, >, \geq\}$ be a relational operator and let a be a value in the range of Z . We use $\Pr[Z \bowtie a]$ to denote the probability that $Z \bowtie a$ holds. We also use $\mathbb{E}[Z]$ and $\text{Var}[Z]$ to denote the expectation and variance, respectively, of Z . An approximate model counter takes as input a formula φ (along with possibly tolerance and confidence parameters) and returns an estimate c that approximates $|\text{Sol}(\varphi)|$. Depending on whether the algorithm is deterministic or randomized, and depending on the type of approximation used, we can identify several variants of approximate model counters. In the following discussion, unless specified otherwise, ε (> 0) represents a (additive or multiplicative) tolerance used in approximating $|\text{Sol}(\varphi)|$, and δ ($0 < \delta \leq 1$) represents a confidence bound for a randomized algorithm.

A *deterministic additive approximate model counter* takes a formula φ and an additive tolerance ε (> 0) as inputs, and returns an estimate c (≥ 0) such that $(|\text{Sol}(\varphi)| - \varepsilon) \leq c \leq (|\text{Sol}(\varphi)| + \varepsilon)$. A *probabilistic additive approximate model counter* takes an additional confidence parameter δ ($0 < \delta \leq 1$) as input, and finds a random estimate c (≥ 0) such that $\Pr[(|\text{Sol}(\varphi)| - \varepsilon) \leq c \leq (|\text{Sol}(\varphi)| + \varepsilon)] \geq 1 - \delta$. Unfortunately, if $\varepsilon \leq 2^{\frac{|\text{Sup}(\varphi)|}{2} - 2}$, both versions of additive approximate model counting are computationally hard. Specifically, the deterministic version continues to be $\#\text{P}$ -complete, while the probabilistic version lies beyond PH, unless the entire PH collapses [CMV19]. Thus, additive approximations do not simplify the problem of counting from a worst-case complexity perspective, and we choose not to elaborate further on this class of counters. It is worth mentioning, however, that approximate counters with additive tolerance have been used in some applications, viz. [SVP⁺16] and [FHO13].

Counters with multiplicative approximations have been much more extensively studied. A *deterministic multiplicative approximate model counter* takes as inputs a formula φ and a multiplicative tolerance ε (> 0) and returns an estimate c (≥ 0) such that $|\text{Sol}(\varphi)| \cdot (1 + \varepsilon)^{-1} \leq c \leq |\text{Sol}(\varphi)| \cdot (1 + \varepsilon)$. A *probabilistic multiplicative approximate model counter*, also called a *probably approximately correct (PAC)* model counter, takes an additional confidence parameter δ ($0 < \delta \leq 1$) as input and returns a random estimate c (≥ 0) such that $\Pr[|\text{Sol}(\varphi)| \cdot (1 + \varepsilon)^{-1} \leq c \leq |\text{Sol}(\varphi)| \cdot (1 + \varepsilon)] \geq 1 - \delta$. In a seminal paper, Stockmeyer showed that approximate counting with multiplicative tolerance can be solved by a deterministic algorithm that makes polynomially many calls to a Σ_2^P oracle [Sto83]. Therefore, practically efficient deterministic algorithms for approximate counting can be designed if we have access to Σ_2^P solvers (also called *2QBF* solvers) that can solve large problem instances efficiently in practice. Unfortunately, despite significant advances in 2QBF solving, this has not yet yielded practically efficient deterministic approximate counters yet. Building on Stockmeyer's work, Jerrum et al. [JVV86] showed that approximate counting

with PAC guarantees can be achieved by a probabilistic Turing machine in polynomial time with access to an NP oracle. Given the spectacular improvement in performance of propositional SAT solvers over the past few decades, research in practically useful approximate model counting has largely focused on variants of approximate counters with PAC guarantees.

The variants of approximate counting discussed above require the estimate to lie within a specified tolerance window on *either* side of the exact count. The required approximation guarantees are therefore two-sided. In some applications this may not be needed, and one-sided approximation guarantees (viz. $c \geq |\text{Sol}(\varphi)| \cdot (1 + \varepsilon)^{-1}$) may be sufficient. Therefore, approximate counting with one-sided guarantees has also been studied in the literature. In this chapter, however, we focus on approximate counters with two-sided guarantees, since they provide the strongest approximation guarantees while still scaling to large problem instances in practice. The interested reader is referred to Chapter 25 for more details on counters with one-sided approximation guarantees and guarantee-less approximate counters.

A brief examination of the differences between approximate model counting for CNF and DNF formulas is in order here. It was Karp and Luby [KL83] who first showed that DNF model counting admits an FPRAS. Their algorithm and analysis were subsequently improved in [KLM89]. Recently, it was re-proved in [CMV16, MSV17] that DNF counting admits an FPRAS using techniques different from those used in [KL83, KLM89]. Unfortunately, as observed in [KL83, KL85], CNF model counting cannot admit an FPRAS unless $\text{NP} = \text{RP}$ – a longstanding unresolved question in complexity theory. The best we know at present is that approximate counting for CNF formulas with PAC guarantees can be solved by a probabilistic Turing machine *with access to an NP oracle* in time polynomial in $|\varphi|$, $\frac{1}{\varepsilon}$ and $\log \frac{1}{\delta}$. Therefore, approximate model counting for CNF and DNF formulas present different sets of challenges and we discuss them separately.

The problems of approximate counting with PAC guarantees and *almost uniform generation* of models are intimately related to each other. Given φ and a tolerance ε (≥ 0), let $\alpha(\varphi)$ be a real number in $(0, 1]$ that depends only on φ . An almost uniform generator is a probabilistic Turing machine that takes as inputs a formula φ and a tolerance ε (> 0), and outputs a random assignment π to variables in $\text{Sup}(\varphi)$ such that $\alpha(\varphi) \cdot (1 + \varepsilon)^{-1} \leq \Pr[\pi \text{ is output}] \leq \alpha(\varphi) \cdot (1 + \varepsilon)$ if π is a solution of φ , and $\Pr[\pi \text{ is output}] = 0$ otherwise. Jerrum et al. [JVV86] showed that approximate counting with PAC guarantees and almost uniform generation are polynomially inter-reducible. Thus, an almost uniform generator can be used as a sub-routine to obtain a approximate counter for φ and vice versa. Furthermore, the time-complexity of each problem is within a polynomial factor of that of the other. It turns out, however, that all practically efficient almost uniform generators developed so far already use an approximate counter (or some variant of it) internally in an intermediate step. Hence, using such a sampler to obtain an approximate counter again is not very meaningful.

26.2. Approximate Model Counting for CNF

In this section, we discuss algorithms for computing a PAC estimate of $|\text{Sol}(\varphi)|$, where φ is a CNF formula. Significantly, all state-of-the-art algorithms for this problem make use of probabilistic hash functions. Therefore, we first present a generic framework for approximate model counting using probabilistic hash functions. We then show how different algorithms developed over the years [Sto83, GSS06, CMV13b, IMMV15, AD16, CMV16, ZCSE16, AT17, AHT18, SM19] can be viewed as instantiations and optimizations of this framework.

26.2.1. Probabilistic hash-based counting

A probabilistic hash function maps elements of a given domain, viz. $\{0, 1\}^n$, to random buckets or “cells” from a finite range, viz. $\{0, 1\}^i$ where $0 \leq i \leq n$. This is achieved by choosing a hash function uniformly at random from a family of functions, each of which maps $\{0, 1\}^n$ to $\{0, 1\}^i$. In probabilistic hash-based counting, the solution space of φ is randomly partitioned into approximately equal-sized “small” cells using probabilistic hash functions. Suppose each hash function in a family has a range of 2^i cells, and we choose one of these at random. By carefully designing the hash family, we can ensure that the count of solutions of φ in an arbitrary cell of the induced partitioning of $\text{Sol}(\varphi)$ is an unbiased estimator of $\frac{|\text{Sol}(\varphi)|}{2^i}$ with small variance. Therefore, if we count the solutions of φ in a single cell and scale it by 2^i , we obtain an estimate of $|\text{Sol}(\varphi)|$.

In order to formalize the above intuition, we need some additional notation. Let $\{x_1, \dots, x_n\}$ be the support of φ . Let h_i denote a hash function that maps elements of $\{0, 1\}^n$ to $\{0, 1\}^i$, where $0 \leq i \leq n$. Let \mathcal{H}_i be a (sub-)family of such hash functions mapping $\{0, 1\}^n$ to $\{0, 1\}^i$. We use \mathcal{H} to denote the family of hash functions obtained by taking the union of all \mathcal{H}_i for $i \in \{0, \dots, n\}$.

The general structure of a probabilistic hash-based approximate counter is shown in Algorithm 1. The algorithm takes as inputs a formula φ , a tolerance bound ε (> 0) and a confidence bound δ ($0 < \delta \leq 1$). It returns an estimate c such that $\Pr [|\text{Sol}(\varphi)| \cdot (1 + \varepsilon)^{-1} \leq c \leq |\text{Sol}(\varphi)| \cdot (1 + \varepsilon)] \geq 1 - \delta$. Let us ignore lines 1 through 4 of Algorithm 1 for now. In line 5, we commit to using a family of hash functions, say \mathcal{H} . In general, \mathcal{H} has sub-families \mathcal{H}_i as discussed above. In line 8, we choose $n + 1$ hash functions, one from each sub-family \mathcal{H}_i in \mathcal{H} . Let these hash functions be $h_i : \{0, 1\}^n \rightarrow \{0, 1\}^i$ for $i \in \{0, \dots, n\}$. Depending on the counter, each h_i may be chosen independently of h_j (for $j \neq i$), or the choice of h_i may be correlated with the choice of h_j . Note that each h_i partitions $\text{Sol}(\varphi)$ into 2^i cells. Furthermore, for every $\mathbf{a} \in \{0, 1\}^i$, the set $\text{Sol}(\varphi \wedge h_i^{-1}(\mathbf{a}))$ consists of exactly those solutions of φ that are mapped to the cell \mathbf{a} by h_i .

The core of Algorithm 1 consists of the loop in lines 10–15. This loop searches for the smallest index i in $\{1, \dots, n\}$ such that the partitioning induced by h_i yields “small” cells with only a few solutions of φ per cell, with high probability. Since the choice of a cell to check for the count of solutions is arbitrary, we focus on the cell labeled all 0s, i.e. $\mathbf{0}^i$. The maximum number of solutions in a cell for it to be considered “small” is defined by a parameter `thresh` that is determined

¹We assume h_0 maps elements of $\{0, 1\}^n$ to a singleton set, chosen to be $\{0\}$.

Algorithm 1 HASHCOUNTER($\varphi, \varepsilon, \delta$)

```

1: thresh  $\leftarrow$  FINDSMALLCELLSIZE( $\varepsilon$ );            $\triangleright$  Size threshold for a cell to be considered "small"
2: smc  $\leftarrow$  SATURATINGCOUNTER( $\varphi$ , thresh);      $\triangleright$  Saturated model count of  $\varphi$ 
3: if (smc  $\neq$   $\top$ ) then return smc;                $\triangleright$  Easy case: Solution space of  $\varphi$  itself is "small"
4: itercount  $\leftarrow$  FINDREPETITIONCOUNT( $\delta$ );     $\triangleright$  # repetitions to amplify confidence
5:  $\mathcal{H} \leftarrow$  CHOOSEHASHFAMILY();
6: CountEst  $\leftarrow$  EmptyList;                      $\triangleright$  List of model count estimates from different iterations
7: repeat itercount times
8:   ( $h_0, \dots, h_n$ )  $\leftarrow$  CHOOSEHASHFUNCTIONS( $\mathcal{H}, n$ );            $\triangleright$   $n$  is # variables in  $\varphi$ 
9:   INITIALIZEARRAY(CellSize,  $n$ );            $\triangleright$  CellSize is an array of size  $n + 1$ 
    $\triangleright$  CellSize[ $i$ ] records (saturated) model count in cell  $\mathbf{0}^i$  induced by  $h_i$ ; CellSize[0] =  $\top$ 
10:  repeat until ALLINDICESASSIGNED(CellSize)
11:    $i \leftarrow$  CHOOSEUNASSIGNEDINDEX(CellSize);            $\triangleright$  Choose  $i$  s.t. CellSize[ $i$ ] =  $\perp$ 
12:   CellSize[ $i$ ]  $\leftarrow$  SATURATINGCOUNTER( $\varphi \wedge h_i^{-1}(\mathbf{0}^i)$ , thresh);
13:   if (CellSize[ $i$ ] < thresh  $\wedge$  CellSize[ $i - 1$ ] =  $\top$ ) then            $\triangleright$  Found right "small" cell
14:     Append CellSize[ $i$ ]  $\times 2^i$  to CountEst;            $\triangleright$  Current model count estimate
15:     go to line 7;            $\triangleright$  Repeat to amplify confidence
16: return COMPUTEMEDIAN(CountEst);

```

in line 1 of Algorithm 1. In general, thresh depends polynomially on $\frac{1}{\varepsilon}$, where ε is the tolerance bound of our PAC estimate. We assume access to a sub-routine `SATURATINGCOUNTER` that counts the solutions of a formula, but only upto a specified bound. Specifically, `SATURATINGCOUNTER`(ψ, c) returns a special symbol \top (denoting saturation of count) if ψ has c or more solutions. Otherwise, it returns the exact count of solutions of ψ . Thus, `SATURATINGCOUNTER`(ψ, c) always returns a value in $\{0, c - 1\} \cup \{\top\}$. We call this a *saturated count* of the solutions of ψ . Algorithm 1 uses `SATURATINGCOUNTER` at two places. In lines 2 through 3, we check if the saturated count of solutions of φ is itself within $\text{thresh} - 1$; if so, we return this count directly. Otherwise, we use `SATURATINGCOUNTER` in line 12 to find the saturated count of solutions of φ in cell $\mathbf{0}^i$ induced by h_i for an appropriately chosen $i \in \{1, \dots, n\}$. This count is then recorded in the i^{th} element of an array named `CellSize`. The sub-routine `INITIALIZEARRAY` is used to initialize `CellSize` prior to starting the iterations of the loop in lines 10–15. Specifically, `INITIALIZEARRAY` sets `CellSize[0]` to \top (since the saturated model count of φ is \top if the check in line 3 fails) and `CellSize[i]` to \perp , representing a value that has not been assigned yet, for $1 \leq i \leq n$.

Recall that the count of solutions of φ in a cell induced by h_i is an unbiased estimator of $\frac{|\text{Sol}(\varphi)|}{2^i}$. Therefore, this count reduces (in expectation) as i increases. In order to find the smallest i where this drops below thresh , we check in line 13 if the count induced by h_i is less than thresh , whereas that induced by h_{i-1} is thresh or more (i.e. saturated at \top). If so, we identify i as the smallest index for which the partitioning of $\text{Sol}(\varphi)$ by h_i yields “small” cells. We also record the value of `CellSize[i] $\times 2^i$` as the current estimate of $|\text{Sol}(\varphi)|$ in a list of estimates named `CountEst`. If, however, the check in line 13 fails, we conclude that the cells induced by h_i are either too small (`CellSize[$i - 1$] $\neq \top$`) or too large (`CellSize[i] = \top`). In this case, we continue the search by choosing another index $i \in \{1, \dots, n\}$ such that `CellSize[i]` has not been assigned yet, i.e. has the value \perp . Different hash-based model counters use different strategies for choosing the next unassigned index. This is represented by an invocation of sub-routine `CHOOSEUNASSIGNEDINDEX`

in line 11 of Algorithm 1.

While the loop in lines 10–15 of Algorithm 1 provides an estimate of $|\text{Sol}(\varphi)|$ within a specified tolerance, the confidence may not be as high as required. The loop in lines 7–15 followed by computation of the median of all estimates in the list `CountEst` serves to amplify the probability of success to the desired level. Every iteration of this loop is required to be independent of all previous and subsequent iterations. The number of iterations needed to achieve the desired confidence is a linear function of $\log \frac{1}{\delta}$ and is calculated in line 4.

In the following subsections, we discuss how different choices of \mathcal{H} and of the subroutines used in Algorithm 1 affect the performance and guarantees of various probabilistic hash-based counting algorithms. We start with a brief overview of the theoretical tools and techniques necessary to analyze different choices.

26.2.2. Theoretical tools and analysis

Let $\text{Cell}_{\langle\varphi, h_i\rangle}$ denote the random set $\{y \in \text{Sol}(\varphi) \mid h_i(y) = \mathbf{0}^i\}$. Now consider an arbitrary iteration of the loop in lines 7–15 of Algorithm 1. We say that the iteration *fails* if either no estimate of the model count is appended to `CountEst` in line 14, or if the estimate that is appended does not lie in the interval $\left[\frac{|\text{Sol}(\varphi)|}{1+\varepsilon}, |\text{Sol}(\varphi)| \cdot (1+\varepsilon)\right]$. Let `IterError` denote the event that the iteration fails in the above sense. Furthermore, let T_i denote the event $(|\text{Cell}_{\langle\varphi, h_i\rangle}| < \text{thresh})$, and let L_i and U_i denote the events $\left(|\text{Cell}_{\langle\varphi, h_i\rangle}| \times 2^i < \frac{|\text{Sol}(\varphi)|}{(1+\varepsilon)}\right)$ and $(|\text{Cell}_{\langle\varphi, h_i\rangle}| > |\text{Sol}(\varphi)|(1+\varepsilon))$, respectively. It now follows from the definition of `IterError` that $\Pr[\text{IterError}] = \Pr\left[\bigcap_{j=0}^n \overline{T}_j \cup \bigcup_{i=1}^n (\overline{T}_{i-1} \cap T_i \cap (L_i \cup U_i))\right]$. A key component of the analysis of Algorithm 1 concerns bounding $\Pr[\text{IterError}]$ from above by a constant strictly less than $\frac{1}{2}$. Once this bound is established, standard arguments for probability amplification via median of independent random variables can be used to bound $\Pr[\text{Error}]$, where `Error` denotes the event that Algorithm 1 doesn't yield a count within the prescribed tolerance bound ε .

To see how probability amplification happens, suppose the loop in lines 7–15 is iterated r independent times. Since we compute the median in line 16, the event `Error` can happen only if `IterError` happens for at least $(r/2) + 1$ iterations, where we have assumed r to be even for simplicity. For notational simplicity, let $\rho (< \frac{1}{2})$ denote $\Pr[\text{IterError}]$. Then, $\Pr[\text{Error}] = \sum_{i=(r/2)+1}^r \binom{r}{i} \rho^i (1-\rho)^{r-i}$. Since $\binom{r}{i} \leq \binom{r}{r/2} \leq 2^r$, algebraic simplification yields $\Pr[\text{Error}] < \left(\frac{1-\rho}{1-2\rho}\right) \times \left(2\sqrt{\rho(1-\rho)}\right)^r$. Therefore, in order to ensure $\Pr[\text{Error}] \leq \delta$, we need $r \geq C(\rho) \times \left(\log \frac{1}{\delta} + D(\rho)\right)$, where $C(\rho)$ and $D(\rho)$ depend only on ρ . This is what sub-routine `FINDREPETITIONCOUNT` computes in line 4 of Algorithm 1.

To obtain a good upper bound of ρ , i.e. $\Pr[\text{IterError}]$, we need to find good bounds of probabilities of the events T_i, L_i , and U_i . In general, different techniques are used to compute these bounds, depending on the choice of \mathcal{H} , and of sub-routines `CHOOSEHASHFAMILY` and `CHOOSEHASHFUNCTIONS`. The following three standard probability bounds are particularly useful in reasoning about $|\text{Cell}_{\langle\varphi, h_i\rangle}|$, where $0 < \beta < 1$, and μ_i and σ_i denote the mean and standard

deviation respectively, of $|\text{Cell}_{\langle\varphi, h_i\rangle}|$.

- (Chebyshev) $\Pr [| \text{Cell}_{\langle\varphi, h_i\rangle}| - \mu_i | \geq \beta\mu_i] \leq \frac{(1+\beta)^2\sigma_i^2}{\beta^2\mu_i^2}$
- (Payley-Zygmund) $\Pr [|\text{Cell}_{\langle\varphi, h_i\rangle}| \leq \beta\mu_i] \leq \frac{\sigma_i^2}{\sigma_i^2 + (1-\beta)^2\mu_i^2}$
- (Markov) $\Pr [|\text{Cell}_{\langle\varphi, h_i\rangle}| \geq \frac{\mu_i}{\beta}] \leq \beta$

The recipe for obtaining good upper bounds of the probabilities of T_i , L_i , and U_i is to use appropriate values of β in the above inequalities, and to use hash-family specific properties to obtain expressions for σ_i^2 and μ_i . Existing techniques typically rewrite the expression for $\Pr [\text{IterError}]$ so that the above bounds can be used for $\mu_i > 1$. Significantly, the choice of **thresh** informs the need for bounding either the coefficient of variation, i.e., $\frac{\sigma_i^2}{\mu_i^2}$, or the dispersion index, $\frac{\sigma_i^2}{\mu_i}$, as discussed below.

26.2.3. Choice of threshold

For an algorithm focused on a problem as hard as (approximately) counting the number of solutions of a CNF formula, it is pleasing to note that except the **SATURATINGCOUNTER** query in line 12, Algorithm 1 is fairly simple to implement and execute. Therefore, it is no surprise that practical implementations of the algorithm spend most of their time in **SATURATINGCOUNTER** queries in line 12 [SM19]. A straightforward way of implementing **SATURATINGCOUNTER** with modern SAT solvers is to enumerate solutions one by one, using blocking clauses for already found solutions, until either **thresh** solutions are generated or there are no more solutions. A more generic approach to implementing **SATURATINGCOUNTER** is described in Section 26.2.6. In all of these approaches, the number of times an underlying SAT solver has to be invoked is linear in **thresh**. Therefore, it is important to ensure that **thresh** grows polynomially in n and $\frac{1}{\varepsilon}$.

There is a fundamental tradeoff between **thresh** and the tolerance bound ε that every approximate counter obtained as an instance of Algorithm 1 must respect. To understand this, suppose a hypothetical algorithm **M** computes a multiplicative $(1 + \varepsilon)$ -approximation of a model count that lies in the interval $[1, 2^n]$. The minimum cardinality of the set of possible output values of **M** has an inverse logarithmic relation with $(1 + \varepsilon)$. Specifically, in order to minimize the count of output values of **M**, we must divide the interval $[1, 2^n]$ into non-overlapping sub-intervals such that the ratio of the upper bound to the lower bound of each sub-interval is $(1 + \varepsilon)^2$. Since the model count being estimated can be anywhere in $[1, 2^n]$, algorithm **M** must have the ability to output at least one value from each of the above sub-intervals. If t denotes the number of sub-intervals, then we must have $\frac{2^n}{(1+\varepsilon)^t} < 1$, i.e. $t > \frac{n}{2\log_2(1+\varepsilon)}$. This gives the minimum count of possible estimates that algorithm **M** must return. Notice that the estimated count appended to **CountEst** in the loop in lines 10–15 of Algorithm 1 can be viewed as $c \times 2^i$ for some $1 \leq c < \text{thresh}$ and $i \in [0, n]$. Therefore, the cardinality of the set of possible values returned by Algorithm 1 is $n \times \text{thresh}$. It follows that $n \times \text{thresh} \geq \frac{n}{2\log_2(1+\varepsilon)}$, i.e., $\text{thresh} \geq \frac{1}{2\log_2(1+\varepsilon)}$.

The lower bound of `thresh` derived above may not be achievable in a given instantiation of Algorithm 1, and typically larger values of `thresh` are used. For example, Chakraborty et al [CMV13b, CMV16] have used `thresh` in $\mathcal{O}(1/\varepsilon^2)$ to ensure a multiplicative $(1 + \varepsilon)$ -approximation. Ermon et al. [EGSS14], Asteris and Dimakis [AD16], and Achlioptas and Theodoropoulos [AT17] have, however, used `thresh` in $\mathcal{O}(1/\varepsilon)$ for the same purpose. Not surprisingly, the choice of `thresh` affects the choice of hash functions that can be used in Algorithm HASHCOUNTER. Specifically, with `thresh` $\in \mathcal{O}(1/\varepsilon^2)$, the dispersion index of $|\text{Cell}_{\langle \varphi, h_i \rangle}|$, i.e. $\frac{\sigma_i^2}{\mu_i}$, must be bounded above by a constant. In contrast, when `thresh` $\in \mathcal{O}(1/\varepsilon)$, the coefficient of variation of $|\text{Cell}_{\langle \varphi, h_i \rangle}|$, i.e. $\frac{\sigma_i^2}{\mu_i^2}$, must be bounded by a constant.

26.2.3.1. Multiplicative approximation amplification

The above discussion implies that as ε decreases, `thresh` must increase if we aspire to obtain a multiplicative $(1 + \varepsilon)$ -factor approximation. If `thresh` becomes too large, the running time of SATURATINGCOUNTER may become a bottleneck. It is therefore interesting to ask if we can avoid increasing `thresh` at the cost of increasing the size of the formula fed as input to SATURATINGCOUNTER, while still obtaining a $(1 + \varepsilon)$ -factor approximation. In 1983, Stockmeyer [Sto83] observed that this can indeed be done: one can transform an algorithm that provides a constant-factor approximation into one that gives a multiplicative $(1 + \varepsilon)$ -approximation. To see how this can be achieved, suppose an algorithm **M** computes model counts with a 2-approximation. Given an input formula φ over the set of variables X , suppose we make two copies of the formula with disjoint sets of variables, i.e. $\psi(X, Y) = \varphi(X) \wedge \varphi(Y)$ where $\varphi(Y)$ is the same formula as $\varphi(X)$, but with variables X replaced by a new set of variables Y . It is easy to see that $|\text{Sol}(\psi)| = |\text{Sol}(\varphi)|^2$. Furthermore, if $\frac{|\text{Sol}(\psi)|}{4} \leq c \leq 4|\text{Sol}(\psi)|$, then $\frac{|\text{Sol}(\varphi)|}{2} \leq \sqrt{c} \leq 2|\text{Sol}(\varphi)|$. Thus, we have effectively reduced the constant multiplicative factor in approximating $|\text{Sol}(\varphi)|$. Extending this argument, if we want an $(1 + \varepsilon)$ -approximation of $|\text{Sol}(\varphi)|$ for small values of ε , we can construct ψ by conjoining $k = \mathcal{O}(1/\varepsilon)$ copies of φ , each with a disjoint set of variables, and compute the k -th root of the estimate of $|\text{Sol}(\psi)|$ returned by algorithm **M**. Therefore, `thresh` can be set to a constant when computing an $(1 + \varepsilon)$ -approximation of $|\text{Sol}(\varphi)|$ if we are willing to invoke Algorithm 1 over a new formula obtained by conjoining $\mathcal{O}(1/\varepsilon)$ copies of φ .

The need for multiple copies of the given formula, however, leads to larger queries, to which SAT solvers are highly sensitive. For classes of formulas not closed under conjunction, the query $\text{SATURATINGCOUNTER}(\psi \wedge h_i^{-1}(\mathbf{0}^i), \text{thresh})$ may not even lie in the same complexity class as $\text{SATURATINGCOUNTER}(\varphi \wedge h_i^{-1}(\mathbf{0}^i), \text{thresh})$. As an example, the class of DNF formulas is not closed under conjunction. If φ is a DNF formula and ψ is a conjunction of DNF formulas, the query $\text{SATURATINGCOUNTER}(\varphi \wedge h_i^{-1}(\mathbf{0}^i), \text{thresh})$ can be answered in polynomial time, while the query $\text{SATURATINGCOUNTER}(\psi \wedge h_i^{-1}(\mathbf{0}^i), \text{thresh})$ is NP-hard in general. This is a crucial consideration for the design of hashing-based FPRAS techniques, which are discussed in detail in Section 26.4.

26.2.4. Choice of hash family

Extending the notation introduced earlier, let $h_i \stackrel{R}{\leftarrow} \mathcal{H}_i$ denote the probability space induced by choosing a function $h_i : \{0, 1\}^n \rightarrow \{0, 1\}^i$ uniformly at random from the sub-family \mathcal{H}_i .

Definition 26.2.1. A sub-family of hash functions \mathcal{H}_i is said to be *uniform* if for all $x \in \{0, 1\}^n$, $\alpha \in \{0, 1\}^i$ and $h_i \stackrel{R}{\leftarrow} \mathcal{H}_i$, $\Pr[h_i(x) = \alpha] = \frac{1}{2^i}$.

Definition 26.2.2. [CW77] A sub-family of hash functions \mathcal{H}_i is said to be *strongly 2-universal* if for all $x, y \in \{0, 1\}^n$ and $h_i \stackrel{R}{\leftarrow} \mathcal{H}_i$, $\Pr[h_i(x) = h_i(y)] = \frac{1}{2^i}$.

Uniform and strongly 2-universal hash functions play a central role in the design and analysis of probabilistic hash-based approximate counters.

Early work on probabilistic hash-based counting, viz. [GSS06, GHSS07b, GHSS07a], made the important observation that properties of strongly 2-universal hash families allow one to design approximate counters with PAC guarantees. Specifically, using strongly 2-universal hash families ensures that the dispersion index of $|\text{Cell}_{\langle F, h_i \rangle}|$, i.e., $\frac{\sigma_i^2}{\mu_i}$, is bounded above by a constant. Note that if $\mu_i > 1$, this also implies that the coefficient of variation is bounded above by a constant. Furthermore, it was observed that there exist strongly 2-universal hash families for which the problem of finding a $y \in h_i^{-1}(\mathbf{0}^i)$ is in NP, and hence can be solved using SAT solvers. Among various hash families that have been studied over the years, two have featured predominately in the literature on hashing-based model counting. These are the families of random XOR-based hash functions, denoted \mathcal{H}_{xor} , and Toeplitz matrix [Gra06] based hash functions, denoted $\mathcal{H}_{\mathcal{T}}$. If we view the variables x_1, x_2, \dots, x_n in the support of the formula φ as a vector X of dimension $n \times 1$, a hash function $h_i : \{0, 1\}^n \mapsto \{0, 1\}^i$ chosen from either \mathcal{H}_{xor} or $\mathcal{H}_{\mathcal{T}}$ can be represented as $h_i(X) = \mathbf{A}X + \mathbf{b}$, where \mathbf{A} is an $m \times n$ 0-1 matrix, \mathbf{b} is $m \times 1$ 0-1 vector and all operations are in \mathbf{GF}_2 . Regardless of whether we use \mathcal{H}_{xor} or $\mathcal{H}_{\mathcal{T}}$, the vector \mathbf{b} is chosen uniformly at random from the space of all $m \times 1$ 0-1 vectors. The way in which \mathbf{A} is chosen, however, differs depending on whether we are using the family \mathcal{H}_{xor} or $\mathcal{H}_{\mathcal{T}}$. In case we are using \mathcal{H}_{xor} , \mathbf{A} is chosen uniformly at random from the space of all $m \times n$ 0-1 matrices. If, on the other hand, we are using $\mathcal{H}_{\mathcal{T}}$, \mathbf{A} is chosen uniformly at random from the space of all $m \times n$ Toeplitz 0-1 matrices. Note that Toeplitz 0-1 matrices form a very small subset of all 0-1 matrices. While no significant performance difference has been reported for probabilistic hash-based approximate counters using these two families of hash functions, the family \mathcal{H}_{xor} seems to be the hash family of choice in the existing literature.

When using the family \mathcal{H}_{xor} , the random selection of h_i can be achieved by choosing each entry of \mathbf{A} to be 1 with probability $p = 1/2$. On an average, this gives $\frac{n}{2}$ 1's in each row of \mathbf{A} . The invocation of SATURATINGCOUNTER in Algorithm 1 necessitates usage of a SAT solver to solve the formula $\varphi \wedge (\mathbf{A}X + \mathbf{b} = 0)$. Thus, the SAT solver needs to reason about formulas that are presented as a conjunction of usual (i.e., OR) clauses and XOR clauses, and each XOR clause has an average size of $\frac{n}{2}$. Gomes et al. [GHSS07b] have observed that the performance of SAT solvers, however, degrades with an increase in the size of XOR clauses.

Therefore recent efforts have focused on the design of sparse hash functions where the count of 1's in every row is $\ll \frac{n}{2}$ [EGSS14, IMMV15, AD16, AT17, AHT18].

Building on the classical notion of definability due to Beth [Bet56], one can define the notion of an *independent support* of a Boolean formula. Specifically, $\mathcal{I} \subseteq X$ is an independent support of φ if whenever two solutions π_1 and π_2 of φ agree on \mathcal{I} , then $\pi_1 = \pi_2$ [LM08, CMV14, LLM16]. Chakraborty et al. [CMV14] observed that strongly 2-universal hash functions defined only over \mathcal{I} (instead of X) lend themselves to exactly the same reasoning as strongly 2-universal hash functions defined over the whole of X , when used to partition the solution space of φ . The importance of this observation comes from the fact that for many important classes of problems, the size of \mathcal{I} can be one to two orders of magnitude smaller than that of X . This in turn leads to XOR clauses that are one to two orders of magnitude smaller than that obtained by using strongly 2-universal hash functions defined over X [IMMV15]. Ivrii et al. have proposed an algorithmic technique, called MIS, to determine the independent support of a given formula via a reduction to the Group-oriented Minimal Unsatisfiable Subformula (GMUS) problem [LS08, Nad10]. Given the hardness of GMUS, the proposed technique MIS can scale to a few tens of thousands of variables, and designing scalable techniques for GMUS is an active area of research.

Gomes et al. [GHSS07b] observed that for some classes of formulas, setting the expected fraction p of 1's in each row of the matrix \mathbf{A} to be significantly smaller than $1/2$ can still provide counts close to those obtained using $p = 1/2$. A straightforward calculation shows that if we choose $h_i(X) = \mathbf{A}X + \mathbf{b}$, with every entry in \mathbf{A} set to 1 with probability p , then for any two distinct vectors $x, y \in \{0, 1\}^n$, $\Pr[h_i(x) = h_i(y)] = (1/2 + 1/2(1-2p)^w)^i = q(w)$ where w is the Hamming weight of $x - y$, i.e., the number of ones in $x - y$. Note that for $p < 1/2$, such a family is not strongly 2-universal. Ermon et al. [EGSS14] observed, however, that using a strongly 2-universal hash family is not a necessary requirement to bound the coefficient of variation from above by a constant. Furthermore, for a given $x \in \{0, 1\}^n$ and for any $k \in \{1, \dots, n\}$, the count of $y \in \{0, 1\}^n$ such that $\Pr[h(x) = h(y)] = q(k)$ is bounded from above by $\binom{n}{k}$. This allowed Ermon et al. to analytically compute values of p that are less than $\frac{1}{2}$, although obtaining a closed-form expression remained elusive. The gap between analytical bounds and closed form bounds was bridged by Zhao et al. [ZCSE16] and Asteris and Dimakis [AD16], who showed that having $p \in \mathcal{O}(\frac{\log i}{i})$ suffices to upper bound the coefficient of variation when $i \in \Theta(n)$. Observe that the smaller the value of p , the sparser the matrix \mathbf{A} .

Motivated by the use of sparse matrices in the design of efficient error-correcting codes, Achlioptas and Theodoropoulos [AT17] showed that one could randomly choose \mathbf{A} from an ensemble of Low-Density Parity Check (LDPC) matrices. Achlioptas, Hammoudeh, and Theodoropoulos [AHT18] put forth the observation that an approximate counter strives to compute an estimate c that satisfies two bounds: (i) a lower bound: $c \leq |\text{Sol}(\varphi)| \cdot (1 + \varepsilon)$ and (ii) an upper bound: $c \geq \frac{\text{Sol}(\varphi)}{1 + \varepsilon}$. Achlioptas et al. [AT17, AHT18] and Gomes et al. [GHSS07b] further observed that obtaining good lower bounds requires the hash family \mathcal{H} to be uniform, while obtaining good upper bounds requires \mathcal{H} to ensure that the coefficient of variation of $|\text{Cell}_{\langle \varphi, h_i \rangle}|$ is bounded from above by a constant.

There are a few issues that arise when translating the above ideas to a hash-based approximate counter with PAC guarantees that also scales in practice. First, the bounds achieved with $p \in \mathcal{O}(\frac{\log i}{i})$ hold only for $i \in \Theta(n)$, while for most practical applications $i \ll n$. Second, bounding the coefficient of variation suffices to provide constant-factor approximation guarantees. In order to guarantee $(1 + \varepsilon)$ -approximation, Stockmeyer’s technique [Sto83] of reducing the tolerance must be used, which in turn leads to large formulas being fed to the SAT solver underlying SATURATINGCOUNTER.

In a departure from earlier works [EGSS14, AD16, ZCSE16] where the focus was to use analytical methods to obtain upper bound on the variance of $|\text{Cell}_{\langle \varphi, h_i \rangle}|$, Meel $\text{\textcircled{R}}$ Akshay [MA20] focused on searching for the set $\text{Sol}(F)$ that would achieve the maximum variance of $|\text{Cell}_{\langle \varphi, h_i \rangle}|$. This allowed them to observe an elegant connection between the maximization of variance as well as dispersion index of $|\text{Cell}_{\langle \varphi, h_i \rangle}|$ and minimization of the “ t -boundary” (the number of pairs with Hamming distance at most t) of sets of points on the Boolean hypercube on n dimensions. Utilizing this connection, they introduced a new family of hash functions, denoted by $\mathcal{H}_{\text{Rennes}}$, which consists of hash functions of the form $\mathbf{A}y + b$, where every entry of $\mathbf{A}[i]$ is set to 1 with $p_i = \mathcal{O}(\frac{\log_2 i}{i})$. The construction of the new family marks a significant departure from prior families in that the density of 1’s in the matrix \mathbf{A} is dependent on the row index of the matrix. Meel $\text{\textcircled{R}}$ Akshay demonstrated that usage of $\mathcal{H}_{\text{Rennes}}$ can lead to significant speedup in runtime while preserving PAC guarantees [MA20].

26.2.5. Using dependent hash functions

Recall that in line 8 of Algorithm 1, the vector of hash functions (h_0, \dots, h_n) is chosen such that h_i maps $\{0, 1\}^n$ to $\{0, 1\}^i$. As already discussed in Section 26.2.2, an analysis and proof of correctness of an instantiation of Algorithm 1 requires us to bound $\text{Pr}[\text{IterError}]$, which in turn involves analyzing expressions involving L_i, U_i , and T_i for different values of i . Since, the dependence of L_i, U_i , and T_i across different values of i stems from the choice of (h_0, \dots, h_n) , a natural alternative is to choose each h_i uniformly randomly from the sub-family \mathcal{H}_i , but independently of the choice of h_j for all $j \neq i$. This minimizes the dependence among events that correspond to different values of i . Not surprisingly, early work on probabilistic hash-based counting relied on this independence of the chosen hash functions for theoretical analysis. Interestingly, independence in the choice of h_i ’s necessitates a linear search among the indices to find the smallest i that satisfies the check in line 13. This is because with independently chosen h_i ’s, one cannot rule out the possibility that $\text{CellSize}[i - 1] < \text{thresh}$ but $\text{CellSize}[i] = \top$. Independence in the choice of h_i ’s, therefore, requires that sub-routine CHOOSEUNASSIGNEDINDEX chooses indices in sequential order from 1 through n . Indeed, it is not known whether we can do better than linear search when h_i ’s are chosen independently.

At this point, one may ask if there is anything to be gained from dependence among hash functions. In this context, the *prefix hash family*, used in [CMV16], is worth examining. Let $\alpha \in \{0, 1\}^i$ be a vector. For $1 \leq j \leq i$, we use $\alpha[j]$ to denote the j^{th} component of α , and $\alpha[1..j]$ to denote the projection of α on the first j dimensions, i.e. $(\alpha[1], \dots, \alpha[j])$. For every hash function $h_i : \{0, 1\}^n \rightarrow \{0, 1\}^i$, we

now define the j^{th} *prefix-slice* of h_i , denoted $h_i[1..j]$ as a map from $\{0, 1\}^n$ to $\{0, 1\}^j$ such that $h_i[1..j](x) = h_i(x)[1..j]$, for all $x \in \{0, 1\}^n$.

Definition 26.2.3. [CMV16] A family of hash functions $\{\mathcal{H}_1, \dots, \mathcal{H}_n\}$ is called a *prefix-family* if for all $h_i \in \mathcal{H}_i$, the j^{th} prefix-slice of h_i is in \mathcal{H}_j for all $j \in \{1, \dots, i\}$. Thus, for all $h_i \in \mathcal{H}_i$, there exists $h_{i-1} \in \mathcal{H}_{i-1}$ such that for every $x \in \{0, 1\}^n$, $h_i(x)$ is simply $h_{i-1}(x)$ augmented with the i^{th} component of $h_i(x)$.

Suppose the hash functions (h_0, \dots, h_n) are chosen from a prefix family such that $h_i = h_n[1..i]$ for $1 \leq i \leq n$ ($h_0 : \{0, 1\}^n \rightarrow \{0\}$ leaves no choice in design). It is easy to see that with this choice of hash functions, $|\text{Cell}_{\langle \varphi, h_i \rangle}| \leq |\text{Cell}_{\langle \varphi, h_{i-1} \rangle}|$ for all $i \in \{1, \dots, n\}$. Therefore, one can perform a binary search to find the smallest (and unique) i such that $\text{CellSize}[i] < \text{thresh}$ but $\text{CellSize}[i-1] = \top$. The runtime of known implementations of $\text{SATURATINGCOUNTER}(\varphi \wedge h_i^{-1}(\mathbf{0}^i))$ has, however, been empirically observed to significantly increase with i . Therefore, a galloping search performs significantly better than binary search. Furthermore, notice that if C is the set of clauses learnt (as by a CDCL SAT solver) while solving $\varphi \wedge h_i^{-1}(\mathbf{0}^i)$, the dependence among different hash functions facilitates incremental SAT solving. In other words, the clauses learnt while solving $(\varphi \wedge h_i^{-1}(\mathbf{0}^i))$ are sound (and hence, can be re-used) for solving $(\varphi \wedge h_j^{-1}(\mathbf{0}^j))$ for $j > i$. While this sounds promising, one needs to re-think theoretical proofs of PAC guarantees, when using such dependent hash functions. Indeed, the dependence among different events may force usage of union bounds over linear (in n) terms when computing $\Pr[\text{IterError}]$, leading to overall weaker bounds. By a carefully constructed sequence of arguments, Chakraborty et al. showed in [CMV16] that one can indeed use dependence to one's advantage even for the theoretical analysis of PAC guarantees. In particular, they showed that when h_i 's are chosen from a prefix family as described above, $\Pr[\text{IterError}] \leq 0.36$. The work of Achlioptas and Theodoropoulos [AT17, AHT18], in which LDPC matrices were used to define hash functions, also provides another example where dependence between h_i 's have been used to advantage in designing better hash-based approximate model counters.

26.2.6. Counting up to a threshold

Finally, we discuss the key sub-routine SATURATINGCOUNTER used in Algorithm 1. Recall that SATURATINGCOUNTER is used to find the saturated count (upto thresh) of models of $\varphi \wedge h_i^{-1}(\mathbf{0}^i)$. Computationally, this is the most expensive step of Algorithm 1. We now show that if satisfiability checking of $\varphi \wedge h_i^{-1}(\mathbf{0}^i)$ is *self-reducible*, then SATURATINGCOUNTER can be implemented with at most $\mathcal{O}(n \cdot \text{thresh})$ calls to a satisfiability checker for $\varphi \wedge h_i^{-1}(\mathbf{0}^i)$. Fortunately, satisfiability checking is indeed self-reducible for a large class of formulas φ and hash functions h_i .

While a general definition of self-reducibility can be found in [Bal88], our requirement can be stated simply as follows. Let \mathcal{C} be a class of propositional formulas, viz. CNF, DNF, CNF+XOR, DNF+XOR, etc. and let ψ be a formula in \mathcal{C} . As an example, if φ is in CNF and $h_i^{-1}(\mathbf{0}^i)$ is a conjunction of XOR clauses, then $\varphi \wedge h_i^{-1}(\mathbf{0}^i)$ is a formula in the CNF+XOR class. Let x_1, \dots, x_n be the

variables in ψ and let $(\pi_1, \dots, \pi_n) \in \{0, 1\}^n$ be an assignment of these variables. Let $\psi|_{x_1 \dots x_i = \pi_1 \dots \pi_i}$ denote the formula obtained by substituting π_j for x_j in ψ , for all $j \in \{1, \dots, i\}$. We say that satisfiability checking is *self-reducible* for the class \mathcal{C} if for every formula $\psi \in \mathcal{C}$, the following hold: (i) $\psi|_{x_1 = \pi_1}$ is in \mathcal{C} , and (ii) $(\pi_1, \dots, \pi_n) \models \psi \Leftrightarrow (\pi_2, \dots, \pi_n) \models \psi|_{x_1 = \pi_1}$. Continuing with our earlier example, let \mathcal{C} denote the CNF+XOR class and ψ denote the formula $\varphi \wedge h_i^{-1}(\mathbf{0}^i)$ in class \mathcal{C} . It is easy to see that (i) $\psi|_{x_1 = \pi_1}$ continues to be a CNF+XOR formula, and (ii) $(\pi_1, \dots, \pi_n) \models \psi \Leftrightarrow (\pi_2, \dots, \pi_n) \models \psi|_{x_1 = \pi_1}$. Hence, satisfiability checking is self-reducible for the CNF+XOR class.

Suppose we have access to a satisfiability checker for formulas in \mathcal{C} . If ψ is unsatisfiable, a single invocation of the checker suffices to detect it. Otherwise, using a standard self-reducibility argument, a solution of ψ can be obtained using at most $\mathcal{O}(n)$ calls to the satisfiability checker. Let $\pi = (\pi_1, \dots, \pi_n)$ be such a solution. For $1 \leq i \leq n$, let $\tilde{\pi}_i$ denote $(\pi_1, \dots, \pi_{i-1}, \bar{\pi}_i)$, where $\bar{1} = 0$ and $\bar{0} = 1$. Following a technique used by Murty [Mur68], we can now partition $\text{Sol}(\psi)$ into $n + 1$ (possibly empty) sets Z_0, \dots, Z_n , where $Z_0 = \{\pi\}$ and $Z_i = \{\tilde{\pi}_i \tau \mid \tau \in \text{Sol}(\psi|_{x_1 \dots x_i = \tilde{\pi}_i})\}$ for $1 \leq i \leq n - 1$, with $\tilde{\pi}_i \tau$ denoting the assignment obtained by concatenating $\tilde{\pi}_i$ and τ . Finally, $Z_n = \{\tilde{\pi}_n\}$ if $\tilde{\pi}_n \models \psi$ and $Z_n = \emptyset$ otherwise. As an example, if $n = 3$ and $\pi = (0, 1, 1)$, then $\text{Sol}(\psi)$ is partitioned into four sets: (i) $Z_0 = \{(0, 1, 1)\}$, (ii) $Z_1 = \{(1, \tau_1, \tau_2) \mid (\tau_1, \tau_2) \in \text{Sol}(\psi|_{x_1=1})\}$, (iii) $Z_2 = \{(0, 0, \tau'_1) \mid \tau'_1 \in \text{Sol}(\psi|_{x_1, x_2=0,0})\}$, and (iv) $Z_3 = \{(0, 1, 0)\}$ assuming $(0, 1, 0) \models \psi$. Observe that starting with a formula ψ with n variables, the above step yields one solution (viz., π) and n self-reduced problem instances (viz. $\psi|_{x_1 \dots x_i = \tilde{\pi}_i}$ for $1 \leq i \leq n$), each with strictly fewer than n variables in their support.

In order to implement SATURATINGCOUNTER, i.e. count the solutions of ψ upto **thresh**, we apply the same step as above to each of the self-reduced problem instances. We stop when a total of **thresh** solutions of ψ have been generated or when all remaining self-reduced problem instances are unsatisfiable. Observe that whenever a new satisfying assignment is found, $\mathcal{O}(n)$ self-reduced problem instances are generated. Since at most **thresh** solutions of ψ are generated (and counted) by SATURATINGCOUNTER, only $\mathcal{O}(n \cdot \text{thresh})$ self-reduced problem instances can be generated. For each of these, we either detect unsatisfiability using a single satisfiability check or obtain a solution using $\mathcal{O}(n)$ satisfiability checks. The latter can, however, happen at most **thresh** times. Therefore, the total number of calls to the satisfiability checker is in $\mathcal{O}(n \cdot \text{thresh})$.

The above technique of implementing SATURATINGCOUNTER using at most $\mathcal{O}(n \cdot \text{thresh})$ invocations of a satisfiability checker works for all class of problems for which satisfiability checking is self-reducible. This includes cases like DNF+XOR formulas, perfect matchings in bi-partite graphs etc.

If \mathcal{C} is a class of propositional formulas for which satisfiability checking is NP-complete, then checking satisfiability of $\varphi \wedge h_i^{-1}(\mathbf{0}^i)$, where $\varphi \in \mathcal{C}$, is also NP-complete. In such cases, we are often interested in the query complexity of SATURATINGCOUNTER, given access to an NP oracle. Interestingly, the technique of implementing SATURATINGCOUNTER as discussed above may not yield optimal query complexity in such cases. Observe that the above technique not only finds the saturated count of solutions but also generates the corresponding

set of solutions. Bellare, Goldreich, and Petrank [BGP00] observed that if we are interested only in the saturated count, then SATURATINGCOUNTER can be implemented with $\mathcal{O}(\text{thresh})$ queries to an NP oracle. Bellare et al.'s technique, however, constructs queries of size $\mathcal{O}(|\varphi| \cdot \text{thresh})$. While this is a polynomial blow-up in the size of the formula fed to the oracle, the performance of modern SAT solvers can be significantly impacted by such a blow up.

It is worth noting here that while an NP oracle simply provides a Yes/No answer to a decision query, modern SAT solvers either provide a satisfying assignment for an input formula or report unsatisfiability of the formula. Given this difference, it is interesting to ask how many invocations of a SAT solver would be needed in order to implement SATURATINGCOUNTER. To formalize this question, we introduce the notion of a *SAT oracle* that takes a propositional formula φ as input, and returns a solution σ if φ is satisfiable and \perp if φ is unsatisfiable. We can now implement SATURATINGCOUNTER by simply enumerating the satisfying assignments of an input formula φ using a SAT oracle, until the oracle either returns \perp or we have already found thresh solutions. It is not hard to see that this requires $\mathcal{O}(\text{thresh})$ invocations of the SAT oracle, and the largest size of a formula used in any invocation is $\mathcal{O}(|\varphi| + \text{thresh} \cdot |\text{Sup}(\varphi)|)$.

ApproxMC: A specific hash-based approximate counter

As discussed earlier, state-of-the-art probabilistic hash-based approximate counters (for CNF formulas) can be viewed as (optimized) instances of the generic Algorithm 1. One such counter is ApproxMC [CMV16], obtained with the following specific choices in Algorithm 1.

- In line 1 of the algorithm, thresh is set to $\mathcal{O}(1/\varepsilon^2)$.
- In line 4, itercount is set to $\mathcal{O}(\log_2 \delta^{-1})$.
- In line 5, the prefix hash family \mathcal{H}_{xor} is chosen.
- In line 8, individual hash functions are chosen such $h_i = h_n[1..i]$ for $1 \leq i \leq n$, with $h_0 : \{0, 1\}^n \rightarrow \{0\}$.
- SATURATINGCOUNTER(φ, thresh) is implemented using $\mathcal{O}(\text{thresh})$ invocations of a SAT oracle (a SAT solver, CryptoMiniSat, in practice).

It is shown in [CMV16] that the resulting algorithm provides the following PAC guarantee.

Theorem 26.2.1. Given a formula φ , tolerance $\varepsilon (> 0)$, and confidence parameter δ ($0 \leq \delta < 1$), invocation of ApproxMC($\varphi, \varepsilon, \delta$) returns a count c such that $\Pr[|\text{Sol}(\varphi)| \cdot (1 + \varepsilon)^{-1} \leq c \leq |\text{Sol}(\varphi)|(1 + \varepsilon)] \geq 1 - \delta$. Furthermore, ApproxMC makes $\mathcal{O}(\log n \cdot \varepsilon^{-2} \cdot \log \delta^{-1})$ calls to a SAT oracle.

26.3. Handling CNF+XOR Constraints

Given the extensive reliance on XOR clauses for partitioning the solution space of φ , it is desirable that the underlying SAT solver in SATURATINGCOUNTER have native support for conjunctions of XOR clauses. While a system of only XOR clauses can be solved in polynomial-time via Gauss-Jordan Elimination (GJE),

predominant CDCL SAT solvers are known to have poor performance in their ability to handle XORs [BM00]. Given the importance and usage of XOR clauses in cryptanalysis, there is a rich and long history of building hybrid solvers that perform CDCL and/or lookahead reasoning for CNF clauses and Gauss-Jordan elimination for XOR clauses [BM00, HDVZVM04, Che09, SNC09, Soo10, LJN10, LJN11, LJN12].

Soos, Nohl and Catelluccia [SNC09] proposed an elegant architecture, best viewed as an instance of CDCL(XOR), that keeps CNF and XOR clauses separately. It performs Gauss-Jordan Elimination on XORs while performing CDCL reasoning on CNF constraints, with support for sharing of the learnt clauses from XOR-based reasoning to CNF-based reasoning. This architecture formed the basis of the widely used SAT solver *CryptoMiniSat*. Han and Jiang [HJ12] observed that performing Gauss-Jordan Elimination ensures that the matrix representing XORs is in row echelon form, which allows for lazy and incremental matrix updates. While the separation of CNF and XOR clauses shares similarities to the architecture of modern SMT solvers that separate different theory clauses, there are important differences as well. The primary difference stems from the fact that SMT solvers reason about clauses over different theories with disjoint signatures, while CNF and XOR clauses are defined over the same set of variables. Han and Jiang [HJ12] observed that partial interpolant generation can still be achieved in the presence of mixed CNF and XOR clauses, and the generated interpolants improve the runtime performance of the solver. Laitinen, Junttila, and Niemelä [LJN12] observed that XOR reasoning can be significantly improved by splitting XORs into different *components* that are connected to each other only by *cut variables*. The decomposition ensures that full propagation for each of the components guarantee propagation for the entire set of XORs. Such a decomposition has been empirically shown to improve the memory usage when solving a conjunction of mixed CNF and XOR clauses.

The architecture of separating XOR and CNF clauses, however, comes at the cost of disabling execution of in-processing steps. Upon closer inspection, the separation of CNF and XOR clauses does not fundamentally imply lack of soundness of in-processing steps. Nevertheless, a sound implementation of in-processing steps is a daunting task, given the need for extensive studies into the effect of every in-processing step on XOR clauses. The lack of usage of pre- and in-processing steps significantly hurts the performance of the backend SAT solver in *SATURATINGCOUNTER* since these techniques have been shown to be crucial to the performance of state-of-the-art SAT solvers.

To allow seamless integration of pre- and in-processing steps, it is important that the solver has access to XOR clauses in CNF form while ensuring native support for XORs to perform Gauss-Jordan elimination. To achieve such integration, Soos and Meel [SM19] recently proposed a new architecture called *BIRD* (an acronym for Blast, In-process, Recover, and Destroy). A high-level pseudocode for *BIRD* is shown in Algorithm 2.

Note that Algorithm *BIRD* exits its main loop as soon as it finds a solution or proves that the formula is unsatisfiable. Furthermore, if the benchmarks have XOR clauses encoded in CNF, *BIRD* can efficiently recover such XORs and use Gauss-Jordan elimination on such recovered XORs. The primary challenge for

Algorithm 2 BIRD(φ) $\triangleright \varphi$ has a mix of CNF and XOR clauses

- 1: **Blast** XOR clauses into normal CNF clauses
 - 2: **In-process** (and pre-process) over CNF clauses
 - 3: **Recover** simplified XOR clauses
 - 4: Perform CDCL on CNF clauses with on-the-fly Gauss-Jordan Elimination on XOR clauses until: (a) in-processing is scheduled, (b) a solution is found, or (c) formula is found to be unsatisfiable
 - 5: **Destroy** XOR clauses and goto line 2 if conditions (b) or (c) above don't hold. Otherwise, **return** solution or report unsatisfiable.
-

BIRD is to ensure that line 3 can be executed efficiently. Towards this end, the core idea of the recovery algorithm proposed by Soos and Meel is to choose a clause, say `base_cl`, and recover the unique XOR defined exactly over the variables in `base_cl`, if such an XOR exists. For example, if `base_cl` is $(x_1 \vee x_2 \vee x_3)$, then the only XOR defined over x_1, x_2, x_3 in which `base_cl` can possibly participate is $x_1 \oplus x_2 \oplus x_3 = 1$. Observe that the right hand side of the XOR clause (i.e., 0 or 1) can be obtained by computing the parity of the variables in `base_cl`. The key idea behind the search for XORs over variables in `base_cl`, say of size t , is to perform a linear pass and check whether there exists a subset of CNF clauses that would imply the 2^{t-1} combination of CNF clauses over t variables that corresponds to the desired XOR clause over these t variables.

Note that a clause may imply multiple CNF clauses over t variables. For example, let `base_cl` := $(x_1 \vee x_2 \vee x_3)$, then a clause `cl` := (x_1) would imply 4 clauses over $\{x_1, x_2, x_3\}$, i.e. $\{(x_1 \vee x_2 \vee \neg x_3), (x_1 \vee x_2 \vee x_3), (x_1 \vee \neg x_2 \vee x_3), (x_1 \vee \neg x_2 \vee \neg x_3)\}$. To this end, Soos and Meel maintain an array of possible combinations of size 2^t . They update the entry, indexed by the binary representation of the clause for a fixed ordering of variables, corresponding to a clause `cl'` to 1 if `cl` \rightarrow `cl'`. Similar to other aspects of SAT solving, efficient data structures are vital to perform the above mentioned checks and updates efficiently. The interested reader is referred to [SM19, SGM20] for a detailed discussion.

26.4. Approximate Model Counting for DNF

We now turn our attention to computing a PAC estimate for $|\text{Sol}(\varphi)|$, where φ is a DNF formula. While the problem of exact counting for DNF formulas is #P-complete, Karp and Luby showed in their seminal work [KL83] that there exists an FPRAS for the problem. Specifically, their work used the Monte Carlo framework to arrive at an FPRAS for DNF counting. Subsequently, there have been several follow-up works based on Monte Carlo counting techniques [KLM89, DKLR00, Vaz13, Hub17, HJ19]. These have yielded an improved theoretical understanding of DNF counting and also algorithms that have improved performance in practice. Recently, Chakraborty et al. [CMV16] and Meel, Shrotri, and Vardi [MSV17] showed that the hashing-based framework discussed in Section 26.2.1 could also be adapted to yield an FPRAS for DNF counting. Thus, we have two different approaches for obtaining an FPRAS for DNF counting. These are discussed in detail below.

We fix some notation before delving into the details. A DNF formula φ is

given as a disjunction of cubes. We assume the cubes are indexed by natural numbers, and we denote the i^{th} cube by φ^i . Thus $\varphi = \varphi^1 \vee \dots \vee \varphi^m$. We use n and m to denote the number of variables and cubes, respectively, in the input DNF formula. The *width* of a cube φ^i refers to the number of literals in φ^i and is denoted by $\text{width}(\varphi^i)$. We use w to denote the minimum width, minimized over all cubes of the formula, i.e. $w = \min_i \text{width}(\varphi^i)$.

26.4.1. DNF counting via Monte Carlo framework

Approximate counting algorithms designed using the Monte Carlo approach effectively determine the value of an estimator through multiple independent random samples. The seminal work of Karp and Luby [KL83] can be viewed as a Monte Carlo algorithm using a 0-1 estimator, as shown in Algorithm 3. This algorithm

Algorithm 3 Monte-Carlo-Count(\mathcal{A}, \mathcal{U}) $\triangleright \mathcal{A} \subseteq \mathcal{U}$

```

1:  $Y \leftarrow 0$ 
2: repeat  $N$  times
3:   Select an element  $t \in \mathcal{U}$  uniformly at random
4:   if  $t \in \mathcal{A}$  then
5:      $Y \leftarrow Y + 1$ 
6: until
7:  $Z \leftarrow \frac{Y}{N} \times |\mathcal{U}|$ 
8: return  $Z$ 

```

estimates the cardinality of a set \mathcal{A} in the universe \mathcal{U} , given access to a sub-routine that samples uniformly from \mathcal{U} and a sub-routine that tests if a randomly chosen element is in the set \mathcal{A} . Here, $\frac{Y}{N}$ is an unbiased estimator for $\rho = \frac{|\mathcal{A}|}{|\mathcal{U}|}$ and Z is an unbiased estimator for $|\mathcal{A}|$. It can be shown [R70] that if $N \geq \frac{1}{\rho \varepsilon^2} \cdot \ln(\frac{2}{\delta})$, then $\Pr[(1 - \varepsilon) \cdot |\mathcal{A}| \leq Z \leq (1 + \varepsilon) \cdot |\mathcal{A}|] \geq 1 - \delta$. Algorithm 3 is an FPRAS if the number of samples N , and the times taken by the sampler in line 3 and by the inclusion checker in line 4, are polynomial in the size of the input.

In the context of counting solutions of DNF formulas, the set \mathcal{U} is the set of all assignments over n variables, and $\mathcal{A} = \text{Sol}(\varphi)$. In this case, the ratio ρ is also called the *density of solutions*. A trivial lower bound on $|\text{Sol}(\varphi)|$ is 2^{n-w} . Thus, $\frac{1}{\rho} \leq 2^w$. If w is bounded above by a logarithmic function of n and m , then $\frac{1}{\rho}$ is polynomial in n and m and we need polynomially many samples. Nevertheless, since the above requirement may not always hold, this straightforward algorithm does not give an FPRAS.

Karp and Luby [KL83] observed that the dependence of N on w can be avoided if, instead of using $\mathcal{A} = \text{Sol}(\varphi)$ and $\mathcal{U} = \{0, 1\}^n$, we use suitably defined alternate sets $\widehat{\mathcal{A}}$ and $\widehat{\mathcal{U}}$, while ensuring that $|\text{Sol}(\varphi)| = |\widehat{\mathcal{A}}|$ and $\frac{1}{\rho} = |\widehat{\mathcal{U}}|/|\widehat{\mathcal{A}}|$ is bounded polynomially in m and n . This is a powerful technique and researchers have used this idea and its variants over the years to achieve improvement in runtime performance and quality of approximations of Monte Carlo DNF counters. We mention below three variants of Monte Carlo approximate DNF counting algorithms.

Karp and Luby's counter Karp and Luby [KL83] developed the first FPRAS for DNF counting, which we refer to as KL Counter. They defined a new universe

$\widehat{\mathcal{U}} = \{(\sigma, \varphi^i) \mid \sigma \models \varphi^i\}$, and the corresponding solution space $\widehat{\mathcal{A}} = \{(\sigma, \varphi^i) \mid \sigma \models \varphi^i \text{ and } \forall j < i, \sigma \not\models \varphi^j\}$ for a fixed ordering of the cubes. They showed that $|\text{Sol}(\varphi)| = |\widehat{\mathcal{A}}|$ and the ratio $\frac{|\widehat{\mathcal{U}}|}{|\widehat{\mathcal{A}}|} \leq m$. Furthermore, executing Step 3 of Algorithm 3 takes $\mathcal{O}(n)$ time, while executing Step 4 takes $\mathcal{O}(mn)$ time. Consequently, the time complexity of KL Counter is in $\mathcal{O}(\frac{m^2 n^2}{\varepsilon^2} \cdot \log(\frac{1}{\delta}))$. Karp and Luby showed that by designing a slightly different unbiased estimator, this complexity can indeed be reduced to $\mathcal{O}(\frac{m^2 n}{\varepsilon^2} \log(\frac{1}{\delta}))$.

Karp, Luby and Madras' counter Karp, Luby and Madras [KLM89] proposed an improvement of KL Counter by employing a non 0-1 estimator. Towards this end, the concept of *coverage* of an assignment σ in \mathcal{U} was introduced as $\text{cover}(\sigma) = \{j \mid \sigma \models \varphi^j\}$. The first key insight of Karp et al. was that $|\widehat{\mathcal{A}}| = \sum_{(\sigma, \varphi^i) \in \widehat{\mathcal{U}}} \frac{1}{|\text{cover}(\sigma)|}$. Their second key insight was to define an estimator for $1/|\text{cover}(\sigma)|$ using the geometric distribution. They were then able to show that the time complexity of the resulting Monte-Carlo algorithm, which we call KLM Counter, is in $\mathcal{O}(\frac{mn}{\varepsilon^2} \cdot \log(\frac{1}{\delta}))$ – an improvement over KL Counter.

Vazirani's counter A variant of KLM Counter, called Vazirani Counter, was described in Vazirani [Vaz13], where $|\text{cover}(\sigma)|$ is computed exactly by iterating over all cubes, avoiding the use of the geometric distribution in [KLM89]. The advantage of Vazirani Counter is that it is able to utilize ideas for optimal Monte Carlo estimation proposed in [DKLR00]. Consequently, Vazirani Counter requires fewer samples than KL Counter to achieve the same error bounds. The time for generating a sample, however, can be considerably more since the check for $\sigma \models \varphi^j$ has to be performed for all cubes.

26.4.2. DNF Counting via Hashing-based Approach

While Monte Carlo techniques have been the predominant paradigm for approximate DNF counting, it turns out that the universal hashing based approach also yields an FPRAS for DNF counting. Recall that Algorithm HASHCOUNTER, described in Section 26.2.1 is a randomized approximation scheme that makes polynomially many invocations to SATURATINGCOUNTER. It has been observed in [CMV16, MSV17] that SATURATINGCOUNTER can be designed to run in time polynomial in the size of the input formula and the threshold, if the input formula is in DNF. To see why this is true, observe that satisfiability checking of $\varphi \wedge h_i^{-1}(0^i)$ is self-reducible if $h_i^{-1}(0^i)$ is a conjunction of XOR constraints and φ is a DNF formula. Furthermore, the satisfiability of $\varphi \wedge h_i^{-1}(0^i)$ can be checked in polynomial time by iterating over all the cubes of the input formula, substituting the forced assignments induced by each cube into the XOR constraints separately, and using Gauss-Jordan Elimination to check satisfiability of the simplified XOR constraints. Interestingly, we can even avoid appealing to the self-reducibility of satisfiability checking of $\varphi \wedge h_i^{-1}(0^i)$ by simply enumerating solutions of the simplified XOR constraints. Note that at no step, one would have to enumerate more than *thresh* solutions. Concretely, this leads to an FPRAS, called DNFApproxMC in [MSV17], for DNF formulas with complexity $\mathcal{O}((mn^3 + mn^2/\varepsilon^2) \log n \log(1/\delta))$.

The existence of universal hashing-based FPRAS for DNF counting leads to an obvious question: *can these algorithms match the asymptotic complexity of Monte Carlo based FPRAS for DNF counting?* Towards this end, Meel et al. [MSV17] sought to avoid the need for Gauss-Jordan elimination originating due to the usage of \mathcal{H}_{xor} or $\mathcal{H}_{\mathcal{T}}$. Specifically, they proposed a new class of hash functions \mathcal{H}_{Rex} such that every hash function $h \in \mathcal{H}_{\text{Rex}}$ that maps $\{0, 1\}^n \mapsto \{0, 1\}^m$ can be represented as $\mathbf{A}x + \mathbf{b}$, where \mathbf{A} is a 0-1 random matrix of dimension $m \times n$ in row-echelon form and \mathbf{b} is a random 0-1 matrix of dimension $m \times 1$. In particular, we can represent \mathbf{A} as $\mathbf{A} = [\mathbf{I} : \mathbf{D}]$, where \mathbf{I} is the identity matrix of size $m \times m$ and \mathbf{D} is a random 0-1 matrix of size $m \times (n - m)$. In follow-up work, Meel et al. [MSV19] sought to avoid the complexity bottleneck presented by the requirement of having to enumerate up to `thresh` solutions in every call to `SATURATINGCOUNTER`. Towards this end, they proposed the search for the right number (m) of cells in reverse order starting from $m = n$ instead of from $m = 0$. This helps in ensuring that only $\mathcal{O}(\text{thresh})$ solutions are enumerated during the entire iteration of the loop in lines 7–15 of Algorithm `HASHCOUNTER` (see Algorithm 1).

In a series of papers [MSV17, MSV19], Meel et al. proposed several other improvements, eventually resulting in a universal hashing-based DNF counting algorithm, called `SymbolicDNFApproxMC`, that runs in time $\tilde{O}(\frac{mn}{\varepsilon^2} \log(1/\delta))$. Note that this matches the asymptotic complexity bound for Monte Carlo techniques discussed above. One would expect that the asymptotic complexity of different FPRAS correlates positively with their empirical run-time behavior when comparing the performance of different FPRAS on a large set of benchmarks. In a rather surprising twist, however, the landscape of empirically observed run-time behavior turns out to be far more nuanced than that captured by worst-case analysis, as shown in [MSV19]. In particular, there is no single algorithm that outperforms all others for all classes of formulas and input parameters. Interestingly, Meel et al. observed that the algorithm, `DNFApproxMC`, with one of the worst-time complexities ended up solving the largest number of benchmarks.

It is worth noting that there has been a long gap of 34 years between Karp and Luby's Monte Carlo-based FPRAS for DNF counting, and the discovery of hashing-based FPRAS for DNF counting. This is despite the fact that hashing techniques for CNF counting have been known at least since Stockmeyer's seminal work in 1983. Interestingly, Stockmeyer's technique for transforming an algorithm with a constant-factor approximation to one with an $(1 + \varepsilon)$ -factor approximation does not work for DNF counting. This is because conjoining a set of DNF formulas (a key component of Stockmeyer's technique) does not always yield a formula representable in DNF without an exponential blow-up. In contrast, in hashing-based approximate counting (ref. Algorithm `HASHCOUNTER`), a $(1 + \varepsilon)$ -factor approximation is easily achieved by choosing `thresh` to be in $\mathcal{O}(1/\varepsilon^2)$.

26.5. Weighted Counting

A natural extension of model counting is to augment the formula φ with a weight function ρ that assigns a non-negative weight to every assignment of values to variables. The problem of weighted model counting, also known as discrete in-

tegration, seeks to compute the weight of φ , defined as the sum of the weight of all its solutions. Note that if ρ assigns weight 1 to each assignment, then the corresponding problem is simply model counting.

Formally, let $\rho : \{0, 1\}^n \rightarrow \mathbb{Q}_+ \cap [0, 1]$ be a *weight function* mapping each truth assignment to a non-negative rational number in $[0, 1]$ such that (i) $\forall \sigma \in \{0, 1\}^n$, $\rho(\sigma)$ is computable in polynomial time, and (ii) $\forall \sigma \in \{0, 1\}^n$, $\rho(\sigma)$ is written in binary representation with p bits. We extend the weight function to sets of truth assignments and Boolean formulas in the obvious way. If Y is a subset of $\{0, 1\}^n$, the weight of Y is defined as the cumulative weight of the truth assignments in Y : $\rho(Y) = \sum_{\sigma \in Y} \rho(\sigma)$. By definition, the weight of the empty set is 0. The weight of a formula φ is defined as the cumulative weight of its solutions, i.e., $\rho(\varphi) = \sum_{\sigma \models \varphi} \rho(\sigma)$. Given ρ and φ , the problem of weighted model counting seeks to compute $\rho(\varphi)$. The polynomial-time computability of $\rho(\sigma)$ implies that the problem of weighted counting is #P-complete.

The recent success of approximate (unweighted) model counters has inspired several attempts for approximate weighted model counting as well [EGSS13a, EGSS13b, CFM⁺14, EGSS14, AJ15, AD16, dCM19]. Despite impressive advances made by these attempts, the inherent hardness of weighted model counting has repeatedly manifested itself as a scalability challenge. This highlights the need and opportunity for both algorithmic and systems-oriented research in this area.

In order to present a unified view of different algorithms proposed for weighted model counting, we follow the treatment of Ermon et al [EGSS13b] and de Colnet and Meel [dCM19], and introduce two additional notions: the *tail function* and *effective weight function*. The tail function τ maps the space of weights (i.e. $\mathbb{Q}_+ \cap [0, 1]$) to \mathbb{N} . Informally, $\tau(u)$ counts the number of models of φ with weight at least as large as u . Formally, $\tau(u) = |\{\sigma \in \{0, 1\}^n \mid \sigma \models \varphi \text{ and } \rho(\sigma) \geq u\}|$. The effective weight function w , which is the dual of the tail function, can be intuitively thought of as mapping non-zero natural numbers to weights. Informally, $w(t)$ gives the largest weight of a model σ of φ that has at least t models of larger or equal weight. For technical reasons, we formally define w as a mapping from the positive reals (instead of positive natural numbers) to the space of weights as follows: $w(t) = \max_{\sigma} \{w(\sigma) \mid \sigma \models \varphi \text{ and } \tau(\rho(\sigma)) \geq t\}$. Note that both the effective weight function and the tail function are non-increasing functions of their argument. It can be shown [EGSS13b, dCM19] that the weighted model count $\rho(\varphi)$ is exactly the area under the $\tau(u)$ (plotted against u) curve, as well as that under the $w(t)$ (plotted against t) curve. In other words, $\rho(\varphi) = \int \tau(u) du = \int w(t) dt$. Both of these are integrals of non-increasing functions defined over \mathbb{R}_+ and are of finite support.

Recent work on approximate weighted model counting can now be broadly described as following a two-step strategy. In the first step, the task of weighted counting is reduced to an integration problem for a suitable real-valued non-increasing function. In the second step, methods based on upper and lower rectangle approximations or Monte Carlo integrators are used to approximate the integral of a real function. We describe below two different approaches that follow this strategy, effectively reducing weighted counting to optimization and unweighted counting respectively.

26.5.1. From weighted counting to optimization

Ermon et al. [EGSS13a, EGSS13b] used the rectangle approximation of $\int \tau(u)du$ to reduce the problem of weighted counting to one of optimization. The first step in this process is the partitioning of the weight (i.e., u) axis into $\mathcal{O}(n)$ intervals, where $n = |\text{Sup}(\varphi)|$. Specifically, the axis is split at the weights $q_0, q_1 \dots, q_n$, where q_i is the maximal weight such that $\tau(q_i) \geq 2^i$; we call these q_i 's *quantile weights*. Observe that the quantile weights are all well-defined, and form a non-increasing sequence. Furthermore, for each positive quantile weight q_i , there exists some truth assignment such that $q_i = \rho(\sigma)$.

The partitioning of the u axis in $\int \tau(u)du$ at the quantile weights gives $\rho(\varphi) = q_n 2^n + \sum_{i=1}^n \int_{q_i}^{q_{i-1}} \tau(u)du$ where $\int_{q_i}^{q_{i-1}}$ represents the integral on $(q_i, q_{i-1}]$. Note that if u is in $(q_i, q_{i-1}]$, then we have $2^{i-1} \leq \tau(u) \leq 2^i$. Therefore, $2^{i-1} (q_{i-1} - q_i) \leq \int_{q_i}^{q_{i-1}} \tau(u)du \leq 2^i (q_{i-1} - q_i)$. Summing all bounds together and rearranging the terms, we obtain $q_0 + \sum_{i=0}^{n-1} q_{i+1} 2^i \leq \rho(\varphi) \leq q_0 + \sum_{i=0}^{n-1} q_i 2^i$. Thus, if W_1 denotes $q_0 + \sum_{i=0}^{n-1} q_{i+1} 2^i$, we have $W_1 \leq \rho(\varphi) \leq 2W_1$.

Given q_0, \dots, q_n , the estimate W_1 can be computed in polynomial time. Recall that for all i , the weight q_i is defined as $\max \{ \rho(\sigma) \mid \sigma \models \varphi \text{ and } \tau(\rho(\sigma)) \geq 2^i \}$. Therefore the task of approximating the weighted model count $\rho(\varphi)$ has effectively been transformed to $n + 1$ optimization problems. While computing q_i exactly is intractable, we can obtain a good approximation of q_i via the usage of 2-universal hash functions. Similar to hashing-based counting, the core technical idea is to employ 2-universal hash functions to partition the space of solutions, viz. $\{0, 1\}^n$, into approximately equal-sized 2^i cells. We then choose an arbitrary cell and use an optimization query (viz. MPE query in [EGSS13b] or MaxSAT query in [dCM19]) to find a solution of φ with maximum weight in the chosen cell. Let us call this σ_{max} . The 2-universality property of the hash family ensures that $\rho(\sigma_{max}) \in [q_{i-2}, q_{i+2}]$ with probability greater than $\frac{1}{2}$. Therefore, we can choose $\rho(\sigma_{max})$ as an estimate \hat{q}_i of q_i . As in the case of counting, the above process of randomly partitioning the space of solutions and finding an estimate of q_i can be repeated an appropriate number (linear in $\log \frac{1}{\delta}$ and $\log n$) of times, and the median of the estimates used with high enough confidence. The estimate \widehat{W}_1 of W_1 computed using the median estimates of q_i s can be shown to be a 16-factor approximation with confidence at least $1 - \delta$ [EGSS13b, dCM19]. To obtain a $(1 + \varepsilon)$ -factor approximation, Stockmeyer's technique, as outlined in Section 26.2.3.1, can be applied.

26.5.2. From weighted counting to counting

We now discuss techniques that effectively use rectangular approximations of $\int w(t)dt$ to estimate a weighted model count. The work of Chakraborty et al. [CFM⁺14] and de Colnet and Meel [dCM19] belong to this category. As in the previous subsection, the first step is to partition the tail (i.e., t) axis. Towards this end, we choose a non-decreasing sequence $\tau_0 \leq \tau_1 \leq \dots \leq \tau_p$ such that $\tau_i = \tau(1/2^i)$ and p is the number of bits in binary representation of $\rho(\sigma)$ as mentioned in Section 26.5. We call these τ_i 's *splitting tails*.

The partitioning of the integral $\int w(t)dt$ at the splitting tails gives $\rho(\varphi) = \tau_0 + \sum_{i=0}^{p-1} \int_{\tau_i}^{\tau_{i+1}} w(t)dt$, where $\int_{\tau_i}^{\tau_{i+1}}$ represents the integral on $(\tau_i, \tau_{i+1}]$. If t is in $(\tau_i, \tau_{i+1}]$, then $2^{-i-1} \leq w(t) \leq 2^{-i}$. So we bound the tails in each interval $(\tau_i, \tau_{i+1}]$ within a factor of 2 as $2^{-i-1}(\tau_{i+1} - \tau_i) \leq \int_{\tau_i}^{\tau_{i+1}} w(t)dt \leq 2^{-i}(\tau_{i+1} - \tau_i)$. Note that the bound holds even when $(\tau_i, \tau_{i+1}]$ is empty (i.e. $\tau_i = \tau_{i+1}$). Summing all bounds together and rearranging the terms, we obtain $\tau_p 2^{-p} + \sum_{i=0}^{p-1} \tau_i 2^{-(i+1)} \leq \rho(\varphi) \leq \tau_p 2^{-p} + \sum_{i=0}^{p-1} \tau_{i+1} 2^{-(i+1)}$. Let W_2 denote $\tau_p 2^{-p} + \sum_{i=0}^{p-1} \tau_i 2^{-(i+1)}$. Then, we have $W_2 \leq \rho(\varphi) \leq 2W_2$. As in the previous subsection, if we are given $\{\tau_0, \dots, \tau_p\}$, the estimate W_2 can be computed in polynomial time. Furthermore, recall that the tail τ_i is defined to be $|\{\sigma \mid \sigma \models \varphi \text{ and } \rho(\sigma) \geq 2^{-i}\}|$. Therefore, the problem of estimating $\rho(\varphi)$ is now transformed to $p + 1$ counting sub-problems. Note that each sub-problem requires us to count not just models of φ , but models with a specified minimum weight. In special cases, where the weight of an assignment is the product or sum of weights of corresponding literals, the set of models of φ with weight at least 2^{-i} can be represented using a Pseudo-Boolean constraint, as has been done in [CFM⁺14]. Estimating the model count of such a constraint can be accomplished using the same hashing-based technique discussed earlier, by partitioning the solution space using random XOR constraints. Let $\hat{\tau}_i$ denote the estimate of τ_i obtained in this manner. Chakraborty et al. [CFM⁺14] and de Colnet and Meel [dCM19] have shown that the estimate \widehat{W}_2 of W_2 obtained by using $\hat{\tau}_i$ instead of τ_i is a constant-factor approximation with confidence at least $1 - \delta$ [dCM19]. As before, Stockmeyer’s technique can be used to obtain a $(1 + \varepsilon)$ -factor approximation of $\rho(\varphi)$.

In a separate line of work, Chakraborty et al. [CFMV15] and Dudek, Fried, and Meel [DFM20] investigated reduction from weighted model counting to unweighted model counting for a specific class of weight functions called *literal weight functions*. In this case, weights are assigned to individual literals, and the weight of an assignment is simply the product of weights of its literals. For a variable x_i in the support of φ and a weight function $\rho(\cdot)$, let $\rho(x_i^1)$ and $\rho(x_i^0)$ denote the weights of the positive and negative literals respectively, of x_i . Without loss of generality, we assume that $\rho(x_i^1) + \rho(x_i^0) = 1$, and that each $\rho(x_i^1) = \frac{k_i}{\ell_i}$, where $k_i, \ell_i \in \mathbb{N}$ and $k_i \leq \ell_i$. The key idea in [CFMV15, DFM20] is to transform a given formula φ into another formula $\widehat{\varphi}$ such that $\rho(\varphi) = C_\rho \cdot |\text{Sol}(\widehat{\varphi})|$, where C_ρ depends only on ℓ_i ’s, and *not* on φ . Once the above transformation is achieved, the problem of estimating $\rho(\varphi)$ reduces to that of counting models of $\widehat{\varphi}$. To achieve the transformation, Chakraborty et al used a gadget called *chain formulas* [CFMV15]. The chain formula ψ_{k_i, ℓ_i} represents a Boolean formula with k_i solutions over $\lceil \log_2 \ell_i \rceil$ fresh variables. The transformed formula $\widehat{\varphi}$ is then obtained as $\varphi \wedge \bigwedge_{i=1}^n ((x_i \rightarrow \psi_{k_i, \ell_i}) \wedge (\neg x_i \rightarrow \psi_{\ell_i - k_i, \ell_i}))$. An approximate counting technique, viz. Algorithm HASHCOUNTER, can now be invoked to obtain a $(1 + \varepsilon)$ -approximation of $|\text{Sol}(\widehat{\varphi})|$ with confidence $1 - \delta$. Since C_ρ is polynomially computable from the ℓ_i ’s, this gives us a PAC estimate of $\rho(\varphi) = C_\rho \cdot |\text{Sol}(\widehat{\varphi})|$.

26.5.3. Scalability challenges

Both the algorithmic approaches to weighted counting outlined above provide rigorous theoretical guarantees on the quality of computed estimates. They have

been implemented and demonstrated to scale to problems involving several thousand propositional variables. Nevertheless, there are factors that have impeded scaling them up to even larger problem sizes. Some of these factors include:

1. The lack of highly efficient MaxSAT or MPE solvers capable of handling constraints with XOR clauses.
2. The lack of solvers capable of handling formulas expressed as a conjunction of CNF, Pseudo-Boolean constraints, and XOR constraints [PJM19].
3. The reduction proposed by Chakraborty et al. [CFMV15] suffers from a linear increase in the number of variables. This results in large XOR constraints when using hash-based approximate counting techniques. Large XOR constraints are known to present scalability hurdles to state-of-the-art satisfiability solvers.

Given these bottlenecks, the spectacular progress witnessed in recent years in MaxSAT, MPE and pseudo-Boolean constraint solving present significant opportunities for pushing the frontiers of the weighted model counting. In addition, the use of short XOR clauses without weakening theoretical guarantees and the integration of Gaussian elimination in MaxSAT, MPE and pseudo-Boolean solvers (akin to what has been done for CNF solvers) present promising research directions to pursue.

26.6. Conclusion

Model counting is a fundamental computational problem with a wide variety of applications. It is not surprising therefore that it has attracted the attention of theoreticians and practitioners for the past four decades. This has resulted in a rich bouquet of algorithms with differing characteristics in terms of guarantees on the quality of estimates and runtime performance. Among them, universal hashing-based approximate counting has emerged as the dominant paradigm over the past decade. The success of hashing-based counters can be attributed to two primary reasons: (i) properties of universal hash functions that allow these algorithms to provide (ε, δ) guarantees, and (ii) the spectacular advances in modern satisfiability solving techniques that allow counting algorithms to scale to constraints involving hundreds of thousands of variables.

While we focused on counting all models of a formula φ in this chapter, the hashing-based techniques described in the preceding sections also generalize to the related problem of projected model counting, wherein given $X \subseteq \text{Sup}(\varphi)$, the task is to compute $|\text{Sol}(\exists X \varphi)|$ [SM19]. Given that usage of the existential quantifier (\exists) can give exponentially succinct formulas vis-a-vis equivalent formulas written without quantifiers, the problem of projected model counting has been employed in several applications ranging from network (un)reliability to neural network verification [DOMPV17, BSS⁺19, NSM⁺19].

The promise exhibited by state-of-the-art approximate model counters has led to the study of several extensions and generalizations: maximum model counting [FRS17], weighted model integration [BPVdB15, KMS⁺18], stochastic satisfiability [LWJ17], and counting over string and bit-vector constraints [LSSD14, ABB15, CMMV16, CDM17]. Each of these generalizations have necessitated the

development of new techniques and have attracted newer applications. Furthermore, approximate model counting and almost-uniform sampling are known to be inter-reducible [JVV86]. The close relationship has led to a long line of fruitful work extending several hashing-based techniques discussed in this chapter to the context of uniform sampling [CMV13a, CMV14, CFM⁺14, CFM⁺15, MVC⁺16, Meel17].

The promise and progress in the development of approximate model counters has opened several new directions of research, that is evident from the recent flurry of activity in the research community studying approximate counting and its applications. The availability of implementations that both scale to large inputs and also provide strong approximation guarantees has ignited interest among practitioners in seeking new applications for counting. Therefore, we look optimistically to the future where the groundwork laid by hashing-based techniques will lead to the development of new paradigms and practical applications of approximate model counting.

Chapter 27

Non-Clausal SAT and ATPG

Rolf Drechsler, Tommi Junttila and Ilkka Niemelä

27.1. Introduction

When studying the propositional satisfiability problem (SAT), that is, the problem of deciding whether a propositional formula is satisfiable, it is typically assumed that the formula is given in the conjunctive normal form (CNF). Also most software tools for deciding satisfiability of a formula (SAT solvers) assume that their input is in CNF. An important reason for this is that it is simpler to develop efficient data structures and algorithms for CNF than for arbitrary formulas. On the other hand, using CNF makes efficient modeling of an application cumbersome. Therefore one often employs a more general formula representation in modeling and then transforms the formula into CNF for SAT solvers. Transforming a propositional formula to an equivalent formula in CNF can increase the size of the formula exponentially in the worst case. However, general propositional formulas can be transformed in polynomial time into CNF while preserving the satisfiability of the instance [PG86, BdlT92, NRW98, JS05, Vel04] (also see Chapter 2 in this handbook). Such translations introduce auxiliary variables which can have an exponential effect on the performance of a SAT solver in the worst-case. Moreover, by translating to CNF one often loses information about the structure of the original problem.

In this chapter we survey methods for solving propositional satisfiability problems when the input formula is not given in a normal form and techniques in a closely related area of automatic test pattern generation (ATPG). Substantial amount of research has been done on developing theorem proving methods working with arbitrary (non-clausal) formulas. A major part of this work is based on tableaux type of calculi [DGHE99, Häh01] but this research has mostly considered the first-order case or non-classical logics. For a comprehensive summary of tableau type calculi for classical propositional logic, see [D'A99]. There has been some work on developing efficient propositional provers based on tableau techniques such as the HARP prover [OS88]. However, in the classical propositional case tableau based approaches have not been as successful as DPLL based techniques (see Chapter 3 in this handbook for more details on the DPLL algorithm). Typical tableau calculi for classical propositional logic are not able to

simulate polynomially even truth tables [DM94] but there has been some work on extending tableau techniques to make them computationally more efficient, e.g., by introducing an explicit cut rule like in the KE system [DM94] or by adding new constraint propagation rules [Mas98]. An interesting generalization of tableaux is provided by dissolution [MR93]. Another major approach to developing a computationally attractive method for deciding satisfiability of a general formula is based on Stålmarck's proof procedure for propositional logic [SS00] (see Chapter 3 in this handbook for more details on Stålmarck's algorithm). In fact, a commercial SAT solver system, *Prover*, is based on this method [Bor97]. Also local search methods for satisfiability have been extended to work on the non-clausal case, e.g., in [Seb94, KMS97, PTS07]. A very successful approach to manipulate general propositional formulas is based on Binary Decision Diagrams (BDDs) [Bry86, Bry92]. However, BDDs are not targeted towards satisfiability checking but provide an attractive normal form that is especially suitable for determining equivalence of formulas.

A substantial number of advanced satisfiability checking techniques that work on non-clausal representation have been developed in the area of digital circuit design. These approaches work typically with *Boolean circuits*. This work is closely related to the area of automatic test pattern generation (ATPG) for digital circuits where similar sophisticated techniques have been developed.

Circuit representation has properties that can be exploited in satisfiability checking in a number of ways: Circuits preserve important structural information and allow sharing of common sub-expressions enabling very concise problem representation. These properties can be used in preprocessing and for efficient Boolean propagation. Moreover, circuit representation enables to detect observability don't cares which are very useful in pruning the search space in satisfiability checking. In addition, circuit structure can be used to guide search heuristics.

In this chapter we survey satisfiability checking methods that work directly on Boolean circuits and techniques for ATPG for digital circuits. In these areas there is a substantial body of literature which is covered in the corresponding sections. The rest of the chapter is structured as follows. We start by introducing Boolean circuits in Section 27.2. Then in Section 27.3 we present methods for Boolean circuit satisfiability checking focusing on successful DPLL type clausal SAT checking techniques generalized and extended to work directly with Boolean circuits. Section 27.4 reviews classical ATPG algorithms, formulation of ATPG as a SAT problem, and advanced techniques for SAT-based ATPG.

27.2. Basic Definitions

Assume the set of Booleans $\mathbb{B} = \{\mathbf{F}, \mathbf{T}\}$ and define $\neg\mathbf{F} = \mathbf{T}$ and $\neg\mathbf{T} = \mathbf{F}$.

A *Boolean circuit* \mathcal{C} is a pair $(\mathcal{G}, \mathcal{E})$, where

- \mathcal{G} is a non-empty, finite set of *gates*, and
- \mathcal{E} is a set of equations such that
 - each equation is of form $g := f(g_1, \dots, g_n)$, where $g, g_1, \dots, g_n \in \mathcal{G}$ and $f \in [\mathbb{B}^n \rightarrow \mathbb{B}]$ is a Boolean function,
 - each gate $g \in \mathcal{G}$ appears at most once as the left hand side in the equations in \mathcal{E} , and

- the equations are not recursive, that is, the directed *dependency graph* $\text{graph}(\mathcal{C}) = (\mathcal{G}, \{(g', g) \mid g := f(\dots, g', \dots) \in \mathcal{E}\})$ is acyclic.

Notice that we use here a definition of Boolean circuits similar to that in [Pap95] where signals of a circuit \mathcal{C} are not represented explicitly but are given implicitly as edges of the graph $\text{graph}(\mathcal{C})$. Figure 27.1 clarifies the correspondence between the graph representation $\text{graph}(\mathcal{C})$ of a Boolean circuit \mathcal{C} and the representation with signals given explicitly.

A gate $g \in \mathcal{G}$ is a *primary input* gate if it does not appear as the left hand side in any equation in \mathcal{E} ; the set of all primary input gates in \mathcal{C} is denoted by $\text{inputs}(\mathcal{C})$. A gate g' is a *child* of a gate g if the edge (g', g) appears in $\text{graph}(\mathcal{C})$, i.e. if g' appears in the equation of g . In this case, g is called the *parent* of g' .¹ The number of children (parents, respectively) of a gate is called the *fan-in* (*fan-out*, respectively) of the gate. The concepts of *descendant* and *ancestor* gates are defined in the intuitive way via the transitive closures of the child and parent relations, respectively. A gate is a *primary output* gate if it has no parents. The following Boolean function families are commonly used in the gates:

- **false, true** : \mathbb{B} are the constant functions with $\text{false}() = \mathbf{F}$ and $\text{true}() = \mathbf{T}$.
- **not** : $\mathbb{B} \rightarrow \mathbb{B}$ with $\text{not}(\mathbf{F}) = \mathbf{T}$ and $\text{not}(\mathbf{T}) = \mathbf{F}$.
- **and** : $\mathbb{B}^n \rightarrow \mathbb{B}$ with $\text{and}(v_1, \dots, v_n) = \mathbf{T}$ iff all v_1, \dots, v_n are \mathbf{T} .
- **or** : $\mathbb{B}^n \rightarrow \mathbb{B}$ with $\text{or}(v_1, \dots, v_n) = \mathbf{T}$ iff at least one of v_1, \dots, v_n is \mathbf{T} .
- **ite** : $\mathbb{B}^3 \rightarrow \mathbb{B}$ is the “if-then-else” function such that $\text{ite}(v_1, v_2, v_3) = \mathbf{T}$ iff (i) $v_1 = \mathbf{T}$ and $v_2 = \mathbf{T}$, or (ii) $v_1 = \mathbf{F}$ and $v_3 = \mathbf{T}$.
- **odd** : $\mathbb{B}^n \rightarrow \mathbb{B}$ is the n -ary parity function such that $\text{odd}(v_1, \dots, v_n) = \mathbf{T}$ iff an odd number of v_1, \dots, v_n are \mathbf{T} ; the case $n = 2$ is usually called the exclusive-or (**xor**) function.
- **equiv** : $\mathbb{B}^n \rightarrow \mathbb{B}$ is the n -ary equivalence function; $\text{equiv}(v_1, \dots, v_n) = \mathbf{T}$ iff either (i) all v_1, \dots, v_n are \mathbf{T} , or (ii) all v_1, \dots, v_n are \mathbf{F} .

Example 27.2.1. Figure 27.1 shows two standard graphical representations for a Boolean circuit describing a full-adder. Formally, the circuit is defined as $\mathcal{C} = (\mathcal{G}, \mathcal{E})$ with the gate set $\mathcal{G} = \{a_0, b_0, c_0, t_1, t_2, t_3, o_0, c_1\}$ and equations

$$\mathcal{E} = \{c_1 := \text{or}(t_1, t_2), t_1 := \text{and}(t_3, c_0), o_0 := \text{odd}(t_3, c_0), \\ t_2 := \text{and}(a_0, b_0), t_3 := \text{odd}(a_0, b_0)\}.$$

For instance, the gate c_1 is an **odd-gate**, a_0 is a primary input gate, and c_1 is a primary output gate. The gate t_3 is a child of the gate t_1 and a descendant of the gate c_1 .

A *truth assignment* for \mathcal{C} is a possibly partial function $\tau : \mathcal{G} \rightarrow \mathbb{B}$. A gate $g \in \mathcal{G}$ is *assigned* in τ if $\tau(g)$ is defined, otherwise it is *unassigned* in τ ; τ is *total* if all gates are assigned in it. If τ is a truth assignment for \mathcal{C} , $g \in \mathcal{G}$, and $v \in \mathbb{B}$, then $\tau[g \rightarrow v]$ is the truth assignment that is equal to τ except that $\tau[g \rightarrow v](g) = v$. A truth assignment τ' is an *extension* of a truth assignment τ if $\tau' \supseteq \tau$. A total truth assignment τ for \mathcal{C} is *consistent* if $\tau(g) = f(\tau(g_1), \dots, \tau(g_n))$ holds for each

¹The terms input and output of a gate are sometimes used instead of child and parent, respectively; we use the latter ones to avoid confusion with primary inputs and outputs.

Figure 27.1. Two graphical representations for a full-adder circuit

equation $g := f(g_1, \dots, g_n) \in \mathcal{E}$. Obviously, there are $2^{|\text{inputs}(\mathcal{C})|}$ consistent total truth assignments for \mathcal{C} .

Example 27.2.2. Consider again the circuit \mathcal{C} in Figure 27.1. In the truth assignment $\tau = \{c_1 \mapsto \mathbf{T}, o_0 \mapsto \mathbf{F}\}$, the gate c_1 is assigned and t_1 is unassigned. The truth assignment

$$\tau' = \{c_1 \mapsto \mathbf{T}, t_1 \mapsto \mathbf{F}, o_0 \mapsto \mathbf{F}, t_2 \mapsto \mathbf{T}, t_3 \mapsto \mathbf{F}, a_0 \mapsto \mathbf{T}, b_0 \mapsto \mathbf{T}, c_0 \mapsto \mathbf{F}\}$$

is a total and consistent extension of τ . On the other hand, no total extension of the truth assignment $\{c_1 \mapsto \mathbf{T}, a_0 \mapsto \mathbf{T}, b_0 \mapsto \mathbf{T}, t_3 \mapsto \mathbf{T}\}$ is consistent as the definition of the gate t_3 will not be respected.

The value of a gate g assigned in a truth assignment τ is *justified* in τ if (i) g is a primary input gate, or (ii) $g := f(g_1, \dots, g_n) \in \mathcal{E}$ and $\tau(g) = f(\tau'(g_1), \dots, \tau'(g_n))$ holds for each total truth assignment $\tau' \supseteq \tau$. That is, the value of a justified gate stays consistent with respect to the definition of the gate, no matter how the truth assignment is extended. By definition it holds that if τ is a total and consistent truth assignment for \mathcal{C} , then the value of each gate is justified in τ .

Example 27.2.3. In the truth assignment $\tau = \{c_1 \mapsto \mathbf{T}, t_1 \mapsto \mathbf{T}, t_3 \mapsto \mathbf{T}\}$ for the circuit in Figure 27.1, the gate c_1 is justified. On the other hand, the gates $t_1, t_2,$ and t_3 are not justified in τ .

A *constrained Boolean circuit* is a pair (\mathcal{C}, τ) , where \mathcal{C} is a Boolean circuit and τ is a truth assignment for \mathcal{C} . A total truth assignment τ' for \mathcal{C} *satisfies* (\mathcal{C}, τ) if it is a consistent total extension of τ . A constrained Boolean circuit (\mathcal{C}, τ) is *satisfiable* if there is a total truth assignment for \mathcal{C} that satisfies (\mathcal{C}, τ) , otherwise (\mathcal{C}, τ) is *unsatisfiable*. Obviously, it is an **NP**-complete problem to decide whether there is a satisfying truth assignment for a given constrained circuit.²

Example 27.2.4. Consider again the circuit \mathcal{C} in Figure 27.1. The pair (\mathcal{C}, τ) , where $\tau = \{c_1 \mapsto \mathbf{T}\}$, is a constrained Boolean circuit with the requirement that

²Provided that all the families of Boolean functions attached to gates are computable in polynomial time; this is assumed in the rest of the chapter.

the carry-out gate c_1 should evaluate to true. It is satisfiable as the total assignment $\tau' = \{c_1 \mapsto \mathbf{T}, t_1 \mapsto \mathbf{F}, o_0 \mapsto \mathbf{F}, t_2 \mapsto \mathbf{T}, t_3 \mapsto \mathbf{F}, a_0 \mapsto \mathbf{T}, b_0 \mapsto \mathbf{T}, c_0 \mapsto \mathbf{F}\}$ satisfies it.

27.3. Satisfiability Checking for Boolean Circuits

In this section we survey satisfiability checking techniques which work on the Boolean circuit representation. We start by a brief discussion on preprocessing and then in Section 27.3.2 outline how the highly successful DPLL method for checking satisfiability of a formula in CNF (see Chapter 3 in this handbook) can be generalized to work directly with circuits. In Section 27.3.3 we discuss how clause learning techniques can be integrated into circuit level DPLL methods. We compare Boolean Constraint Propagation (BCP) techniques on the circuit level to those used in clausal level in Section 27.3.4 and elaborate efficient implementation techniques of circuit level BCP in Section 27.3.5. Exploiting observability don't cares is discussed in Section 27.3.6. Section 27.3.7 considers search heuristics exploiting the circuit structure and Section 27.3.8 briefly reviews incomplete local search techniques for Boolean circuit satisfiability.

27.3.1. Preprocessing

When solving a circuit satisfiability problem it is often useful to simplify the circuit with preprocessing techniques preserving satisfiability. Here we briefly discuss some techniques taking advantage of the circuit representation.

A key difference to the flat CNF representation is that circuits allow *sharing of common sub-expressions*. That is, if a circuit has two similar equations, $g := f(g_1, \dots, g_n)$ and $g' := f(g_1, \dots, g_n)$, then one of them, say, $g' := f(g_1, \dots, g_n)$ can be removed from the circuit and all the occurrences of g' can be substituted with g .

Sharing of common sub-expressions can be enhanced and a more compact representation obtained by translating a circuit to some efficient *reduced representation* such as Boolean Expression Diagrams (BEDs) [AH02, WAH03], Reduced Boolean Circuits (RBCs) [ABE00], and And-Inverter Graphs (AIGs) [KGP01, KPKG02]. In addition, logic synthesis and minimization techniques can be applied to further reduce the circuit size, see e.g. [EMS07].

When considering a constrained circuit, where certain gates have been assigned truth values, further simplifications are enabled, for instance, in two ways:

- *Propagation and rewriting based on assigned truth values*
Naturally, the values of the assigned gates can propagate values to other gates. For instance, if an **and**-gate is assigned to **T**, then all its children can be assigned to **T**. In addition, if a gate has an assigned child, the connection to the child can be removed and the gate definition changed accordingly. For example, if for a gate $g := \text{ite}(g_1, g_2, g_3)$ the truth value of the child g_2 is set to **T**, then the equation can be simplified to $g := \text{or}(g_1, g_3)$.
- *Cone of influence reduction*
If a gate is not constrained and no other equation refers to it (i.e. it is an unconstrained primary output gate), it can be removed.

27.3.2. Basic Tableau Method for Circuit Satisfiability Checking

In the circuit satisfiability problem we are given a constrained Boolean circuit (\mathcal{C}, τ) and the task is to determine whether there is a total truth assignment satisfying (\mathcal{C}, τ) . We start by presenting a circuit satisfiability checking method which generalizes the DPLL method for clausal satisfiability to circuits. We formulate the circuit level DPLL method as a tableau system, which we called **BC**, following the approach in [JN00]. First we discuss a basic sound and complete version of the tableau system and then extend it with additional rules enhancing its efficiency.

The basic system consists of the rules shown in Figure 27.2. Note that the versions of the rules obtained by permuting the children of gates with symmetric Boolean functions are not shown in Figures 27.2 and 27.3; for instance,

$$\frac{g := \text{odd}(g_1, g_2, g_3) \quad \mathbf{T}g_1, \mathbf{T}g_3 \quad \mathbf{F}g_2}{\mathbf{F}g}$$

obtained by instantiating the rightmost rule in Figure 27.2(g) for $k = 3$ is also a rule. Given a constrained Boolean circuit (\mathcal{C}, τ) , a **BC-tableau** for (\mathcal{C}, τ) is a binary tree where

- the root node of the tree consists of (i) the equations \mathcal{E} in $\mathcal{C} = (\mathcal{G}, \mathcal{E})$ and (ii) for each gate g assigned in τ , the entry $\mathbf{T}g$ if $\tau(g) = \mathbf{T}$ or $\mathbf{F}g$ if $\tau(g) = \mathbf{F}$;
- the other nodes in the tree are entries of the form $\mathbf{T}g$ or $\mathbf{F}g$, where $g \in \mathcal{G}$, generated by extending the tableau using the tableau rules in the standard way [D'A99]: given a tableau rule and a branch in the tableau such that the prerequisites of the rule hold in the branch, the tableau can be extended by adding new nodes to the end of the branch as specified by the rule.

If the tableau is extended with the explicit cut rule (Figure 27.2 (a)), then entries $\mathbf{T}g$ and $\mathbf{F}g$ are added as the left and right child in the end of the branch. For the other, *non-branching rules* the consequents of the rule are added to the end of the branch (as a linear sub-tree in case of multiple consequents).

A branch in the tableau is *contradictory* if it contains both $\mathbf{F}g$ and $\mathbf{T}g$ entries for a gate $g \in \mathcal{G}$. Otherwise, the branch is *open*. A branch is *complete* if it is contradictory, or if there is a $\mathbf{F}g$ or a $\mathbf{T}g$ entry for each $g \in \mathcal{G}$ in the branch and the branch is closed under the “up” rules (b–g) in Figure 27.2. A tableau is *finished* if all the branches of the tableau are complete. A tableau is *closed* if all of its branches are contradictory. A closed **BC-tableau** for a constrained circuit is called a **BC-refutation** for the circuit.

The basic tableau system **BC** can be shown to be a *refutationally sound and complete* proof system in the sense that there is a **BC-refutation** (closed tableau) for a constrained circuit iff the circuit is unsatisfiable. Also for finding satisfying truth assignments the tableau system is

- *sound* in the sense that if there is an open complete branch in a tableau, then the branch provides a total truth assignment satisfying the constrained circuit and

$$\frac{g \in \mathcal{G}}{\mathbf{T}g \mid \mathbf{F}g} \qquad \frac{g := \text{true}()}{\mathbf{T}g} \qquad \frac{g := \text{false}()}{\mathbf{F}g} \qquad \frac{g := \text{not}(g_1)}{\mathbf{F}g_1} \qquad \frac{g := \text{not}(g_1)}{\mathbf{T}g_1}$$

(a) The explicit cut rule. (b) Constant rules. (c) “Up” rules for not-gates.

$$\frac{g := \text{or}(g_1, \dots, g_k)}{\mathbf{F}g_1, \dots, \mathbf{F}g_k} \qquad \frac{g := \text{and}(g_1, \dots, g_k)}{\mathbf{T}g_1, \dots, \mathbf{T}g_k} \qquad \frac{g := \text{or}(g_1, \dots, g_k)}{\mathbf{T}g_i, i \in \{1, \dots, k\}} \qquad \frac{g := \text{and}(g_1, \dots, g_k)}{\mathbf{F}g_i, i \in \{1, \dots, k\}}$$

(d) “Up” rules for or- and and-gates.

$$\frac{g := \text{ite}(g_1, g_2, g_3)}{\mathbf{T}g_1, \mathbf{T}g_2} \qquad \frac{g := \text{ite}(g_1, g_2, g_3)}{\mathbf{F}g_1, \mathbf{T}g_3} \qquad \frac{g := \text{ite}(g_1, g_2, g_3)}{\mathbf{T}g_1, \mathbf{F}g_2} \qquad \frac{g := \text{ite}(g_1, g_2, g_3)}{\mathbf{F}g_1, \mathbf{F}g_3}$$

(e) “Up” rules for ite-gates.

$$\frac{g := \text{equiv}(g_1, \dots, g_k)}{\mathbf{T}g_1, \dots, \mathbf{T}g_k} \qquad \frac{g := \text{equiv}(g_1, \dots, g_k)}{\mathbf{F}g_1, \dots, \mathbf{F}g_k} \qquad \frac{g := \text{equiv}(g_1, \dots, g_k)}{\mathbf{T}g_i, i \in \{1, \dots, k\}} \qquad \frac{g := \text{equiv}(g_1, \dots, g_k)}{\mathbf{F}g_j, j \in \{1, \dots, k\}}$$

(f) “Up” rules for equiv-gates.

$$\frac{g := \text{odd}(g_1, \dots, g_k)}{\mathbf{T}g_1, \dots, \mathbf{T}g_j, j \text{ is odd}} \qquad \frac{g := \text{odd}(g_1, \dots, g_k)}{\mathbf{T}g_1, \dots, \mathbf{T}g_j, j \text{ is even}} \qquad \frac{g := \text{odd}(g_1, \dots, g_k)}{\mathbf{F}g_{j+1}, \dots, \mathbf{F}g_k} \qquad \frac{g := \text{odd}(g_1, \dots, g_k)}{\mathbf{F}g_{j+1}, \dots, \mathbf{F}g_k}$$

(g) “Up” rules for odd-gates.

Figure 27.2. Basic rules.

- *complete* in the sense that if the circuit is satisfiable, then any finished tableau contains an open branch that provides a total truth assignment satisfying the constrained circuit.

In order to enhance the efficiency of the tableau system additional rules given in Figure 27.3 can be added without compromising the soundness and completeness of the system. For a gate $g \in \mathcal{G}$, we say that an entry $\mathbf{T}g$ ($\mathbf{F}g$) can be *deduced* in a branch if the entry $\mathbf{T}g$ ($\mathbf{F}g$) can be generated by applying non-branching rules, i.e., other rules than the cut rule (Figure 27.2 (a)).

Example 27.3.1. Consider again the circuit \mathcal{C} in Figure 27.1 and constraints $\tau = \{c_1 \mapsto \mathbf{T}, b_0 \mapsto \mathbf{F}\}$. A BC-tableau for the constrained circuit (\mathcal{C}, τ) is shown in Figure 27.4. For instance, the entry 8. $\mathbf{F}t_1$ has been generated by applying the explicit cut rule (Figure 27.2 (a)) and the entry 9. $\mathbf{T}t_2$ has been deduced from entries 1. $c_1 := \text{or}(t_1, t_2)$, 6. $\mathbf{T}c_1$, and 8. $\mathbf{F}t_1$ using the “Indirect down” rule for or-gates (Figure 27.3 (b)).

The tableau is finished and the left branch is contradictory (marked with \times) as it contains entries $\mathbf{F}b_0$ (7) and $\mathbf{T}b_0$ (11). However, the right branch is open

$$\begin{array}{c}
g := \text{not}(g_1) \quad g := \text{not}(g_1) \quad g := \text{or}(g_1, \dots, g_k) \quad g := \text{and}(g_1, \dots, g_k) \\
\frac{\mathbf{T}g}{\mathbf{F}g_1} \quad \frac{\mathbf{F}g}{\mathbf{T}g_1} \quad \frac{\mathbf{F}g}{\mathbf{F}g_1, \dots, \mathbf{F}g_k} \quad \frac{\mathbf{T}g}{\mathbf{T}g_1, \dots, \mathbf{T}g_k}
\end{array}$$

(a) “Direct down” rules for not-, or-, and and-gates.

$$\begin{array}{c}
g := \text{or}(g_1, \dots, g_k) \quad g := \text{and}(g_1, \dots, g_k) \\
\frac{\mathbf{T}g}{\mathbf{F}g_1, \dots, \mathbf{F}g_{k-1}} \quad \frac{\mathbf{F}g}{\mathbf{T}g_1, \dots, \mathbf{T}g_{k-1}} \\
\frac{\mathbf{F}g_1, \dots, \mathbf{F}g_{k-1}}{\mathbf{T}g_k} \quad \frac{\mathbf{T}g_1, \dots, \mathbf{T}g_{k-1}}{\mathbf{F}g_k}
\end{array}$$

$$\begin{array}{c}
g := \text{ite}(g_1, g_2, g_3) \quad g := \text{ite}(g_1, g_2, g_3) \\
\frac{\mathbf{T}g}{\mathbf{T}g_1} \quad \frac{\mathbf{F}g}{\mathbf{T}g_1} \\
\frac{\mathbf{T}g_1}{\mathbf{T}g_2} \quad \frac{\mathbf{F}g_1}{\mathbf{T}g_3}
\end{array}$$

$$\begin{array}{c}
g := \text{ite}(g_1, g_2, g_3) \quad g := \text{ite}(g_1, g_2, g_3) \\
\frac{\mathbf{T}g}{\mathbf{F}g_1, \mathbf{T}g_3} \quad \frac{\mathbf{T}g}{\mathbf{F}g_2, \mathbf{T}g_3} \\
\frac{\mathbf{F}g_2, \mathbf{T}g_3}{\mathbf{T}g} \quad \frac{\mathbf{F}g_2, \mathbf{F}g_3}{\mathbf{F}g}
\end{array}$$

(b) “Indirect down” rules for or and and. (c) Redundant “up” rules for ite-gates.

$$\begin{array}{c}
g := \text{ite}(g_1, g_2, g_3) \quad g := \text{ite}(g_1, g_2, g_3) \quad g := \text{ite}(g_1, g_2, g_3) \quad g := \text{ite}(g_1, g_2, g_3) \\
\frac{\mathbf{T}g}{\mathbf{T}g_1} \quad \frac{\mathbf{T}g}{\mathbf{F}g_1} \quad \frac{\mathbf{T}g}{\mathbf{F}g_2} \quad \frac{\mathbf{T}g}{\mathbf{F}g_3} \\
\frac{\mathbf{T}g_1}{\mathbf{T}g_2} \quad \frac{\mathbf{F}g_1}{\mathbf{T}g_3} \quad \frac{\mathbf{F}g_1, \mathbf{T}g_3}{\mathbf{F}g_2, \mathbf{T}g_3} \quad \frac{\mathbf{T}g_1, \mathbf{T}g_2}{\mathbf{T}g_1, \mathbf{T}g_2}
\end{array}$$

$$\begin{array}{c}
g := \text{ite}(g_1, g_2, g_3) \quad g := \text{ite}(g_1, g_2, g_3) \quad g := \text{ite}(g_1, g_2, g_3) \quad g := \text{ite}(g_1, g_2, g_3) \\
\frac{\mathbf{F}g}{\mathbf{T}g_1} \quad \frac{\mathbf{F}g}{\mathbf{F}g_1} \quad \frac{\mathbf{F}g}{\mathbf{T}g_2} \quad \frac{\mathbf{F}g}{\mathbf{T}g_3} \\
\frac{\mathbf{F}g_1}{\mathbf{F}g_2} \quad \frac{\mathbf{F}g_1}{\mathbf{F}g_3} \quad \frac{\mathbf{F}g_1, \mathbf{F}g_3}{\mathbf{F}g_1, \mathbf{F}g_3} \quad \frac{\mathbf{T}g_2}{\mathbf{T}g_1, \mathbf{F}g_2}
\end{array}$$

(d) “Indirect down” rules for ite-gates.

$$\begin{array}{c}
g := \text{equiv}(g_1, \dots, g_k) \quad g := \text{equiv}(g_1, \dots, g_k) \\
\frac{\mathbf{T}g}{\mathbf{T}g_i, i \in \{1, \dots, k\}} \quad \frac{\mathbf{T}g}{\mathbf{F}g_i, i \in \{1, \dots, k\}} \\
\frac{\mathbf{T}g_i, i \in \{1, \dots, k\}}{\mathbf{T}g_1, \dots, \mathbf{T}g_k} \quad \frac{\mathbf{F}g_i, i \in \{1, \dots, k\}}{\mathbf{F}g_1, \dots, \mathbf{F}g_k}
\end{array}$$

$$\begin{array}{c}
g := \text{equiv}(g_1, \dots, g_k) \quad g := \text{equiv}(g_1, \dots, g_k) \\
\frac{\mathbf{F}g}{\mathbf{T}g_1, \dots, \mathbf{T}g_{k-1}} \quad \frac{\mathbf{F}g}{\mathbf{F}g_1, \dots, \mathbf{F}g_{k-1}} \\
\frac{\mathbf{T}g_1, \dots, \mathbf{T}g_{k-1}}{\mathbf{F}g_k} \quad \frac{\mathbf{F}g_1, \dots, \mathbf{F}g_{k-1}}{\mathbf{T}g_k}
\end{array}$$

(e) “Indirect down” rules for equiv-gates.

$$\begin{array}{c}
g := \text{odd}(g_1, \dots, g_k) \quad g := \text{odd}(g_1, \dots, g_k) \\
\frac{\mathbf{T}g}{\mathbf{T}g_1, \dots, \mathbf{T}g_j, j \text{ is odd}} \quad \frac{\mathbf{F}g}{\mathbf{T}g_1, \dots, \mathbf{T}g_j, j \text{ is odd}} \\
\frac{\mathbf{F}g_{j+1}, \dots, \mathbf{F}g_{k-1}}{\mathbf{F}g_k} \quad \frac{\mathbf{F}g_{j+1}, \dots, \mathbf{F}g_{k-1}}{\mathbf{T}g_k}
\end{array}$$

$$\begin{array}{c}
g := \text{odd}(g_1, \dots, g_k) \quad g := \text{odd}(g_1, \dots, g_k) \\
\frac{\mathbf{T}g}{\mathbf{T}g_1, \dots, \mathbf{T}g_j, j \text{ is even}} \quad \frac{\mathbf{F}g}{\mathbf{T}g_1, \dots, \mathbf{T}g_j, j \text{ is even}} \\
\frac{\mathbf{F}g_{j+1}, \dots, \mathbf{F}g_{k-1}}{\mathbf{T}g_k} \quad \frac{\mathbf{F}g_{j+1}, \dots, \mathbf{F}g_{k-1}}{\mathbf{F}g_k}
\end{array}$$

(f) “Indirect down” rules for odd-gates.

	18. $\mathbf{F}t_2$ (4, 7, 17)

Figure 27.4. A BC-tableau for (\mathcal{C}, τ)

The tableau system **BC** can be seen as a generalization of DPLL to Boolean circuits. First, the explicit cut rule (Figure 27.2 (a)) corresponds to the branching step in DPLL. Second, for Boolean constraint propagation (BCP) the non-branching rules (Figure 27.2 (b–g) and Figure 27.3) play the role of unit propagation (unit resolution) used in DPLL. In Section 27.3.4 we discuss the relationship of BCP using non-branching rules on the circuit level and clausal BCP in more detail.

27.3.3. Implication Graphs, Conflict Driven Learning, and Non-Chronological Backtracking

Conflict driven learning and non-chronological backtracking (backjumping), see Chapters 3 and 4 in this handbook, are techniques applied in state-of-the-art CNF-based SAT solvers to reduce the search spaces. They are based on analyzing each conflict encountered during the search to find (i) a new conflict clause that, when learned (that is, added to the CNF formula), will prevent similar conflicts from occurring again, and (ii) information about which parts of the current branch were irrelevant for the conflict and can thus be jumped over when backtracking. The conflict analysis is based on implication graphs that capture how decisions and Boolean constraint propagation were performed in the branch under consideration.

Integrating conflict driven learning and backjumping into circuit level DPLL is quite straightforward if we interpret the non-branching rules above as implications. For instance, the leftmost “up” rule in Figure 27.2 for an odd-gate $g := \text{odd}(g_1, g_2, g_3)$ can be read as “if g_1 is false, g_2 is true, and g_3 is false, then g

is true”, or thought as a clause $(\neg g_1 \wedge g_2 \wedge \neg g_3 \rightarrow g) \equiv (g_1 \vee \neg g_2 \vee g_3 \vee g)$. Because of this interpretation, one can track the use of the non-branching rules during the DPLL search to build an implication graph and derive a conflict clause from it in a way similar to that in Chapter 3 of this handbook. The conflict clause $(g'_1 \vee \dots \vee g'_l \vee \neg g''_{l+1} \vee \dots \vee \neg g''_m)$ can then be added (either explicitly or implicitly, see Section 27.3.5) to the circuit as the or-gate $g' := \text{or}(g'_1, \dots, g'_l, g''_{l+1}, \dots, g''_m)$ that is constrained to **T** and where $g''_j := \text{not}(g'_j)$ for $l + 1 \leq j \leq m$. The addition of such constrained gates derived by the conflict analysis is sound in the sense that all satisfying truth assignments of the constrained circuit are preserved.

27.3.4. Boolean Constraint Propagation: Rules versus Clauses

We now briefly compare circuit and CNF level Boolean constraint propagation. Let us first consider the non-branching rules for an or-gate $g := \text{or}(g_1, \dots, g_k)$ in Figures 27.2 and 27.3 with the clauses

$$(\hat{g} \vee \neg \hat{g}_1), \dots, (\hat{g} \vee \neg \hat{g}_k), (\neg \hat{g} \vee \hat{g}_1 \vee \dots \vee \hat{g}_k)$$

in the corresponding Tseitin CNF translation where the variable \hat{g} corresponds to the gate g , \hat{g}_1 to g_1 and so on (c.f. Chapter 2 in this handbook). Note that the clauses are nothing but the rules interpreted as clauses as in Section 27.3.3. It is obvious that the rules and the clauses have a very close correspondence when considering Boolean constraint propagation: a rule is applicable if and only if the “corresponding” clause induces unit propagation in corresponding partial truth assignments. A similar close correspondence applies to not and and-gates, too, although it should be mentioned that not-gates are not usually translated to CNF gates but “inlined” to the signs of the literals in the CNF formula. The not-gates are also handled implicitly in some circuit based propagation techniques by extending the edges in the circuit with sign information (e.g. in the And-Inverter Graph based approach of [KPKG02]).

The situation is somewhat different for odd-gates with n children as the straightforward CNF translation obtained by simply interpreting the rules as implications has 2^n clauses; for instance, the CNF translation of $g := \text{odd}(g_1, g_2, g_3)$ would be

$$\begin{aligned} &(\hat{g}_1 \vee \hat{g}_2 \vee \hat{g}_3 \vee \neg \hat{g}) \wedge (\hat{g}_1 \vee \hat{g}_2 \vee \neg \hat{g}_3 \vee \hat{g}) \wedge \\ &(\hat{g}_1 \vee \neg \hat{g}_2 \vee \hat{g}_3 \vee \hat{g}) \wedge (\hat{g}_1 \vee \neg \hat{g}_2 \vee \neg \hat{g}_3 \vee \neg \hat{g}) \wedge \\ &(\neg \hat{g}_1 \vee \hat{g}_2 \vee \hat{g}_3 \vee \hat{g}) \wedge (\neg \hat{g}_1 \vee \hat{g}_2 \vee \neg \hat{g}_3 \vee \neg \hat{g}) \wedge \\ &(\neg \hat{g}_1 \vee \neg \hat{g}_2 \vee \hat{g}_3 \vee \neg \hat{g}) \wedge (\neg \hat{g}_1 \vee \neg \hat{g}_2 \vee \neg \hat{g}_3 \vee \hat{g}). \end{aligned}$$

However, it is well-known that by (virtually) rewriting an n -ary odd-gate as $n - 1$ binary odd-gates and then translating each of them to CNF with 4 ternary clauses, one can obtain a CNF translation that has $4(n - 1)$ clauses and $n - 1$ auxiliary variables. This translation has the desirable property that if a non-branching rule on a gate $g := \text{odd}(g_1, \dots, g_n)$ is applicable in a partial truth assignment, then unit propagation will produce the same propagation in the corresponding truth assignment in the translated formula.

Similar translations and analyzes can be obtained for equiv and ite-gates, too. In addition to the gate types considered so far, cardinality gates, i.e. gates of the form $g := \text{card}_l^u(g_1, \dots, g_k)$ that evaluate to true iff at least l but at most u of the

children are true, and their sub-classes such as the “at most one child is true”-gate, are of special interest in some applications. Translating such gates to CNF is bit more complicated, see e.g. [BB03, BB04, Sin05, MSL07] and Chapter 28 in this handbook for some approaches.

As a summary, for the gate types considered above it is possible to obtain CNF translations that enable CNF-level unit propagation to simulate circuit-level Boolean constraint propagation. However, if Boolean constraint propagation is implemented directly on the circuit-level (this is discussed in the next subsection), one can take the available gate type information into account when designing data structures and algorithms for BCP. In [JBH12] it is shown that, under the common CNF translation schemes, the CNF preprocessing techniques such as variable elimination and blocked clause elimination can to a large extent simulate circuit level transformations such as cone of influence reduction. On the other hand, circuit level techniques such as observability don't cares discussed in Section 27.3.6 can be applied relatively efficiently during the search as well.

27.3.5. Implementation Techniques for Boolean Constraint Propagation

As Boolean Constraint Propagation (BCP), i.e. applying the non-branching rules in Figures 27.2 and 27.3, lies in the inner loop of a DPLL-based satisfiability checker for circuits, implementing it efficiently is of great importance. Naturally, if one transforms the circuit in question into an equi-satisfiable CNF formula by using the standard Tseitin-translation (cf. Section 27.3.4 and Chapter 2 in this handbook), one can apply all the BCP techniques developed for CNF-based SAT-solvers (see Chapter 4 in this handbook). In the rest of this section we review circuit-based BCP implementation techniques that are not based on direct CNF translation.

27.3.5.1. The Straightforward Way

The most straightforward way to implement BCP is described below. First, a queue (or stack, or unordered set) of assigned but not yet propagated gates is maintained and the following is repeated until the queue becomes empty. First, get and remove a gate from the queue. Then check whether the value of the gate implies a value to an unassigned child by a “direct down” rule (e.g. a true **and**-gate implies that all its children are true); if it does, assign the child to the value and add it in the queue. Next check whether the value of the gate and the values of the already assigned child gates imply a value to an unassigned child by an “indirect down” rule (e.g. a false **and**-gate with all but one child assigned to true imply that the unassigned child is false); if yes, assign and queue the child as described earlier. Finally, for each parent of the gate, check whether any “up” or “indirect down” rule involving the gate is applicable (e.g. if the gate is assigned to true and it has a false **and**-parent with all but one child assigned to true); if yes, apply the rule (e.g. the unassigned child is assigned to false) and queue the newly assigned gate. Naturally, a conflict may occur in any of these cases, e.g. when an **and**-gate is assigned to true but one of its children is already false.

In such a situation, the propagation is canceled and, if conflict driven learning or non-chronological backtracking is applied, the reason for the conflict is analyzed.

This simple propagation technique works in a local way in the circuit. It requires that the list of parents of a gate is maintained in addition to the type and the children of the gate. One drawback is that if the applicability of a non-branching rule depends on the values of the children of a gate, then the values of the children must be fetched each time the applicability is checked. However, backtracking is efficient as only the values of the assigned gates have to be cleared.

27.3.5.2. A Counter Based Approach

To reduce the number of times the values of the children of a gate have to be fetched during BCP, one can assign two counters to each gate with a symmetric Boolean function (i.e. all other gates except *ite*-gates considered in this chapter); similar techniques have been used in the context of CNF-based SAT and stable models logic programming [DG84, CA93, NS96]. The counters are maintained during the propagation process to tell how many of the children are assigned to false and true, respectively. Each time a gate with symmetric Boolean function is assigned to a value, it is easy to check the applicability of the “down” rules by just considering the values of the counters. For instance, if an n -ary *and*-gate is assigned to false, the number of true child gates is $n - 1$, and the number of false children is 0, then the last unassigned child is searched and assigned to false. However, if the number of true children is less than $n - 1$, then nothing is done. In addition, each time a gate is assigned to a value, the counters of the parent gates (with symmetric Boolean functions) are updated and the applicability of the “up” and “indirect down” rules of the parent gates are checked by using the values of counters. Note that backtracking in this counter-based scheme is more time consuming than in the straightforward way described above because the values of the counters have to be decremented in addition to just clearing the assigned values.

27.3.5.3. A Lookup Table Based Approach

Another kind of BCP technique is described in [KGP01, KPKG02]. It assumes the circuits to be composed of primary input, *not*-, and binary *and*-gates only (also called the *And-Inverter Graph* representation for Boolean circuits). As the fan-in of the gates is fixed to a very small constant, it is feasible to enumerate all the possible local propagation cases in a lookup table. Each time a gate is assigned a value, the lookup table for that gate as well as for each of its parents is consulted for finding out the possible propagations. In the case where no propagation is possible, i.e. when an *and*-gate is assigned to false and none of its two children is currently assigned, the gate is appended to the justification queue; the DPLL-like backtracking search process selects the next gate to be branched on by popping a gate from the justification queue and then branches on one of its children, trying to justify the value of the gate (cf. Section 27.3.7.2). In [KGP01, KPKG02] the learned conflict clauses (recall Section 27.3.3) are decomposed into *not*- and binary *and*-gates and added to the circuit structure. Thus, propagation induced by them is handled by the same lookup table mechanism.

27.3.5.4. Watched Literal Techniques

In [GZA⁺02] the lookup table based technique of [KGP01, KPKG02] for binary gates is combined with the “watched literal” technique applied in state-of-the-art CNF-based SAT solvers ([MMZ⁺01], also see Chapter 4 in this handbook). The idea is that the propagation in the original circuit structure is done with lookup tables while the propagation induced by the learned conflict clauses is implemented with the watched literal technique. This is motivated by the fact that learned clauses can contain hundreds of literals and the watched literal technique is efficient especially for such long clauses. Forgetting of learned conflict clauses, a technique applied in clause learning DPLL-style SAT solvers to reduce memory consumption and propagation overhead, is also easier to implement in this scheme as the learned clauses are stored separately while the circuit structure stays unmodified.

In [TBW04] a variant of the CNF-based watched literal technique is introduced for unbounded fan-in and- and or-gates. First, direct propagation (e.g. a true and-gate implies that all its children are true, and a false gate implies that each of its and-parent is false) does not involve watches but is performed in the straightforward way. For an and-gate, two of its children are watched for true value, the invariant to be maintained being that “neither of the watched children should be assigned to true unless there is no other choice or the other watched child is assigned to false”. Each time a watched child becomes assigned to true, it is checked whether the invariant holds (the other watched child is false) or can be made to hold by watching some other child. If this is not possible, then either all or all but one of the children are true. In the first case, the and-gate is propagated to true. In the second case, it is checked whether the and-gate is false; if it is, then the “indirect down” propagation rule is activated and the yet unassigned child is assigned to false; otherwise it is waited until the and-gate obtains a value. When an and-gate is assigned to false, it is checked whether either of the watched children is true; if yes, then all but one of the children are true and thus the remaining unassigned child is propagated to false.

In [WLLH07], the watched literal technique is generalized from CNF-level to Boolean circuits with arbitrary gate types. Instead of watching only the children of a gate like in [TBW04], the gate itself can also be watched. For and- and or-gates the generalized watched literal scheme follows easily from their Tseitin CNF translations. For instance, the CNF translation of an n -ary and-gate $g := \text{and}(g_1, \dots, g_n)$ is composed of n binary clauses of form $(\neg g \vee g_i)$ and one longer clause $(g \vee \neg g_1 \vee \dots \vee \neg g_n)$. The propagation corresponding to the binary clauses (i.e. the non-branching rules with only one antecedent) is handled simply by attaching each gate with two lists of (gate,value) pairs: those that are directly implied when the gate becomes false or true, respectively (for instance, the pair (g_1, \mathbf{T}) would be in the “true list” of g when $g := \text{and}(g_1, \dots, g_n)$). The propagation corresponding to the clause $(g \vee \neg g_1 \vee \dots \vee \neg g_n)$ is performed by watching two of the (gate,value) pairs in $\{(g, \mathbf{F}), (g_1, \mathbf{T}), \dots, (g_n, \mathbf{T})\}$. The invariant to be maintained is that “neither of the watched pairs should be assigned to true (a pair (g, v) is assigned to true [false] if g is assigned to v [$\neg v$, respectively]) or one of the watched pairs is assigned to false”. Whenever a watched (gate,value) pair becomes assigned to true, it is checked whether the invariant can be made

Figure 27.5. A constrained circuit.

to hold by watching some other pair; if it cannot be, then the last remaining unassigned pair is propagated to false. For instance, if all g_1, \dots, g_{n-1} are true and g becomes assigned to false, the only way to make the invariant hold on the set $\{(g, \mathbf{F}), (g_1, \mathbf{T}), \dots, (g_n, \mathbf{T})\}$ is to assign the gate g_n to false. The watched literal technique for other gate types, such as **odd** and **ite**, applies “watching-known pointers”: both values of a gate are watched at the same time. As an example, for an **odd**-gate $g := \text{odd}(g_1, \dots, g_n)$, two of the gates in the set $\{g, g_1, \dots, g_n\}$ are watched. The invariant to be maintained is now “neither of the watched gates should be assigned to any value unless there is no other choice”. Each time a watched gate becomes assigned, one tries to maintain the invariant by watching some other gate; if this is not possible, then propagation is triggered; in our example, when all g, g_1, \dots, g_{n-1} are assigned, then g_n is propagated to the value determined by the equation $g := \text{odd}(g_1, \dots, g_n)$. The paper gives rules to determine how many of the gates should be watched for a given gate type; for instance, **odd**-gates need two watched gates, an **ite** gate $g := \text{ite}(g_i, g_t, g_e)$ requires three of the gates in $\{g, g_i, g_t, g_e\}$ to be watched, and n -ary **equiv**-gates must have n gates watched.

Like with the CNF-based watched literal techniques, backtracking is efficient when using circuit-level watched literal techniques as only the assigned values have to be reset but the watches do not have to be touched at all.

27.3.6. Exploiting Observability Don’t Cares

Observability don’t cares are one of the concepts easily visible in the circuit level but lost in a flat CNF representation. In a nutshell, an observability don’t care is a gate whose value cannot influence the constraints of the circuit under the current partial truth assignment. As an example, consider the constrained Boolean circuit in Figure 27.5. If the first branching in the search assigns the gate i to \mathbf{T} , then the value of the constrained primary output gate j becomes justified in the resulting partial truth assignment. This implies that the value of the gate h cannot influence the value of j (or any other constrained ancestor gate) anymore and thus cannot cause a conflict by upward constraint propagation. Or in other words, the constrained gate j cannot observe the value of the gate h , and

h is called an observability don't care. Observability don't cares can be exploited during the DPLL-search by restricting the branching on the gates that are not don't cares, i.e. that are still relevant for the search. For instance, in the example above one does not need to branch on the gates h and f in the sub-tree originating from the first branching. If at some point of the search all the non-don't care gates are assigned without having a conflict by Boolean constraint propagation, the partial truth assignment can be extended to a satisfying truth assignment by evaluating the don't care gates (if there is a don't care primary input gate, it can be assigned to an arbitrary value in the extension).

As noted in [SVDL04], don't cares can also “mask” earlier, possibly bad, decisions made during the search. For instance, consider again the constrained circuit in Figure 27.5. Assume that the search first branches on the gate g , assigning it to **T**. No truth value is propagated by this. Then assume that the next branching step assigns the gate h to **T**, propagating b and f to **T** and c to **F**. The value of the originally constrained gate j is now justified by the value of h , the value of h is justified by the values of b and f , and so on down to the primary input gates. Therefore, the partial assignment $\{b \mapsto \mathbf{T}, c \mapsto \mathbf{F}\}$ on primary inputs is enough to make the gate j to evaluate to **T**; we can pick an arbitrary value for the unassigned primary input gate a and evaluate all the other gates to obtain a satisfying truth assignment for the constrained circuit. But note that, independent of the value we choose for a , the gate g will evaluate to **F**, not to **T** as assigned in the first branching step of the search. This can happen because, after the second branching step and subsequent propagation, the value of the gate g is in fact unobservable with respect to the original constraints of the circuit. If such unobservability can be detected during the search, the satisfiability of the circuit can sometimes be decided and the search terminated even though the current assignment contains gates that are assigned but not justified. In the running example, for instance, the search can be terminated after the second branching step as g is unobservable. However, if the unobservability of g is *not* detected, the search has to eventually backtrack to the second level, flip the value of the gate h and then find a satisfying assignment in which the gates b and c have the same value so that g can evaluate to **T**.

If branching during the search is restricted to happen in a top-down manner so that branching steps are only made on the gates that are children of currently assigned but unjustified gates, then observability don't cares work similarly to the so-called justification frontier heuristics (see Section 27.3.7.2). However, as the second paragraph above exemplifies, observability don't cares can also be applied when the use of the branching rule is not restricted.

In addition to satisfiability checking, observability don't cares have also been exploited in circuit-based quantified Boolean formula evaluation [GIB09].

Implementation Techniques

In [GGZA01] a CNF-based SAT solver is applied but some information is brought from the circuit level to the CNF level when the circuit-to-CNF translation is applied. Namely, each CNF variable (corresponding to a gate in the circuit) is attached with the list of clauses that describe the functionality of the gate in the CNF formula. After each branching and Boolean constraint propagation, starting

from the variables corresponding to the primary output gates, a sweep over the CNF formula variables is made and the non-don't care variables (gates) as well as the clauses that define their functionality are marked by using the attached clause information on the yet unsatisfied clauses. This marking information is then used to dynamically remove the functionality defining clauses of the don't care variables from the CNF formula.

In [SVDL04] a similar technique is applied but directly at the circuit level. Each gate is marked either as non-don't care (free in the paper) or don't care (lazy in the paper). After each branching and Boolean constraint propagation, the don't care information is recomputed by using the circuit structure and the current truth assignment. The don't care information is exploited by excluding the don't care gates from the set of gates that the SAT solver can branch on. The way the don't care information is computed makes it possible to exploit the “masking of earlier decisions” phenomenon described above.

Computation of don't care information is improved in [TBW04] by using a “don't care watch parent” technique, resembling the watched literal technique applied in Boolean constraint propagation (see Chapter 4 in this handbook and Section 27.3.5.4). The idea is that each gate (excluding primary outputs) is associated with a “don't care watch parent” that is one of its parents. When a gate becomes justified or don't care while being a “don't care watch parent” of one of its children, then one tries to find another parent of the child that is not yet justified or don't care and mark that as the new “don't care watch parent” of the child; if no such parent is found, the child becomes a don't care and the same process is applied recursively. This technique helps especially when a gate has a large number of parents ([TBW04] reports that some circuits they experimented with have 23 parents per gate on average) as it is not necessary to always check whether a gate becomes a don't care when one its parents becomes justified or don't care.

27.3.7. Structure-Based Search Heuristics

Compared to the flat CNF encoding of a problem, the structure preserving Boolean circuit representation offers some natural heuristics for guiding DPLL-based search procedures.

27.3.7.1. Branching on Primary Input Gates Only

In a Boolean circuit encoding of a structural problem typically only a very small portion of the gates are primary input gates. As the values of the primary input gates determine the values of all the other gates, it is sufficient to branch (i.e. to use the explicit cut rule) only on them in DPLL-based backtracking search. Intuitively this helps in reducing the worst case size of the search space from the order of $2^{|\mathcal{G}|}$ to $2^{|\text{inputs}(\mathcal{C})|}$, where $|\text{inputs}(\mathcal{C})| \leq |\mathcal{G}|$ for a circuit \mathcal{C} with a set of gates \mathcal{G} . This has been observed and experimentally evaluated in many papers in the area of SAT e.g. [GMS98, Str00, GMT02, JN08] and automated test pattern generation [Goe81]. According to the experimental evaluations, the effect of primary input restricted branching seems to be highly dependent on the problem class: both positive and negative results have been obtained (see e.g. [GMT02, JN08]).

However, if the best-case complexity is considered, then it can be proven that branching only on primary input gates can actually be very harmful for the solver efficiency. That is, there are families of Boolean circuits such that (i) for primary input restricted branching the smallest possible search space for a DPLL-based algorithm is of super-polynomial size with respect to the size of the circuit, while (ii) there are polynomially sized search spaces when branching is allowed on all gates [JJN05, JJ07].

27.3.7.2. Top-Down Search with Justification Frontiers

An opposite approach to guiding the DPLL-based search is to start from the constrained gates of the circuit and branch downwards in the circuit structure, see e.g. [KPKG02, LWCH03]. That is, branching is performed only on the children of currently assigned but not yet justified gates, trying to justify the value of the gate in question. For instance, if there is an **and**-gate that is assigned to false but has none of its children assigned to false, then the children are potential gates to be branched on (preferably with the value false as it makes the value of the **and**-gate justified). If there are no gates that are assigned but not justified, then the current, potentially partial truth assignment can be extended to a satisfying total truth assignment and the search can be terminated.

A slight variant of the DPLL-style top-down branching scheme is presented e.g. in [KGP01], where the branching is not performed on a gate and its values but on a set of gates. For instance, if there is a binary **and**-gate that is assigned to false but is not yet justified, then two branches are considered: the one in which the “left” child is false, and the other in which the “right” child is false.

In [JJN05, JJ08] it is shown that, for the DPLL-based search procedure (both with and without conflict driven learning), this kind of top-down use of branching can negatively effect the sizes of the minimal search spaces; there are families of circuits for which the minimal search spaces are super-polynomially larger than in the case of allowing unrestricted branching on all gates.

27.3.7.3. Exploiting Signal Correlation

Another interesting way to exploit circuit structure for guiding DPLL-based search is presented in [LWCH03, LWC⁺04]. Two gates, g and g' , are said to be positively (negatively, respectively) correlated if it holds with high probability that their values are the same (the opposite, respectively) in randomly generated consistent truth assignments for the circuit. In fact, g' can also be the constant **F** meaning if a gate g is positively (negatively, respectively) correlated with **F**, then it's value is **F** (**T**, respectively) with high probability. The correlations are approximated by performing a fixed amount of simulations on the circuit: the primary input gates are assigned to random values, the rest of the gates are evaluated, and the correlation relationship is refined according to the simulated values.

The correlations are exploited in two ways. First, whenever a gate g is assigned to a value in the search, the gates that are correlated with it are favored in the branching heuristics and are more likely to be assigned with the value that is against the correlation. The reasoning behind this is that if two gates are correlated, then assigning them values against the correlation is likely to cause the

search to encounter conflicts quickly and thus learn valuable information on the search space by using conflict driven learning.

The second way to exploit correlations is to use them together with the topological structure of the circuit to form smaller sub-problems that are solved in a bottom-up fashion by the DPLL-search. For instance, if a gate g is negatively correlated with the constant \mathbf{F} , then the subproblem consisting of the gate and its descendant gates only is tried to be solved with the constraint that g is assigned to \mathbf{T} . This is likely to cause valuable conflict clauses to be found. After this subproblem, the search will move on to subproblems that are topologically higher and reuse the conflict clauses found while solving the subproblem.

27.3.8. Non-clausal stochastic local search methods

The more structural representation offered by non-CNF formulas and circuits has also been used in many satisfiability algorithms based on stochastic local search (see Chapter 6 in this handbook for clausal stochastic local search methods such as GSAT and Walksat). In many formula-level approaches [Seb94, PTS07, Sta02, SB08], the flips are only applied to the variables appearing in the formula (corresponding to input gates in circuits) while the variable selection is guided by the structure of the formula.

A different approach is taken in [JJN08a, JJN08b], where the circuit-level Walksat-style local search is driven mainly top-down so that the flips are performed on the justification frontier gates and their children. This allows the search to exploit the observability don't cares. To make the search probabilistically approximately complete, i.e., to ensure that a satisfying assignment (if one exists) is eventually found with probability 1 without using restarts, "upward" flips on the justification frontier gates as well as choosing non-greedy justifications for justified gates are also done with some non-zero probability. The justification-frontier approach is modified in [BS10, BJS11] so that the flips can be performed on all unjustified gates, whether in the frontier or below it. In addition, a bounded amount of constraint propagation is performed after each flip.

27.4. Automatic Test Pattern Generation

After producing a chip the functional correctness of the integrated circuit has to be checked. Otherwise products with malfunctions would be delivered to customers which is not acceptable for any company. During this post-production test input stimuli are applied and the correctness of the output response is controlled. These input stimuli are called test patterns. Many algorithms for *Automatic Test Pattern Generation* (ATPG) have been proposed in the last 30 years. But due to the ever increasing design complexity new techniques have to be developed that can cope with today's circuits.

While classical approaches are based on backtracking on the circuit structure, since the early 80s several approaches based on *Boolean Satisfiability* (SAT) have been proposed (see e.g. [SBSV96, MSS97, TGH97, TG99]). In [SBSV96] comparisons to more than 40 other "classical" approaches based on FAN, PODEM and

Figure 27.6. Basic gates

the D-algorithm are provided showing the robustness and effectiveness of SAT-based techniques. In contrast to the early work in the 80s, where ATPG was often reduced to PROLOG or logic programming, the ATPG techniques developed by Larrabee [Lar92] and Stephan et al. [SBSV96] used many simplification and learning approaches, like global implications [TGH97]. By this, these algorithms combined the power of SAT with algorithms from the testing domain.

Recently, there is a renewed interest in SAT, and many improvements for proof engines have been proposed. SAT solvers make use of learning and implication procedures (see e.g. [MSS99, MMZ⁺01] and Chapters 3, 4 and 5 of this handbook).

In this section we give an introduction to ATPG. The basic concept and classical ATPG algorithms are briefly reviewed. Then, the formulation as a SAT problem is considered. The transformation of ATPG onto SAT is discussed. Advanced techniques for SAT-based ATPG are explained for the ATPG tool *PASSAT* (PAttern Search using SAT). In contrast to previous SAT approaches, which only considered Boolean values, we study the problem for a multi-valued logic encoding, i.e. *PASSAT* can also consider unknown values and tri-states. The influence of different branching heuristics is studied to tune the SAT solver towards test generation, i.e. variable selection strategies known from SAT and strategies applied in classical ATPG [Goe81, FS83]. Some experimental results are shown to give an impression on the efficiency of the approach.

27.4.1. Preliminaries

This section provides the necessary notions to introduce the ATPG problem. First, fault models are presented. Then, the reduction of a sequential ATPG problem to a combinational problem is explained. Finally, classical ATPG algorithms working on the circuit structure are briefly reviewed. The presentation is kept brief, for further reading we refer to [JG03].

27.4.1.1. Stuck-At Fault Model

The definition of a circuit has been formally introduced at the beginning of this chapter. To simplify the readability, in the following we assume that the circuits consist of gates of type *and*, *or*, *xor* and *not* only (see Figure 27.6). Extending this library to other Boolean gates if necessary is straightforward. Notice again that for gates that represent non-symmetric functions (e.g. multiplexors or tri-state elements) a unique order for the inputs is given by ordering the predecessors of a gate.

After producing a chip the functional correctness of this chip with respect to the Boolean gate-level specification has to be checked. Without this check an

Figure 27.7. Example for the SAFM

erroneous chip would be delivered to customers that may result in a malfunction of the final product. This, of course, is not acceptable. On the other hand a large range of malfunctions is possible due to defects in the material, process variations during production etc. But directly checking for all possible physical defects is not feasible. Therefore an abstraction in terms of a *fault model* is introduced.

The *Stuck-At Fault Model* (SAFM) [BF76] is well-known and widely used in practice. In this fault model a single line is assumed to be stuck at a fixed value instead of depending on the input values. When a line is stuck at the value 0, this is called a *stuck-at-0* (SA0) fault. Analogously, if the line is stuck at the value 1, this is a *stuck-at-1* (SA1) fault.

Example 27.4.1. Consider the circuit shown in Figure 27.7(a). When a SA0 fault is introduced on line *d* the faulty circuit in Figure 27.7(b) is resulting. The output of the and-gate is disconnected and the input of the or-gate constantly assumes the value 0.

Besides the SAFM a number of other fault models have been proposed, e.g. the cellular fault model [Fri73], where the function of a single gate is changed, or the bridging fault model [KP80], where two lines are assumed to settle to a single value. These fault models mainly cover static physical defects like opens or shorts. Dynamic effects are covered by delay fault models. In the path delay fault model [Smi85] a single fault means that a value change along a path from the inputs to the outputs in the circuit does not arrive within the clock-cycle time. Instead of paths the gate delay fault model [HRVD77, SB77] considers the delay at gates.

In the following only the SAFM is considered further due to the high relevance in practical applications. This relevance can be attributed to two observations: the number of faults is in the order of the size of the circuit and fault modeling in the SAFM is relatively easy, i.e. for the static fault model the computational complexity of test pattern generation is lower compared to dynamic fault models.

27.4.1.2. Combinational ATPG

Automatic Test Pattern Generation (ATPG) is the task of calculating a set of test patterns for a given circuit with respect to a fault model. A test pattern for a particular fault is an assignment to the primary inputs of the circuit that leads to different output values depending on the presence of the fault. Calculating the Boolean difference of the faulty and fault free circuit yields all test patterns for a

Figure 27.8. Boolean difference of faulty circuit and fault free circuit

particular fault. This construction is similar to a Miter circuit [Bra83] as it can be used for combinational equivalence checking.

Example 27.4.2. Again, consider the SA0 fault in the circuit in Figure 27.7. The input assignment $a = 1, b = 1, c = 1$ leads to the output value $f = 1$ for the correct circuit and to the output value $f = 0$ if the fault is present. Therefore this input assignment is a test pattern for the fault d SA0. The construction to calculate the Boolean difference of the fault free circuit and faulty circuit is shown in Figure 27.8.

When a test pattern exists for a particular fault, this fault is classified as being *testable*. When no test pattern exists, the fault is called *redundant*. The decision problem to classify a fault as redundant or testable is **NP**-complete. The aim is to classify all faults and to create a set of test patterns that contains at least one test pattern for each testable fault.

Generating test patterns for circuits that contain state elements like flip-flops is computationally more difficult, because the state elements can not directly be set to a particular value. Instead the behavior of the circuit over time has to be considered during ATPG. A number of tools have been proposed that directly address this sequential problem, e.g. HITEC [NP91]. But in practice, the resulting model often is too complex to be handled by ATPG tools. Therefore the *full scan mode* is often considered to overcome this problem by connecting all state elements in a scan chain [WA73, EW77]. In the test mode the scan chain combines all state elements into a shift register, in normal operation mode the state elements are driven by the ordinary logic in the circuit. As a result the state elements can be considered as primary inputs and outputs for testing purposes and a combinational problem results.

27.4.1.3. Classical ATPG Algorithms

Classical algorithms for ATPG usually work directly on the circuit structure to solve the ATPG problem for a particular fault. Some of these algorithms are

Figure 27.9. Justification and propagation

briefly reviewed in the following. For an in-depth discussion we refer the reader to text books on ATPG, e.g. [JG03].

One of the first complete algorithms dedicated to ATPG was the *D-algorithm* proposed by Roth [Rot66]. The basic ideas of the algorithm can be summarized as follows:

- An error is observed due to differing values at a line in the circuit with or without failure. Such a divergence is denoted by values D or \bar{D} to mark differences 1/0 or 0/1, respectively.
- Instead of Boolean values, the set $\{0, 1, D, \bar{D}\}$ is used to evaluate gates and carry out logical implications by propagating the values.
- A gate that is not on a path between the error and any output never has a D -value.
- A necessary condition for testability is the existence of a path from the error to an output, where all intermediate gates either have a D -value or are not assigned yet. Such a path is called a potential D-chain.
- A gate is on a D-chain, if it is on a path from the error location to an output and all intermediate gates have a D -value.

On this basis an ATPG algorithm can focus on justifying a D -value at the fault site and propagating this D -value to an output as shown in Figure 27.9. The algorithm starts with injecting the D -value at the fault site. Then, this value has to be propagated towards the outputs. For example, to propagate the value D at one input across a 2-input and-gate the other input must have the non-controlling value 1. After reaching an output the search proceeds towards the inputs in the same manner to justify the D -value at the fault site. At some stages in the search decisions are possible. For example, to produce a 0 at the output of an and-gate either one or both inputs can have the value 0. Such a decision may be wrong and may lead to a conflict later on. For example, due to a reconvergence as shown in Figure 27.9 justification may not be possible due to conditions from propagation. In this case, a backtrack search has to be applied. In summary the D-algorithm is confronted with a search space of $O(2^s)$ for a circuit with s signals including inputs, outputs and internal signals.

A number of improvements have been proposed for this basic procedure. PODEM [Goe81] for instance branches only on the values for primary inputs.

This reduces the search space for test pattern generation to $O(2^n)$ for a circuit with n primary inputs. But as a disadvantage time is wasted, if all internal values are implied from a given input pattern that finally does not detect the fault. FAN [FS83] improves upon this problem by branching on stems of fan-out points as well, i.e. all internal points are considered where signals branch. This allows to calculate conditions for a test pattern due to the internal structure of the circuit as well. The branching order and value assignments are determined by heuristics. Moreover, the algorithm keeps track of a justification frontier moving towards the inputs and a propagation frontier moving towards the outputs. Therefore FAN can make the “most important decision” first – based on a heuristic – while the D-algorithm applied a more static order doing only propagation at first and justification afterwards. SOCRATES [STS87] includes the use of global static implications by considering the circuit structure. Based on particular structures in the circuit indirect implications are possible, i.e. implications that are not directly obvious due to assignments at a single gate, but implications that result from functional arguments across several gates. These indirect implications are directly applied during the search process to imply values earlier from partial assignments and, by this, prevent wrong decisions. HANNIBAL [Kun93] further improves this idea. While SOCRATES only uses a predefined set of indirect implications, HANNIBAL learns from the circuit structure in a preprocessing step. For this task recursive learning [KP94] is applied. In principle, recursive learning is complete itself, but too time consuming to be used as a stand alone procedure. Therefore learning is done in a preprocessing step. During this step the effect of value assignments is calculated and the resulting implications are learned. These implications are stored for the following run of the search procedure. In HANNIBAL the FAN algorithm was used to realize this search step.

These algorithms only address the problem of generating a test pattern for a single fault. In the professional application such basic ATPG procedures are complemented by a preprocessing step and a postprocessing step. In the preprocessing phase easy-to-detect faults are classified in order to save run time afterwards. Postprocessing concentrates on test pattern compaction, i.e. reducing the number of test patterns in the test set.

27.4.2. Boolean Satisfiability

Before introducing an ATPG engine based on *Boolean Satisfiability* the standard conversion of a given circuit into a set of clauses for a SAT solver is briefly reviewed to make the chapter self-contained. For a more detailed introduction see Chapter 2 in this handbook.

27.4.2.1. Circuit to CNF Conversion

A SAT solver can be applied as a powerful black-box engine to solve a problem. In this case transforming the problem instance into a SAT instance and the SAT solution into a solution for the original problem is crucial. In particular, for SAT-based ATPG one step is the transformation of the circuit into a CNF. For example, in [Lar92] the basic procedure has been presented.

Table 27.1. Transformation of an and-gate into CNF

(a) Truth-table			(b) Clauses	(c) Minimized
<i>a</i>	<i>b</i>	<i>c</i>	$c \leftrightarrow a \wedge b$	
0	0	0	1	
0	0	1	0	$a \vee b \vee \bar{c}$
0	1	0	1	
0	1	1	0	$a \vee \bar{b} \vee \bar{c}$
1	0	0	1	
1	0	1	0	$\bar{a} \vee b \vee \bar{c}$
1	1	0	0	$\bar{a} \vee \bar{b} \vee c$
1	1	1	1	

The transformation of a single and-gate into a set of clauses is shown in Table 27.1. The goal is to create a CNF that models an and-gate, i.e. a CNF that is only satisfied for assignments that may occur for an and-gate. For an and-gate with two inputs a and b , the output c must always be equal to $a \wedge b$. The truth-table for this CNF formula is shown in Table 27.1(a). From the truth-table a CNF formula is generated by extracting one clause for each assignment where the formula evaluates to 0. These clauses are shown in Table 27.1(b). This CNF representation is not minimal and can therefore be reduced by two-level logic minimization, e.g. using SIS [SSL⁺92]. The clauses in Table 27.1(c) are the final result.

Now, the generation of the CNF for a complete circuit is straightforward. For each gate, clauses are generated according to the type of the gate. The output variables and input variables of a gate and its successors are identical and therefore establish the overall circuit structure within the CNF. This approach gives the well-known Tseitin encoding of a circuit discussed in Chapter 2 in this handbook.

Example 27.4.3. Consider the circuit shown in Figure 27.7(a). This circuit is translated into the following CNF formula:

$$\begin{aligned}
 & \underbrace{(a \vee \bar{d}) \wedge (b \vee \bar{d}) \wedge (\bar{a} \vee \bar{b} \vee d)}_{d \leftrightarrow a \wedge b} \\
 & \wedge \underbrace{(c \vee e) \wedge (\bar{c} \vee \bar{e})}_{e \leftrightarrow \bar{c}} \\
 & \wedge \underbrace{(\bar{d} \vee f) \wedge (\bar{e} \vee f) \wedge (d \vee e \vee \bar{f})}_{f \leftrightarrow d \vee e}
 \end{aligned}$$

An advantage of this transformation is the linear size complexity. Given a circuit where n is the sum of the numbers of inputs, outputs and gates, the number of variables in the SAT instance is also n and the number of clauses is in $O(n)$.

A disadvantage is the loss of structural information. Only a set of clauses is presented to the SAT solver. Information about predecessors and successors of a gate is lost and is not used during the SAT search. But as will be shown later this information can be partially recovered by introducing additional constraints into the SAT instance.

Figure 27.10. Influenced circuit parts

27.4.3. SAT-based ATPG

In this section SAT-based ATPG is explained in detail. The basic problem transformation is presented at first. Then, an improvement of this basic transformation by exploiting structural information is shown. This is enhanced for the practical application to multi-valued modelling of circuits.

27.4.3.1. Basic Problem Transformation

In the following we describe a SAT-based ATPG tool that works on a SAT instance in CNF. It would also be possible to use a circuit SAT solver, but by experiments so far the CNF-based solvers turned out to be more efficient for this application.

The transformation is formulated for a single fault. Then, the process iterates over all faults to generate a complete test set. Alternatively, the SAT-based engine can be integrated within an ATPG tool that uses other engines as well.

First, the fault site is located in the circuit. Then, the parts of the circuit that are influenced by the fault site are calculated as shown in Figure 27.10. From the fault site towards the outputs all gates in the transitive fan-out, i.e. all gates that can structurally be reached from the faulty line, are influenced, this is also called the *fault shadow*. Then, the cone of influence of the outputs in the fault shadow is calculated. These gates have to be considered when creating the ATPG instance. Analogously to the construction of the Boolean difference shown in Figure 27.8 a fault free model and a faulty model of the circuit are joined into a single SAT instance to calculate the Boolean difference between both versions. All gates not contained in the transitive fan-out of the fault site have the same behavior in both versions. Therefore only the fault shadow is duplicated as shown in Figure 27.11. Then, the Boolean difference of corresponding outputs is calculated. At least one of these Boolean differences must assume the value 1 to obtain a test pattern for the fault. In Figure 27.11 this corresponds to constraining the output of the or-gate to the value 1. Now, the complete ATPG instance is formulated in terms of a circuit and can be transformed into a CNF. If the SAT solver returns a satisfying assignment this directly determines the values for the primary inputs to test the fault. If the SAT solver returns unsatisfiable, the considered fault is redundant.

Figure 27.11. Influenced circuit parts

27.4.3.2. Structural Information

As explained earlier most of the structural information is lost during the transformation of the original problem into CNF. But this can be recovered by additional constraints. This has been suggested for the SAT-based test pattern generator TEGUS [SBSV96]. Improvements on the justification and propagation have been proposed in [TGH97, TG99].

In particular, the observations from the D-algorithm as explained in Section 27.4.1.3 are made explicit in the CNF. Now, three variables are used for each gate g :

- g_f denotes the value in the faulty circuit.
- g_c denotes the value in the correct circuit.
- $g_d = 1$, iff g is on a D-chain.

This notation allows to introduce additional implications into the CNF:

- If g is on a D-chain, the values in the faulty and the correct circuit are different: $g_d \rightarrow (g_f \neq g_c)$.
- If g is on a D-chain, at least one successor of g must be on the D-chain as well: Let $h^i, 1 \leq i \leq q$ be the successors of g , then $g_d \rightarrow \bigvee_{i=1}^q h_d^i$.
- If a gate g is not on a D-chain, the values in the faulty and the correct circuit are identical: $\bar{g}_d \rightarrow (g_f = g_c)$.

Without these implications the fault shadow in the fault free version and the faulty version of the circuit are only connected via the variables on the cut to the shared portions of the circuit. In contrast the g_d variables establish direct links between these structures. Therefore implications are possible even when the cut variables are not assigned yet. Moreover, the information about successors of a gate and the notion of D-chains are directly encoded in the SAT instance.

27.4.3.3. Encoding

In this section the techniques to handle non-Boolean values are discussed. These techniques have been proposed for the tool PASSAT [SFD⁺05, DEF⁺08]. First,

the use of multi-valued logic during ATPG is motivated and the four-valued logic is introduced. Then, different possibilities to encode the multi-valued problem in a Boolean SAT instance are discussed.

27.4.3.3.1. Four-Valued Logic For practical purposes it is not sufficient to consider only the Boolean values 0 and 1 during test pattern generation as it has been done in earlier approaches (e.g. [SBSV96]). This has mainly two reasons.

Firstly, circuits usually have tri-state elements. Therefore, besides the basic gates already shown in Figure 27.6 also tri-state elements may occur in a circuit. These are used if a single signal is driven by multiple sources. These gates behave as follows:

- **busdriver**, Inputs: a, b , Output: c
Function: $c = \begin{cases} Z, & \text{if } a = 0 \\ b, & \text{if } a = 1 \end{cases}$
- **bus0**, Inputs: a_1, \dots, a_n , Output c
Function: $c = \begin{cases} 0, & \text{if } a_1 = Z, \dots, a_n = Z \text{ or } \exists i \in \{1, \dots, n\} a_i = 0 \\ 1, & \exists i \in \{1, \dots, n\} a_i = 1 \end{cases}$
Note, that the output value is not defined, if there are two inputs with the opposite values 0 and 1.
- **bus1** behaves as bus0, but assumes the value 1 if not being driven.
- **bus** behaves as bus0 and bus1, but assumes the value Z if not being driven.

From a modeling point of view the tri-state elements could be transformed into a Boolean structure with the same functionality, e.g. by inserting multiplexers. But during test pattern generation additional constraints apply to signals driven by tri-state elements. For example, no two drivers must drive the signal with opposite values or if all drivers are in the high impedance state the driven signal has an unknown value. The value Z is used to properly model these constraints and the transition function of tri-state elements.

Environment constraints that apply to a circuit are another problem. Usually the circuit is embedded in a larger environment. As a result some inputs of the circuit may not be controllable. Thus, the value of such a non-controllable input is assumed to be unknown during ATPG. The logic value U is used to model this situation. This has to be encoded explicitly in the SAT instance, because otherwise the SAT solver would also assign Boolean values to non-controllable inputs.

Therefore a four-valued logic over $\{0, 1, Z, U\}$ is considered in PASSAT.

27.4.3.3.2. Boolean Encoding The multi-valued ATPG problem has to be transformed into a Boolean problem to use a modern Boolean SAT solver on the four-valued logic. Therefore each signal of the circuit is encoded by two Boolean variables. One encoding out of the $4! = 24$ mappings of four values onto two Boolean values has to be chosen. The chosen encoding determines which clauses are needed to model particular gates. This, in turn, influences the size of the resulting SAT instance and the efficiency of the SAT search.

All possible encodings are summarized in Tables 27.2(a)-27.2(c). The two Boolean variables are denoted by x and \bar{x} , the letters a and b are placeholders for

Table 27.2. Boolean encodings

(a) Set 1

s	x	\bar{x}
0	a	b
1	a	\bar{b}
U	\bar{a}	b
Z	\bar{a}	\bar{b}

(b) Set 2

s	x	\bar{x}
0	a	b
1	a	\bar{b}
U	\bar{a}	\bar{b}
Z	\bar{a}	b

(c) Set 3

s	x	\bar{x}
0	a	b
1	\bar{a}	\bar{b}
U	\bar{a}	b
Z	a	\bar{b}

(d) Example: Set 1,
 $a = 0, b = 0, x = c_s$

s	c_s	c_s^*
0	0	0
1	0	1
U	1	0
Z	1	1

Boolean values. The following notations define the interpretation of the tables more formally:

- A signal s is encoded by the two Boolean variables c_s and c_s^* .
- $x \in \{c_s, c_s^*\}, \bar{x} \in \{c_s, c_s^*\} \setminus \{x\}$
- $a \in \{0, 1\}, \bar{a} \in \{0, 1\} \setminus \{a\}$
- $b \in \{0, 1\}, \bar{b} \in \{0, 1\} \setminus \{b\}$

Example 27.4.4. Consider Set 1 as defined in Table 27.2(a) and the following assignment: $a = 0, b = 0, x = c_s$. Then, the encoding in Table 27.2(d) results.

Thus, a particular encoding is determined by choosing values for a, b and x . Each table defines a set of eight encodings.

Note, that for encodings in Set 1 or Set 2 one Boolean variable is sufficient to decide, if the value of s is in the Boolean domain, i.e. in $\{0, 1\}$, or in the non-Boolean domain, i.e. in $\{U, Z\}$. In contrast encodings in Set 3 do not have this property. This observation will be important when the efficiency of a particular encoding for SAT solving is determined.

27.4.3.3.3. Transformation to SAT Instance The clauses to model a particular gate type can be determined if a particular encoding and the truth-table of the gate are given. This is done analogously to the procedure in Section 27.4.2.1. The set of clauses can be reduced by two-level logic-optimization. Again, the tool ESPRESSO contained in SIS [SSL⁺92] was used for this purpose. For the small number of clauses for the basic gate types ESPRESSO is capable of calculating a minimal representation. The following example illustrates this flow.

Example 27.4.5. Table 27.3(a) shows the truth-table of an and-gate $s = t \wedge u$ over $\{0, 1, Z, U\}$. The truth-table is mapped onto the Boolean domain using the encoding from Example 27.4.4. The encoded truth-table is shown in Table 27.3(b) (for compactness the notation “ $\neq 0$ ” is used to denote that at least one of two variables must be different from 0; “-” denotes “don’t care”). A CNF is extracted from this truth-table and optimized by ESPRESSO.

Statistics for each possible encoding are presented in Table 27.4. For each gate type the number of clauses needed to model the gate are given. Besides the well-known Boolean gates (and, or, ...) also the non-Boolean gates *busdriver*, *bus0* and *bus1* are considered. The last column *All* in the table gives the sum of the numbers of clauses for all gate types.

Table 27.3. and-gate over $\{0, 1, Z, U\}$

(a) 4-valued			(b) Encoded					
t	u	s	c_t	c_t^*	c_u	c_u^*	c_s	c_s^*
0	–	0	0	0	–	–	0	0
–	0	0	–	–	0	0	0	0
1	1	1	0	1	0	1	0	1
U	$\neq 0$	U	1	0	$\neq 0$	0	1	0
Z	$\neq 0$	U	1	1	$\neq 0$	0	1	0
$\neq 0$	U	U	$\neq 0$	0	1	0	1	0
$\neq 0$	Z	U	$\neq 0$	0	1	1	1	0

Table 27.4. Number of clauses for each encoding

Set	nand	nor	and	bus	bus0	bus1	busdriver	xor	not	or	All
1	8	9	9	10	11	10	9	5	5	8	100
2	9	8	8	10	10	11	9	5	5	9	100
3	11	11	11	8	9	9	11	5	6	11	108

Table 27.5. Number of gates for each type

circ.	IN	OUT	FANO.	not	and	nand	or	nor	bus	busdriver
p44k	2356	2232	6845	16869	12365	528	5484	1128	0	0
p88k	4712	4565	14560	20913	27643	2838	16941	5883	144	268
p177k	11273	11031	33605	48582	49911	5707	30933	5962	0	560

All encodings of a given set lead to clauses that are isomorphic to each other. By mapping the polarity of literals and the choice of variables the other encodings of the set are retrieved. Particularly, Boolean gates are modeled efficiently by encodings from Set 1 and Set 2. The sum of clauses needed for all gates is equal for both sets. The difference is that, for example, the encodings of one set are more efficient for **nand**-gates, while the encodings of the other set are more efficient for **nor**-gates. Both gate types occur with a similar frequency in the industrial benchmarks as shown in Table 27.5. The same observation is true for the other gates where the efficiency of the encodings differs. Therefore no significant trade-off for the encodings occurs on the benchmarks.

In contrast more clauses are needed to model Boolean gates if an encoding of Set 3 is used. At the same time this encoding is more efficient for non-Boolean gates. In most circuits the number of non-Boolean gates is usually much smaller than the number of Boolean gates. Therefore more compact SAT instances will result if an encoding from Set 1 or Set 2 is used. The behavior of the SAT solver does not necessarily depend on the size of the SAT instance, but if the same problem is encoded in a much smaller instance also better performance of the SAT solver can be expected. These hypotheses are strengthened by experimental results.

27.4.4. Variable Selection

A SAT solver traverses the search space by a backtracking scheme. While BCP and conflict analysis have greatly improved the speed of SAT solvers, the variable selection strategy is crucial for an efficient traversal of the search space. But no

Figure 27.12. Decision variables in dedicated variable selection strategies

general way to choose the best variable is known, as the decision about satisfiability of a given CNF formula is **NP**-complete [Coo71]. Therefore SAT solvers have sophisticated heuristics to select variables (see Chapters 4, 5, and 8 in the handbook). Usually the heuristic accumulates some statistics about the CNF formula during run time of the SAT solver to use this data as the basis for decisions. This leads to a trade-off between the quality of a decision and the overhead needed to update the statistics. Also, the quality of a given heuristic often depends on the problem domain. The default variable selection strategy applied by ZCHAFF is the quite robust VSIDS strategy (see Chapter 4 in the handbook).

Decisions based on variable selection also occur in classical test pattern generation. Here, usually structural methods are employed to determine a good choice for the next selection. Besides the default variable selection strategy from ZCHAFF the tool PASSAT provides two strategies similar to strategies known from classical ATPG: selecting primary inputs only or selecting fan-out points only, i.e. all internal points are considered where signals branch.

Making decisions on primary inputs only was the improvement of PODEM [Goe81] upon the D-algorithm. Any other internal value can be implied from the primary inputs. This yields a reduction of the search space and motivates to apply the same strategy for SAT-based test pattern generation as well. For SAT solving this is done by restricting the variable selection of the SAT solver to those variables corresponding to primary inputs or state bits of the circuit. Within these variables the VSIDS strategy is applied to benefit from the feedback of conflict analysis and current position in the search space. Figure 27.12 visualizes this strategy. Only the variables in the dashed oval are allowed for selection.

Restricting the variable selection to fan-out gates only has been proposed in FAN [FS83] for the first time. Again, the idea is to restrict the search space while getting a large number of implications from a single decision. Conflicts resulting from a decision are often due to a small region within the circuit. PASSAT applies the VSIDS strategy to select fan-out gates or primary inputs. In Figure 27.12 this corresponds to the areas in the dashed oval and in the circles within the circuit. Including primary inputs in this selection strategy is crucial for the SAT procedure because this ensures that all other variable assignments can be implied from decision variables. This is necessary because otherwise conflicts may remain undetected.

The experiments in Section 27.4.6 show that some heuristics are quite robust, i.e. can classify all faults, while others are fast for some faults but abort on other

faults. Therefore an iterative approach turned out to be most effective:

1. One strategy is run with a given time out.
2. If the first strategy does not yield a test pattern a second, more robust, strategy is applied.

Experimental results show that this approach ensures fast test pattern generation where possible, while a more sophisticated search is done for the remaining faults. For the experiments selecting only inputs was used as the first strategy, and selecting any variable as the second.

27.4.5. Experimental Results

In this section we report experimental results to validate the efficiency of particular techniques presented above by discussing the two SAT-based approaches TEGUS and PASSAT. The latter tool is based on the SAT solver ZCHAFF [MMZ⁺01]³. First, PASSAT is compared to previous FAN-based and SAT-based approaches for ATPG. Then, the influence of the encoding is studied. The variable selection strategies are evaluated in another experiment. Finally, results for industrial benchmarks are presented.

27.4.5.1. ISCAS Benchmarks

First we study the run time behavior of the two SAT-based approaches for some of the benchmarks from ISCAS89. (More detailed experimental studies and more information on the parameter settings can be found in original papers.) To demonstrate the quality of SAT-based approaches a comparison to an improved version of Atalanta, that is based on the FAN algorithm [FS83], is given⁴. Atalanta was used to also generate test patterns for each fault. The backtrack limit was set to 10. The results are shown in Table 27.6. The first column gives the name of the benchmark. Then the run time is given in CPU seconds for each approach. Run times for Atalanta with fault simulation and without fault simulation are given in columns *fs* and *no fs*, respectively. (For more details on fault simulation see [JG03].) On circuits “s35932” and “s38584.1” Atalanta gave no results, when fault simulation was disabled. For TEGUS and PASSAT the run time to generate the SAT instance and the time for SAT-solving are separately given in Columns *Eqn* and *SAT*, respectively.

Both SAT approaches are significantly faster than the classical FAN-based algorithm and solve all benchmarks in nearly no time. No fault simulation has been applied in the SAT approaches, therefore the run times should be compared to Atalanta without fault simulation. Especially for large circuits the SAT approaches show a run time improvement of several orders of magnitude. But even when fault simulation is enabled in Atalanta the SAT approaches are faster by up to more than two orders of magnitude (see e.g. “s35932” and “s38584.1”).

³More recent experimental results can be found in [DEF⁺08], where MiniSAT was used as the underlying solver.

⁴Atalanta is available as public domain software from <http://www.ee.vt.edu/~ha/cadtools/cadtools.html>.

s38584.1	24680	1079	857	7.37	27.3	25210	1834	0	40.9	15.1

Considering only the SAT approaches, TEGUS is faster for these simple cases. Here test patterns for all faults are generated. In this scenario the speed-up gained by PASSAT for difficult faults (see below) is overruled by the overhead for sophisticated variable selection and conflict analysis. Furthermore the simple two-valued encoding is used in these experiments. Thus, the 4-valued encoding used in PASSAT only generated overhead. This can clearly be seen when looking at the times needed for the generation of the instances. The situation changes, if more complex circuits or tri-states are considered (see below).

27.4.5.2. Encoding

Again, we study the benchmarks from ISCAS89 and consider single stuck-at faults. But this time we use the 4-valued encoding allowing tri-states and unknown values as discussed in Section 27.4.3.3. The results are shown in Table 27.7. Additionally, the numbers of testable, redundant and aborted faults are shown in columns *Ct*, *Red* and *Ab*, respectively⁵. As can be seen, TEGUS now has a large number of aborted faults. The increase in run time compared to the Boolean encoding in Table 27.6 is due to the increased size of the SAT instance as explained in Section 27.4.3.3 and due to more decisions that are necessary in this case.

⁵Notice that the numbers might vary slightly to numbers reported in the literature due to the underlying AND/INVERTER graph structure.

27.4.6. Variable Selection

Next, we study the influence of the different variable selection strategies introduced in Section 27.4.4. The 4-valued circuit model is considered. Table 27.8 shows the results for the default strategy known from ZCHAFF, using fan-out gates only, using inputs only, and the iterative strategy. For the iterative strategy a time out of 1 second while selecting only inputs was allowed per fault, then the default strategy was applied. In case of the default strategy no time out was used, for the remaining strategies 2 seconds were used to guarantee that a single fault does not block the test generation for remaining faults. The table shows that the default strategy is the most robust strategy among the non-iterative strategies. No abortions occur for this heuristic for the ISCAS benchmarks considered. The selection of fan-outs only yields improvements in some cases (e.g. “s35932”), but can not classify all faults in several cases. The reason here is that the reduction of the search space does not compensate for the weak influence of conflict analysis on further decisions. The search space is more drastically pruned, when only inputs are allowed for selection. This yields a large speed up of up to 6 times in case of “s35932”. On the other hand difficult faults are often aborted, because internal conflicts during SAT-solving are detected too late. Therefore the iterative strategy was applied to retrieve a fast solution where possible, while using the more sophisticated VSIDS strategy on all variables, where a fast solution was not possible. As a result the iterative strategy does not lead to any aborted faults. In most cases even a remarkable speed-up compared to the default strategy is gained. Only for a few cases a penalty occurs. But the improvement often is significant, e.g. less than 20% are needed in case of “s35932”. Especially for the larger benchmarks significant run time improvements were achieved.

27.4.6.1. Industrial Circuits

Finally, two industrial circuits from Philips Semiconductors are considered, i.e. large circuits that also contain buses. We gave a 20 second CPU time limit to the SAT solver. The results are given in Table 27.9. As can be seen for these circuits only very few faults remain unclassified, i.e. only 204 for circuit “p565k” that consists of more than 565k gates. For the same benchmark TEGUS gives up on more than 340,000 faults (!) demonstrating how hard the circuit is to test.

Table 27.9. PASSAT for industrial benchmarks

Circ.	Ct	Red	Ab	Eqn	SAT
p88k	127,084	2,354	14	12,186	9,584
p565k	1,203,690	26,426	204	5,291	8,155

27.5. Conclusions

In this chapter we have surveyed methods for solving non-clausal SAT problems and automatic test pattern generation (ATPG) techniques. For non-clausal SAT we have focused on Boolean circuit satisfiability checking, that is, on the variant of propositional satisfiability problem where the input formula is given as a Boolean circuit and on techniques which work directly with circuit representation. We have shown how the highly successful DPLL method for checking satisfiability of a formula in CNF (see Chapter 3 in this handbook) can be generalized to work directly with circuits and how to incorporate, for instance, efficient circuit level Boolean constraint propagation techniques, conflict driven learning, don't care values, and search heuristics exploiting circuit structure.

For ATPG we have reviewed basic concepts and classical algorithms and explained how to formulate ATPG as a SAT problem. We have also presented an efficient approach for SAT-based test pattern generation aiming at circuits that include tri-state elements. Due to recent advances in SAT solving the approach is more robust than previous ones.

Chapter 28

Pseudo-Boolean and Cardinality Constraints

Olivier Roussel and Vasco Manquinho

28.1. Introduction

In its broadest sense, a pseudo-Boolean function is a function that maps n Boolean values to a real number. The term pseudo-Boolean comes from the fact that, although these functions are not Boolean, they remain very close to Boolean functions. These pseudo-Boolean functions are studied since the mid 1960s ([HR68]) in the context of Operations Research and 0-1 programming. During the last fifty years, an impressive number of works have been published in this field and this chapter will not even attempt to summarize them (see for example [BH02] for a survey). Instead, this presentation will concentrate on the most recent developments originating from the last advances in the logic community. Specifically, the presentation will be restricted to pseudo-Boolean functions and constraints defined by polynomials with integer coefficients. Imposing that coefficients be integer numbers instead of real numbers is not a concern in practice because applications never require an unlimited precision. Besides, approximate computations on real numbers are not compatible with logical computations.

Pseudo-Boolean functions are a very rich subject of study since numerous problems in various fields (Operations Research, graph theory, combinatorial mathematics, computer science, VLSI design, economics, manufacturing, among others) can be expressed as the problem of optimizing the value of a pseudo-Boolean function. Pseudo-Boolean constraints offer a more expressive and natural way to express constraints than clauses and yet, this formalism remains close enough to the SAT problem to benefit from the recent advances in SAT solving. Simultaneously, pseudo-Boolean solvers benefit from the huge experience in Integer Linear Programming (ILP) and more specifically 0-1 programming. This is particularly true when optimization problems are considered. Powerful inference rules allow to solve some problems polynomially when encoded with pseudo-Boolean constraints while resolution of the problem encoded with clauses requires an exponential number of steps. In a few words, pseudo-Boolean constraints appear as a nice compromise between the expressive power of the formalism used to represent a problem and the difficulty to solve the problem in that formalism.

This chapter will first introduce the definitions of pseudo-Boolean and cardinality constraints and present the decision and optimization problems built on these constraints. The expressive power of the constraints as well as the usual inference rules are then detailed. The next section presents how the most recent SAT algorithms can be transposed to the pseudo-Boolean case and the specific problems posed by this formalism. Specific techniques to solve the optimization problem are also presented. At last, several methods of translating pseudo-Boolean problems to the SAT formalism are studied.

28.2. Basic Definitions

A pseudo-Boolean constraint (PB constraint) is defined over a finite set of Boolean variables x_j . Boolean variables can take only two values *false* and *true* which can be represented equivalently either by $\{\mathbb{F}, \mathbb{T}\}$ or by $\{0, 1\}$. A literal l_j is either a Boolean variable x_j or its negation \bar{x}_j . A positive literal (x_j) evaluates to \mathbb{T} if and only if the corresponding variable x_j is also true, a negative literal (\bar{x}_j) evaluates to \mathbb{T} if and only if the corresponding variable x_j is false.

In pseudo-Boolean constraints, literals are always assigned a constant integer coefficient even if a coefficient of 1 is often omitted in the representation of the constraint. The multiplication of an integer constant by a Boolean variable is defined in a natural way when Booleans are represented by 0 or 1 values. When Boolean are represented by \mathbb{F} or \mathbb{T} values, multiplication is defined equivalently by $\forall a \in \mathbb{Z}, a \cdot \mathbb{T} = a$ and $a \cdot \mathbb{F} = 0$.

28.2.1. Linear Pseudo-Boolean Constraints

A **linear pseudo-Boolean constraint** (LPB constraint) has the following form

$$\sum_j a_j l_j \triangleright b$$

where a_j and b are integer constants, l_j are literals and \triangleright is one of the classical relational operators ($=, >, \geq, <$ or \leq).

The right side of the constraint is often called the **degree** of the constraint.

The addition operator and the relational operators have their usual mathematical meaning. The constraint is satisfied when the left and right term of the constraint evaluate to integers which satisfy the relational operator.

Any constraint which can be rewritten in a straightforward way to match the pattern $\sum_j a_j l_j \triangleright b$ is also considered as a linear pseudo-Boolean constraint.

Example 28.2.1. A first example of a linear pseudo-Boolean constraint is $3x_1 + 4.\bar{x}_2 + 5x_3 \geq 7$. It is satisfied when $x_1 = 1, x_2 = 0$ or $x_1 = 1, x_3 = 1$ or $x_2 = 0, x_3 = 1$.

Here are some other examples:

$$\begin{aligned} x_1 + x_2 + \bar{x}_4 &< 3 \\ 5 + x_1 &= 6 - x_2 \\ 8x_4 + 4x_3 + 2x_2 + x_1 &\leq 8y_4 + 4y_3 + 2y_2 + y_1 \end{aligned}$$

28.2.2. Non-Linear Pseudo-Boolean Constraints

A **non-linear pseudo-Boolean constraint** has the following form

$$\sum_j a_j \cdot \left(\prod_k l_{j,k} \right) \triangleright b$$

where a_j and b are integer constants, $l_{j,k}$ are literals and \triangleright is one of the classical relational operators ($=, >, \geq, <$ or \leq). The semantics of a product of literals is defined in a natural way when Boolean are represented as $\{0, 1\}$ and corresponds equivalently to a logical AND when Booleans are represented as $\{\mathbb{F}, \mathbb{T}\}$. The constraint is satisfied when the left and right term of the constraint evaluate to integers which satisfy the relational operator. Section 28.2.6 gives some methods to translate a non-linear constraint into an equivalent set of linear constraints.

Example 28.2.2. The two pseudo-Boolean constraints below are non-linear:

$$\begin{aligned} 7x_1x_2 + 3x_1 + x_3 + 2x_4 &\geq 8 \\ 7\bar{x}_2 + 3x_1\bar{x}_3 + 2x_4x_2x_1 &\geq 8 \end{aligned}$$

The constraint $x_1 + \bar{x}_1x_2 \geq 1$ is satisfied either when $x_1 = 1$ or when $x_1 = 0$ and $x_2 = 1$. The constraint $x_1 + \bar{x}_1x_2 \geq 2$ is unsatisfiable.

28.2.3. Cardinality Constraints

A **cardinality constraint** is a constraint on the number of literals which are true among a given set of literals. Three cardinality constraints can be defined. The constraint $atleast(k, \{x_1, x_2, \dots, x_n\})$ is true if and only if at least k literals among x_1, x_2, \dots, x_n are true. The constraint $atmost(k, \{x_1, x_2, \dots, x_n\})$ is true if and only if at most k literals among x_1, x_2, \dots, x_n are true. The constraint $exactly(k, \{x_1, x_2, \dots, x_n\})$ is true if and only if exactly k literals among x_1, x_2, \dots, x_n are true. Some obvious relations between these constraints are $atmost(k, \{x_1, x_2, \dots, x_n\}) \equiv atleast(n - k, \{\bar{x}_1, \bar{x}_2, \dots, \bar{x}_n\})$ and $exactly(k, \{x_1, x_2, \dots, x_n\}) \equiv atleast(k, \{x_1, x_2, \dots, x_n\}) \wedge atmost(k, \{x_1, x_2, \dots, x_n\})$. Therefore, the constraint $atleast$ is sufficient to express any cardinality constraint.

The cardinality constraint $atleast(k, \{x_1, x_2, \dots, x_n\})$ translates to the pseudo-Boolean constraint $x_1 + x_2 + \dots + x_n \geq k$ (and the cardinality constraint $atmost(k, \{x_1, x_2, \dots, x_n\})$ translates to $x_1 + x_2 + \dots + x_n \leq k$). Conversely, a pseudo-Boolean constraint where all coefficients are equal such as $\sum_{j=1}^n ax_j \geq b$ is actually a cardinality constraint: $\sum_{j=1}^n ax_j \geq b \equiv atleast(\lceil b/a \rceil, \{x_1, x_2, \dots, x_n\})$ ($\lceil b/a \rceil$ is the smallest integer greater than or equal to b/a). Clearly, a cardinality constraint is a special kind of pseudo-Boolean constraint.

The cardinality constraint $atleast(k, \{x_1, x_2, \dots, x_n\})$ can be translated into an equivalent conjunction of clauses which unfortunately can be of exponential size when no auxiliary variable is introduced [BS94]. The idea of this translation is to express that no more than $n - k$ literals can be false, which means that as soon as $n - k + 1$ literals are selected, at least one of them must be true (this constraint is a clause). So, the constraint $atleast(k, \{x_1, x_2, \dots, x_n\})$ is equivalent to the conjunction of all possible clauses obtained by choosing $n - k + 1$ literals

among $\{x_1, x_2, \dots, x_n\}$. There are obviously $\binom{n}{n-k+1}$ such clauses. The worst case is obtained when $k = n/2 - 1$ and since $\binom{n}{n/2} \geq 2^{n/2}$, this encoding is of exponential size. This means that a cardinality encoding of a problem can be exponentially shorter than a clausal encoding.

Polynomial clausal encodings of cardinality constraints exist [War98, BB03, Sin05] but they all require the introduction of auxiliary variables (see Part 1, Chapter 2).

28.2.4. Clauses

A **clause** $x_1 \vee x_2 \vee \dots \vee x_n$ is by definition equivalent to the cardinality constraint *atleast*(1, $\{x_1, x_2, \dots, x_n\}$) which in turn is equivalent to the pseudo-Boolean constraint $x_1 + x_2 + \dots + x_n \geq 1$. Therefore, clauses are a subset of cardinality constraints which in turn are a subset of all possible pseudo-Boolean constraints. Pseudo-Boolean constraints generalize cardinality constraints which are already a generalization of clauses.

28.2.5. Normalization of Pseudo-Boolean Constraints

Although several relational operators can be used in the definition of a pseudo-Boolean constraint, all pseudo-Boolean constraints can be **normalized** into the following form:

$$\sum_{j=1}^n a_j l_j \geq b, \quad a_j, b \in \mathbb{N}_0^+ \quad (28.1)$$

where l_j denotes either a variable x_j or its complement \bar{x}_j and all coefficients a_j and right-hand side b are non-negative [Bar95a] (a pseudo-Boolean function with only positive coefficients is called *posiform* [BH02]). Moreover, equality constraints or other types of inequality constraints (such as *greater than*, *smaller than* or *smaller than or equal to*), can also be transformed in linear time into *greater than or equal to* constraints.

In order to normalize a pseudo-Boolean constraint, one can start by changing it into a *greater than or equal to* constraint. If the constraint operator is $>$, add 1 to the right-hand side and change it to an inequality with sign \geq . Instead, if the constraint operator is $<$, subtract 1 to the right-hand side and change it to an inequality with sign \leq . Note that these transformations are valid since all coefficients a_j are integers. For equality constraints, one can replace it with two constraints, with the same left and right-hand side, but one with sign \geq and the other with sign \leq . Finally, for constraints with sign \leq , multiply by -1 both the left and right-hand side coefficients and change the sign to \geq .

Next, change the constraint such that all literal coefficients a_j and right-hand-side b are non-negative. For all literals x_j and \bar{x}_j with negative coefficients, replace them with $1 - \bar{x}_j$ and $1 - x_j$, respectively. All literal coefficients are now non-negative and by algebraic manipulation, constant terms can be moved to the right-hand side. If a constraint with a non-positive right-hand side is obtained, that means that the constraint is trivially satisfied.

This procedure allows the mapping in linear time of all pseudo-Boolean constraints into a normalized formulation (28.1). Therefore, to simplify the following

Using only clauses	Using PB constraints
$v \vee \neg l_1 \vee \neg l_2 \vee \dots \vee \neg l_n$	$v \vee \neg l_1 \vee \neg l_2 \vee \dots \vee \neg l_n$
$l_1 \vee \neg v$	$\sum_{k=1}^n l_k - nv \geq 0$
$l_2 \vee \neg v$	
\vdots	
$l_n \vee \neg v$	

Figure 28.1. Two simple methods to linearize an instance by adding extra variables and enforce that $v \Leftrightarrow \prod_{k=1}^n l_k$

descriptions, we will always assume the formulation of pseudo-Boolean constraints in this normalized form.

28.2.6. Linearization Methods

Linearization is a method to convert a non-linear instance into an equivalent linear instance. This is easily done by introducing one extra variable v for each product $\prod_{k=1}^n l_k$. Constraints are added so that v is true if and only if $\prod_{k=1}^n l_k$ is true. A single clause $v \vee \neg l_1 \vee \neg l_2 \vee \dots \vee \neg l_n$ enforces that v be true when all l_k are true. To encode the converse, one can use either n clauses ($\bigwedge_k l_k \vee \neg v$) or use one single pseudo-Boolean constraint $\sum_{k=1}^n l_k - nv \geq 0$. Figure 28.1 summarizes the constraints that are added.

Many linearization methods have been proposed in the context of Operations Research. Fortet's method is probably the oldest one [For60] and is equivalent to the method previously described which introduces one extra variable per product and uses clauses to enforce that the new variable is equivalent to the product. The downside of this kind of method is that a new variable must be introduced for each different product found in the instance. Other methods have been proposed in different contexts to reduce the number of auxiliary variables or even avoid any introduction of auxiliary variables [BM84a, BM84b].

28.3. Decision Problem versus Optimization Problem

Given a formula f which is a conjunction of pseudo-Boolean constraints, one natural question is to identify if this formula is satisfiable or not, that is to say if there exists a valuation of variables such that all constraints are satisfied. This is a decision problem because the only answer which is expected is “yes, it is satisfiable” or “no, these constraints cannot be satisfied”. This **decision problem** is named Pseudo-Boolean Solving (**PBS**). The satisfiability of PB constraints is very close to the SAT problem which deals with the satisfiability of clauses. In such a decision problem, it is not expected in theory that the solver gives a solution when the formula is satisfiable. However, in practice, most solvers which prove satisfiability have identified internally a solution and it is appreciated that they communicate this solution to the user.

Another question which is often dealt with in the pseudo-Boolean context is the optimization problem. Given a formula f which is a conjunction of pseudo-Boolean constraints, decide if this formula has a solution and if it is satisfiable, identify one of the best possible solutions. This is an **optimization problem**: the Pseudo-Boolean Optimization (**PBO**) problem. The solver is expected to answer either “no, these constraints cannot be satisfied” or “yes, the formula is satisfiable and here is the best solution. No other solution can be strictly better”. The best possible solutions are called optimal solutions (or **optimums**) and a problem may have several optimal solutions. In practice, the user is also interested in sub-optimal solutions when a solver does not have enough time to find an optimal solution. When a solver exceeds the given resources, it is usually expected to provide the best solution it has been able to find within its allocated resources. Even if this answer is not the optimum, it is a bound on the optimal solution.

In the optimization problem, there are several ways to identify if a solution is better than another. A common way is to define a function o named objective function which maps each solution S to an integer $o(S)$. Depending on the actual meaning of this function, one may want to minimize its value (in this case, o is called a **cost function** and S is preferred to S' when $o(S) < o(S')$) or one may want to maximize its value (in this case o is called a **utility function**: S is preferred to S' when $o(S) > o(S')$). Since maximizing a function $o(S)$ is equivalent to minimizing $-o(S)$, it is always possible to consider any optimization problem defined by such a function o as a problem of minimizing a cost function.

Therefore, a general representation of the most common pseudo-Boolean optimization problem is:

$$\begin{aligned} & \text{minimize } Cost(x_1, x_2, \dots, x_n) \\ & \text{subject to } \bigwedge_i \sum_j a_{i,j} x_j \geq b_i \end{aligned} \tag{28.2}$$

The cost function is usually defined as a linear function of the pseudo-Boolean variables, that is to say $Cost(x_1, x_2, \dots, x_n) = \sum_j c_j x_j$ with $\forall j, c_j \in \mathbb{Z}$. It may also be defined as a non-linear function of the pseudo-Boolean variables, that is to say $Cost(x_1, x_2, \dots, x_n) = \sum_j c_j \cdot \prod_k x_{j,k}$ with $\forall j, c_j \in \mathbb{Z}$.

The wide use of the optimization problem defined by a linear cost function is undoubtedly linked to the pseudo-Boolean formalism having its roots in the ILP formalism.

Among the many other ways to define that a solution S is better than a solution S' , an interesting approach seems to use several cost functions instead of a single one [LGS⁺07]. Each cost function defines a ranking of solutions based on one criterion and when the criteria cannot be compared, these cost functions cannot be merged as a single cost function. In this context, pareto-optimal solutions are sought. A solution is pareto-optimal if no other solution is at least as good on $n-1$ cost functions and strictly better on the last cost function¹. With this definition, there are now several sets of pareto-optimal solutions which are incomparable.

¹ S is preferred to S' iff $\exists j (\forall i \neq j, Cost_i(S) \leq Cost_i(S') \wedge Cost_j(S) < Cost_j(S'))$

28.3.1. Quadratic Optimization

When the optimization problem is considered, a specific normalization method may be used. Indeed, the optimization of any non-linear instance (with products of any size) can be reduced to the **optimization of a quadratic instance** (with products of size at most 2) by introducing extra variables but no new constraint [BH02].

The idea is to recursively decompose a product of more than two variables by introducing a new variable z which will be forced to be equivalent to the product of two other variables xy . When z is substituted to xy , the size of the product is decreased by one and this can be iterated until the product becomes of size 2.

Instead of introducing new constraints to enforce $z \Leftrightarrow xy$, this approach adds a prevalent penalty to the cost function when $z \not\Leftarrow xy$. Therefore, interpretations where $z \Leftrightarrow xy$ will be preferred to interpretation which do not satisfy this constraint. The penalty function $P(x, y, z) = xy - 2xz - 2yz + 3z$ is such that $P(x, y, z) = 0$ when $z \Leftrightarrow xy$ and $P(x, y, z) > 0$ when $z \not\Leftarrow xy$. For each new variable z , the penalty $c.P(x, y, z)$ is added to the cost function with c being any constant integer greater than the maximum value of the initial cost function. See [HS89, BH02] for an introduction to the huge field of quadratic optimization.

28.4. Expressive Power of Cardinality and Pseudo-Boolean Constraints

28.4.1. Expressiveness

Pseudo-Boolean constraints are more expressive than clauses and a single pseudo-Boolean constraint may replace an exponential number of clauses. More precisely, the translation of a non-trivial pseudo-Boolean constraint to a set of clauses which is semantically equivalent (in the usual sense, i.e. without introducing extra variables) has an exponential complexity in the worst case. One simple example of an exponential case is the constraint $atleast(k, \{x_1, \dots, x_n\})$ which translates to $\binom{n}{n-k+1}$ clauses.

Another simple example of the conciseness of pseudo-Boolean constraints is the encoding of a binary adder. A binary adder is a circuit that sums two integer numbers A and B represented on n bits to obtain a new integer C of $n + 1$ bits. Let a_i, b_i, c_i be the bits of the binary decomposition of respectively A, B, C (such that $A = \sum_{i=0}^{n-1} 2^i a_i$, etc.). The binary adder can be easily encoded as one single pseudo-Boolean constraint: $\sum_{i=0}^{n-1} 2^i a_i + \sum_{i=0}^{n-1} 2^i b_i = \sum_{i=0}^n 2^i c_i$. In contrast, several techniques can be used to encode this problem as clauses but all of them require the introduction of carry variables to obtain an encoding of polynomial size. Several clauses are needed to encode the addition of two bits a_i, b_i and several others are needed to compute the carries. A polynomial encoding of this problem as clauses necessarily uses more variables and more constraints than the pseudo-Boolean encoding. Moreover, it explicitly encodes addition which is otherwise already hard-wired in a pseudo-Boolean solver.

The encoding of the factorization problem is yet another example of the expressive power of PB constraints. Given an integer N , identify two numbers

P and Q such that $N = P.Q$ and $P > 1, Q > 1$ to forbid trivial factorization. The constraint $N = P.Q$ can be encoded as one single non-linear PB constraint: $\sum_i \sum_j 2^{i+j} p_i q_j = N$. Encoding this problem as clauses requires the introduction of extra variables and several binary adders to obtain a polynomial encoding.

28.4.2. Size of Coefficients

As suggested by the factorization example, the coefficients used in a pseudo-Boolean constraint can be of arbitrary size, even in encodings of concrete problems. Since coefficients cannot be assumed to be of bounded size in the general case, the size of the input problem to be considered in complexity analysis must include the size of coefficients. The size of the input formula is $\sum_i (s + size(b_i) + \sum_j (size(a_{i,j}) + size(x_{i,j})))$ where $size(y)$ is the size of the encoding of y , $a_{i,j}$ is the coefficient of the j -th variable in the i -th constraint ($x_{i,j}$) and s is the size of a constraints separator. In contrast, the size of a clausal formula is only $\sum_i (s + \sum_j size(x_{i,j}))$.

A straightforward consequence of this observation is that a solver cannot be correct on any formula if it does not use arbitrary precision arithmetic, which of course has a cost. A solver which uses fixed precision arithmetic will be faced to integer overflows in some cases. These integer overflows may occur during the parsing of the formula. It is easy to check for this case and abort the solver. However, depending on the solver technology, integer overflow may also occur while it infers new constraints from existing constraints. This problem is harder to fix and directly impacts the solver correctness. The use of arbitrary precision arithmetic is the price to pay for correctness on any instance.

28.4.3. Complexity

The satisfiability of pseudo-Boolean constraints (decision problem) is an NP-complete problem. Indeed, checking if an interpretation satisfies a pseudo-Boolean problem can be done in polynomial time with respect to the size of the problem because that size includes the size of coefficients (that check is not polynomial with respect to the sole number of literals in the problem). Therefore, the satisfiability of pseudo-Boolean constraints is in NP. It is also an NP-complete problem since it contains the SAT problem which is NP-complete. The Pseudo-Boolean Optimization problem (PBO) is NP-hard.

Table 28.1 compares the worst case complexity of a few very basic problems with respect to the kind of constraint used (clauses and linear or non-linear pseudo-Boolean constraints using only the *greater than or equal to* operator). The difference of complexity illustrates both the expressive power of pseudo-Boolean constraints and the difficulty to obtain efficient methods to solve pseudo-Boolean problems.

Deciding if a single clause is satisfiable is a trivial problem. The only check to do is to verify that it is not empty (constant time). Checking if a *greater than or equal to* LPB constraint is satisfiable is slightly more complex since it requires to compute the bounds of the values of the left side which has a linear complexity.

Table 28.1. Comparison of the worst case complexity of a few problems with respect to the kind of constraint used

	Clauses	Linear PB constraints (\geq)	Non-linear PB constraints (\geq)
satisfiability of 1 constraint	$O(1)$	$O(n)$	NP-complete
satisfiability of 2 constraints	$O(n)$	NP-complete	NP-complete

Deciding the satisfiability of one single *greater than or equal to* non-linear constraint is much harder since it is a NP-complete problem. Indeed, any 3-SAT instance can be linearly transformed into a single *greater than or equal to* constraint with non-linear terms. Each clause $C = l_1 \vee l_2 \vee l_3$ can be transformed into a constraint $f(C) = 1$ where $f(C) = l_1 + l_2 + l_3 - l_1l_2 - l_1l_3 - l_2l_3 + l_1l_2l_3$. The constraint $f(C) = 1$ is true if and only if the clause is satisfied (otherwise, $f(C) = 0$). The whole 3-SAT formula $\bigwedge_i C_i$ is transformed into the equivalent non-linear pseudo-Boolean constraint $\sum_i f(C_i) \geq n$ where n is the number of clauses in the formula.

Deciding if two clauses are satisfiable amounts to finding a literal in each clause such that the chosen literals are not complementary. This can be done in linear time.

The satisfiability of two pseudo-Boolean constraints (linear or non-linear) is a NP-complete problem because the subset sum problem can be encoded as two *greater than or equal to* PB constraints. The subset sum problem consists in determining if a subset of a given set of integer can be summed to obtain a given constant integer. This problem is known to be NP-complete. Let $\{a_0, a_1, \dots, a_n\}$ and k be the input of the subset sum problem. This problem is trivially encoded by the linear pseudo-Boolean constraint $\sum_{i \in [0..n]} a_i x_i = k$ where x_i indicates whether a_i should be in the chosen subset or not. This equality constraint can be rewritten as two *greater than or equal to* linear constraints.

28.5. Inference Rules

This section presents a review on the main inference rules that can be used on pseudo-Boolean constraints. It is assumed that constraints have been normalized to use strictly positive coefficients (generalization to non-normalized constraints is straightforward).

We first review some fundamental rules which are either definitions or immediately derived from the axioms.

$$\frac{}{\bar{x} = 1 - x} \quad (\text{negation})$$

$$\frac{}{x.x = x} \quad (\text{idempotence})$$

$$\frac{}{x \geq 0} \quad (bounds)$$

$$\frac{}{-x \geq -1}$$

The negation rule allows the normalization of constraints so that they contain only positive coefficients. The idempotence rule implies that no exponent is needed in a product of literals. At last, the bounds rule is a direct implication from the axiom $x = 0 \vee x = 1$ and is used to obtain a few simplification rules presented below.

The following rules can be applied to both linear and non-linear constraints. Therefore, L_j will denote either a literal or a product of literals. By definition, L_j is either 0 or 1 and therefore $0 \leq L_j \leq 1$.

The next three rules are the ones used in the **cutting plane proof system**.

$$\frac{\sum_j a_j L_j \geq b \quad \sum_j c_j L_j \geq d}{\sum_j (a_j + c_j) L_j \geq b + d} \quad (\text{addition})$$

$$\frac{\sum_j a_j L_j \geq b \quad \alpha > 0 \quad \alpha \in \mathbb{N}}{\sum_j \alpha a_j L_j \geq \alpha b} \quad (\text{multiplication})$$

$$\frac{\sum_j a_j L_j \geq b \quad \alpha > 0}{\sum_j \lceil \frac{a_j}{\alpha} \rceil L_j \geq \lceil \frac{b}{\alpha} \rceil} \quad (\text{division})$$

These three rules form a complete proof system[Gom63], which means that whenever the constraints are unsatisfiable, these rules allow to derive the contradiction $0 \geq 1$.

It is important to notice that, even when all initial constraints are cardinality constraints, the addition rule cannot be restricted to generate only cardinality constraints. In other words, proof of unsatisfiability of a set of cardinality constraints requires in general the use of generic intermediate pseudo-Boolean constraints. As an example, the conjunction of the two cardinality constraints $\{a + b + c + d \geq 3, a + \bar{b} + \bar{c} + \bar{d} \geq 3\}$ is unsatisfiable. This cannot be proved without inferring by the addition rule $2a \geq 3$ which is not a cardinality constraint.

The multiplication rule is essentially a commodity rule since it can be replaced by iterated applications of the addition rule. The condition $\alpha \in \mathbb{N}$ in the multiplication rule is only used to obtain a constraint which still has integer coefficients. The multiplication and division rules could be unified as one single rule where α is not required to be an integer.

$$\frac{\sum_j a_j L_j \geq b \quad \alpha > 0}{\sum_j \lceil \alpha a_j \rceil L_j \geq \lceil \alpha b \rceil} \quad (\text{multiplication/division})$$

$\lceil r \rceil$ is the ceiling function which returns the smallest integer number which is greater than or equal to r . The correctness of this rule derives from $\forall r_j \in \mathbb{R}, \sum_j \lceil r_j \rceil \geq \lceil \sum_j r_j \rceil$.

The addition and multiplication rules are often combined together in a single rule which allows to infer a new constraint with one or more variables eliminated.

$$\frac{\begin{array}{l} \sum_j a_j L_j \geq b \\ \sum_j c_j L_j \geq d \\ \alpha \in \mathbb{N}, \beta \in \mathbb{N} \\ \alpha > 0, \beta > 0 \end{array}}{\sum_j (\alpha a_j + \beta c_j) L_j \geq \alpha b + \beta d} \quad (\text{generalized resolution})$$

Usually, α and β are chosen in order to eliminate at least one of the literals from the inferred rule. If $p.l$ appears in the first constraint and $q.\bar{l}$ in the second, choosing $\alpha = q/\text{GCD}(p, q)$ and $\beta = p/\text{GCD}(p, q)$ will generate in the sum the term $p.q/\text{GCD}(p, q).(l+\bar{l})$ which is a constant since $l+\bar{l} = 1$. It should be noticed that several literals can be removed simultaneously. For example, eliminating x_1 in $\{x_1 + x_2 + x_3 \geq 1, 2\bar{x}_1 + 2\bar{x}_2 + x_4 \geq 3\}$ also eliminates x_2 and generates $2x_3 + x_4 \geq 1$ which will be simplified to $x_3 + x_4 \geq 1$ by the saturation rule.

The saturation rule indicates that when the constraint is normalized and one of the coefficients is larger than the degree (the right side of the inequation), it can be truncated to become equal to the degree.

$$\frac{\begin{array}{l} \sum_j a_j L_j \geq b \\ \forall j, a_j \geq 0 \\ a_k > b \end{array}}{bL_k + \sum_{j \neq k} a_j L_j \geq b} \quad (\text{saturation})$$

From a logical point of view, this rule is straightforward. When $a_j > b$, assigning true to L_j is enough to satisfy the constraint and indeed, any coefficient greater than or equal to b will have the same effect and the saturation rule simply chooses the least of these coefficients. This saturation rule can be replaced by iterated applications of the multiplication/division rule with α chosen so that any coefficient strictly greater than b will be reduced at least by 1 and any coefficient smaller or equal to b will not be modified (these two conditions are satisfied when $(b-1)/b < \alpha \leq b/(b+1)$).

It must be noticed that the generalized resolution rule is not sufficient to obtain a complete proof system because it cannot remove all non-integer solutions. For example, generalized resolution will not infer inconsistency from $\{a \vee b, a \vee \neg b, \neg a \vee b, \neg a \vee \neg b\}$ because $a = 1/2, b = 1/2$ is a solution of the initial constraints and all constraints generated by generalized resolution. The saturation rule (or equivalently the division rule) is required to cut the non-integer solutions.

The last rules are just a direct application of the addition rule and the bounds axioms but appear particularly useful in some constraint driven algorithms. These rules (weakening rules) allow to remove some occurrences of a literal in a constraint. However, the derived constraint is in general weaker than the initial

constraint (i.e. it forbids fewer interpretations than the initial constraint). The derived constraint may even become a tautology.

$$\frac{\sum_j a_j L_j \geq b}{a_k > 0} \quad (\text{weakening})$$

$$\frac{\sum_{j \neq k} a_j L_j \geq b - a_j}{\sum_j a_j L_j \geq b}$$

$$\frac{\sum_j a_j L_j \geq b}{a_k > 0}$$

$$\frac{a_k > a > 0}{(a_k - a)L_j + \sum_{j \neq k} a_j L_j \geq b - a} \quad (\text{partial weakening})$$

Since each inference rule which was presented can be derived from the rules of the cutting plane proof system (addition, multiplication, division) and the axioms, the term “cutting plane rules” will be used indistinctly in the rest of this chapter to refer to the application of one or several of these rules.

28.5.1. Inference Power

28.5.1.1. Comparison with SAT Inference Rules

Two inference rules are used in propositional calculus: resolution and merging.

$$\frac{l \vee A \quad \neg l \vee B}{\neg \exists l' \text{ s.t. } l' \in A \wedge \neg l' \in B} \quad (\text{resolution})$$

$$\frac{A \vee B}{A \vee B}$$

$$\frac{l \vee l \vee C}{l \vee C} \quad (\text{merging})$$

If the resolution rule is well known, the merging rule is often ignored because usually, clauses are defined as sets of literals and the merging rule is directly obtained from the definition of a set. This rule is more visible in predicate calculus where a most general unifier must be computed to merge literals. However, merging is actually required to obtain a complete proof system in propositional calculus.

The resolution rule in propositional calculus directly corresponds to the addition rule. The two clauses $l \vee A$ and $\neg l \vee B$ correspond to the PB constraints $l + \sum_j l_j^A \geq 1$ and $1 - l + \sum_j l_j^B \geq 1$. The sum of these constraints is $\sum_j l_j^A + \sum_j l_j^B \geq 1$. Provided A and B does not contain a pair of complementary literals, this sum corresponds to a clause (possibly with some literals repeated if some l_j^A is equal to a l_j^B). If A and B contained a pair of complementary literals, these literals would disappear and the degree of the PB constraints would become 0 which corresponds to a tautology.

The merging rule is a straightforward application of the saturation rule. $l \vee l \vee C$ corresponds to $2l + \sum_j l_j^C \geq 1$ which is reduced by the saturation rule as $l + \sum_j l_j^C \geq 1$ which represents $l \vee C$.

This comparison proves that the cutting plane proof system can polynomially simulate the resolution proof system. This means that the cutting plane proof system is at least as powerful as the resolution proof system.

28.5.1.2. The Cutting Plane System is more Powerful than Resolution: The Pigeon-Hole Example

This section presents an example of a problem which has a polynomial proof in the cutting plane proof system while no polynomial proof exists in the resolution proof system. This proves that the cutting plane proof system is strictly more powerful than the resolution proof system. This example problem is the well-known pigeon-hole problem. Interestingly, this example will show that conflict-driven constraint learning solvers (described in Part 1, Chapter 4) can easily discover this polynomial proof.

The pigeon-hole problem consists in placing p pigeons in h holes such that each hole contains at most one pigeon and each pigeon is placed in at most one hole. This second constraint can be omitted when only the satisfiability of the problem is considered. This problem is well known since it was used to prove the intractability of resolution [Hak85]. In its clausal form, an exponential number of resolution steps is required to prove the unsatisfiability of the problem when $p > h$.

However, when cardinality constraints and the cutting plane proof system are used, a polynomial number of inferences suffices to prove unsatisfiability and a conflict-driven constraint learning solver can easily find this proof.

As an example, let us consider the pigeon-hole problem with $p = 5$ and $h = 4$ (5 pigeons, only 4 holes) in its satisfiability oriented encoding. Let $P_{p,h}$ be a Boolean variable which is true if and only if pigeon number p is placed in hole number h . This problem can be encoded by the following cardinality constraints:

$$P_{1,1} + P_{1,2} + P_{1,3} + P_{1,4} \geq 1 \quad (\text{P1})$$

$$P_{2,1} + P_{2,2} + P_{2,3} + P_{2,4} \geq 1 \quad (\text{P2})$$

$$P_{3,1} + P_{3,2} + P_{3,3} + P_{3,4} \geq 1 \quad (\text{P3})$$

$$P_{4,1} + P_{4,2} + P_{4,3} + P_{4,4} \geq 1 \quad (\text{P4})$$

$$P_{5,1} + P_{5,2} + P_{5,3} + P_{5,4} \geq 1 \quad (\text{P5})$$

$$\overline{P_{1,1}} + \overline{P_{2,1}} + \overline{P_{3,1}} + \overline{P_{4,1}} + \overline{P_{5,1}} \geq 4 \quad (\text{H1})$$

$$\overline{P_{1,2}} + \overline{P_{2,2}} + \overline{P_{3,2}} + \overline{P_{4,2}} + \overline{P_{5,2}} \geq 4 \quad (\text{H2})$$

$$\overline{P_{1,3}} + \overline{P_{2,3}} + \overline{P_{3,3}} + \overline{P_{4,3}} + \overline{P_{5,3}} \geq 4 \quad (\text{H3})$$

$$\overline{P_{1,4}} + \overline{P_{2,4}} + \overline{P_{3,4}} + \overline{P_{4,4}} + \overline{P_{5,4}} \geq 4 \quad (\text{H4})$$

The first five constraints (P1 to P5) encode that a pigeon must be in at least one hole and the last four constraints (H1 to H4) encode that a hole can contain at most one pigeon (H1 is a normalized form of $P_{1,1} + P_{2,1} + P_{3,1} + P_{4,1} + P_{5,1} \leq 1$).

A conflict-driven constraint learning solver may start by assigning true to $P_{1,1}$ at level 1 of the decision tree ($v@l$ will denote that the solver assigns value v to a variable at the decision level l , so $P_{1,1}$ is assigned $1@1$). By H1, $P_{2,1}$, $P_{3,1}$, $P_{4,1}$, $P_{5,1}$ are all set to false. Since (P1) is now satisfied, the next decision variable can be $P_{2,2}$ at level 2. Once this variable is assigned true, H2 implies that $P_{1,2}$, $P_{3,2}$, $P_{4,2}$, $P_{5,2}$ are all false. Next, $P_{3,3}$ may be assigned true at level 3. This implies that $P_{1,3}$, $P_{2,3}$, $P_{4,3}$, $P_{5,3}$ are all false (by H3), $P_{4,4}$ is true (by P4) and then $P_{1,4}$,

Literal	val@lvl	reason	Literal	val@lvl	reason	Literal	val@lvl	reason	Literal	val@lvl	reason

(d) final step

Figure 28.2. Summary of the decisions and propagations in the pigeon-hole example. Each line in a table represents which value (val) is assigned to which literal at which level (lvl) and what is the reason of this assignment.

$P_{2,4}$, $P_{3,4}$, $P_{5,4}$ are false (by H4). Figure 28.2(a) summarizes the decisions and propagations which occurred. The reason of each propagation is indicated in that figure as well as the decision level of each propagation or decision.

At this point, constraint P5 is falsified and conflict analysis can start. The first step is to combine the conflicting constraint (P5) $\overline{P_{5,1}} + \overline{P_{5,2}} + \overline{P_{5,3}} + \overline{P_{5,4}} \geq 1$ with the reason of the last propagated literal (H4) $\overline{P_{1,4}} + \overline{P_{2,4}} + \overline{P_{3,4}} + \overline{P_{4,4}} + \overline{P_{5,4}} \geq 4$ to eliminate the propagated variable. This yields a new constraint $\overline{P_{5,1}} + \overline{P_{5,2}} + \overline{P_{5,3}} + \overline{P_{1,4}} + \overline{P_{2,4}} + \overline{P_{3,4}} + \overline{P_{4,4}} \geq 4$. Since this constraint will not propagate any literal when we backtrack to level 2, conflict analysis goes on. Another resolution step is performed with (P4) which is the reason of the propagation of $P_{4,4}$ to obtain $\overline{P_{4,1}} + \overline{P_{4,2}} + \overline{P_{4,3}} + \overline{P_{5,1}} + \overline{P_{5,2}} + \overline{P_{5,3}} + \overline{P_{1,4}} + \overline{P_{2,4}} + \overline{P_{3,4}} \geq 4$. Once again, this constraint implies no literal at level 2. Therefore, it is combined with (H3) to eliminate $\overline{P_{4,3}}$ and $\overline{P_{5,3}}$. This yields constraint (L1) $\overline{P_{4,1}} + \overline{P_{4,2}} + \overline{P_{5,1}} + \overline{P_{5,2}} + \overline{P_{1,3}} + \overline{P_{1,4}} + \overline{P_{2,3}} + \overline{P_{2,4}} + \overline{P_{3,3}} + \overline{P_{3,4}} \geq 6$ which will propagate literals when the solver backtracks to level 2. Conflict analysis stops and this constraint is learnt.

Figure 28.3 represents the derivation of constraint L1 from the conflict constraint and the different reasons of propagations. Literals that are erased in a resolution step are written in parentheses.

The first inferred constraint in this derivation presented in figure 28.3 is a nice illustration of the difference between the SAT encoding and the cardinality encoding of the pigeon-hole problem. In a SAT encoding, the reason of the propagation of $\overline{P_{5,4}}$ would be the clause $\neg P_{4,4} \vee \neg P_{5,4}$ and the resolvent with the conflict would be $\overline{P_{5,1}} \vee \overline{P_{5,2}} \vee \overline{P_{5,3}} \vee \neg P_{4,4}$. The semantics of this clause can be expressed as 'when $P_{4,4}$ is true, one of $P_{5,1}$, $P_{5,2}$ or $P_{5,3}$ must be true'. In contrast, the semantics of the pseudo-Boolean constraint (in combination with H4)

Figure 28.3. First conflict analysis in the pigeon-hole example

Figure 28.4. Second conflict analysis in the pigeon-hole example

is 'when any of $P_{1,4}, P_{2,4}, P_{3,4}, P_{4,4}$ is true, then one of $P_{5,1}, P_{5,2}$ or $P_{5,3}$ must be true'. The strength of the pseudo-Boolean formulation in this case is that one PB constraint replaces several clauses and this single constraint captures several symmetries of the problem.

After the first conflict analysis, the solver backtracks to level 2. At this level, $P_{4,1}, P_{4,2}, P_{5,1}, P_{5,2}$ are all false. Therefore, constraint (L1) propagates $P_{1,3}, P_{1,4}, P_{2,3}, P_{2,4}, P_{3,3}, P_{3,4}$ equal false but since $P_{3,1}, P_{3,2}$ are already false, (P3) $P_{3,1} + P_{3,2} + P_{3,3} + P_{3,4} \geq 1$ is a new conflict. Figure 28.2(b) presents the propagations just before the conflict and figure 28.4 represents the conflicts analysis which leads to constraint (L2) which is learnt.

When the solver backtracks to level 1, $P_{3,1}, P_{4,1}, P_{5,1}$ are false and therefore constraint (L2) implies that $P_{1,2}, P_{1,3}, P_{1,4}, P_{2,2}, P_{2,3}, P_{2,4}$ are false. But since $P_{2,1}$ is false, (P2) $P_{2,1} + P_{2,2} + P_{2,3} + P_{2,4} \geq 1$ is a new conflict. Figure 28.2(c) shows the assignment stack just before the conflict is detected and figure 28.5 presents the resulting conflicts analysis.

Figure 28.5. Third conflict analysis in the pigeon-hole example

Algorithm 28.1 Generic Pseudo-Boolean Solving Algorithm

```

1: function GENERIC_PB_SOLVER(P)
2:   while true do
3:     if Solution_Found(P) then
4:       return SATISFIABLE
5:     else
6:       Decide(P)
7:     end if
8:     while Deduce(P)=CONFLICT do
9:       if Diagnose(P)=CONFLICT then
10:        return UNSATISFIABLE
11:      end if
12:    end while
13:   end while
14: end function

```

When the solver backtracks to level 0, constraint (L3) implies that $P_{1,1}$, $P_{1,2}$, $P_{1,3}$, $P_{1,4}$ are all false, but this assignment conflicts with $P_{1,1} + P_{1,2} + P_{1,3} + P_{1,4} \geq 1$. Figure 28.2(d) presents the assignments when the solver backtracks to level 0. Since there is no decision that can be changed at level 0, the solver has proved unsatisfiability, and this required only a polynomial number of steps.

28.6. Current Algorithms

Due to the recent developments in algorithms for Propositional Satisfiability (SAT), algorithms for Pseudo-Boolean Solving (PBS) and Optimization (PBO) have also been the subject of thorough research work, mainly in applying generalizations of successful ideas already used in SAT algorithms. Nevertheless, other techniques used in Operations Research algorithms have also been proposed.

In this section, the main algorithmic techniques for solving pseudo-Boolean formulations are described. We start by presenting the generalization of commonly used techniques in SAT solvers, namely Boolean constraint propagation and conflict-driven learning and backtracking. Finally, we focus on specific techniques for pseudo-Boolean optimization, with emphasis on lower bounding procedures and cutting plane generation.

Algorithm 28.1 presents the pseudo-code for a generic pseudo-Boolean solver based on a backtrack search approach where a depth-first tree is built to explore all possible assignments to the problem variables. Each branch of the search tree corresponds to a partial assignment to problem variables.

The algorithm starts with an empty search tree (no assigned variables) and at each step the **Decision** procedure extends a branch of the search tree (partial assignment) by assigning one of the unassigned variables from problem instance P . Next, the **Deduce** procedure identifies necessary assignments by applying Boolean constraint propagation [DP60, ZM88]. This procedure can also be modified in order to apply problem reduction techniques [Cou93, VKBSV97]. If there exists a conflict, i.e. an unsatisfied constraint, the **Deduce** procedure returns **CONFLICT**. Whenever a conflict occurs, **Diagnose** applies the conflict analysis procedure to resolve the conflict and backtrack in the search tree. When the algorithm is unable to backtrack any further, the search stops and returns **UNSATISFIABLE**.

If at any step of the search, all constraints from P are satisfied, the algorithm returns SATISFIABLE.

28.6.1. Boolean Constraint Propagation

The **unit clause rule** [DP60] applied to propositional clauses in SAT algorithms, states that given a partial assignment and a unit clause ω (with one unassigned literal l_j and all other literals assigned value 0), the unassigned literal l_j in the unit clause must have value 1. Hence, the associated variable assignment can be added to the current partial assignment. The successive application of the unit clause rule is known as **Boolean constraint propagation** or **unit propagation** [DP60, ZM88]. A generalized version of Boolean constraint propagation can also be applied to pseudo-Boolean constraints, using a similar definition of unit constraint. The main difference is that more than one literal might be assigned value 1 due to a single pseudo-Boolean constraint.

Consider a pseudo-Boolean constraint ω in normalized form. Given a partial assignment, let ω^v denote the set of literals in constraint ω with value $v \in \{0, 1\}$. Let also L_ω be the current value on the left hand side of the constraint defined as:

$$L_\omega = \sum_{l_j \in \omega^1} a_j \quad (28.3)$$

Finally, let s_ω denote the slack of constraint ω defined as:

$$s_\omega = \sum_{l_j \notin \omega^0} a_j - b \quad (28.4)$$

The slack represents the maximal amount by which the left side may exceed the right side of the constraint (when all yet unassigned variables are set to true). Given a partial assignment, a constraint ω is said to be *satisfied* if $L_\omega \geq b$. In contrast, if $s_\omega < 0$, ω is said to be *unsatisfied*. In this case, it is guaranteed that with the current partial assignment, ω cannot be satisfied. A constraint ω is said to be *unresolved* if $L_\omega < b$ and $s_\omega \geq 0$. This means that ω can still become satisfied or unsatisfied, depending on the assignments to currently unassigned variables. A special case of the unresolved constraints is when there is at least one unassigned literal $l_j \in \omega$ such that $s_\omega - a_j < 0$. Then ω is said to be a *unit* constraint since literal l_j *must* be assigned value 1 in order for ω to become satisfied. Observe that in a unit pseudo-Boolean constraint ω , more than one literal might have to be assigned value 1 for the constraint to be satisfied. It is possible that after assigning value 1 to l_j , pseudo-Boolean constraint ω remains unit and other literals must be assigned value 1.

Example 28.6.1. Let ω be the constraint $5x_1 + 3x_2 + 3x_3 + x_4 \geq 6$. When all variables are unassigned, $L_\omega = 0$ and $s_\omega = 6$. This constraint is unresolved (i.e. not yet satisfied but some affectations of the variables may still satisfy the constraint because $s_\omega \geq 0$). If x_1 is assigned false, $L_\omega = 0$ and $s_\omega = 1$. The constraint is unresolved but since $s_\omega - a_2 < 0$, x_2 must be assigned true otherwise the constraint becomes unsatisfied. Once x_2 is assigned true, $L_\omega = 3$ and $s_\omega = 1$. The constraint is still unresolved and since $s_\omega - a_3 < 0$, x_3 must also

be assigned true. Now, $L_\omega = 6$ and $s_\omega = 1$, the constraint is now satisfied and propagation stops. In this example, the assignment of one variable (x_1) implied the propagation of two other variables (x_2 and x_3) which in this particular case is enough to satisfy the constraint. This example also illustrates that some variables (x_4) can remain unassigned after the propagation, which does not happen with clauses.

A solver can incrementally compute the slack of each constraint to detect unit constraints. This is the analog of the counter scheme formerly used in SAT. But in order to engineer a good pseudo-Boolean solver, it is necessary to quickly detect when a constraint becomes unit for Boolean constraint propagation or unsatisfied to backtrack in the search tree. Therefore, the use of efficient data structures to manipulate problem constraints is vital. Propositional clauses are a particular case of pseudo-Boolean constraints and specific data structures have been developed for SAT solvers in order to efficiently manipulate these constraints. More recently, new data structures have also been proposed for other types of pseudo-Boolean constraints.

The purpose of **lazy data structures** is to be able to easily detect when a constraint becomes unsatisfied (to backtrack in the search tree) or unit (to detect necessary assignments) while avoiding unnecessary processing on unresolved constraints. As described in Part 1, Chapter 4, in propositional clauses, watching two literals is enough to accomplish these objectives and several strategies for choosing which literals to watch have already been developed [Zha97, MMZ⁺01, LMS05]. However, in cardinality constraints and general pseudo-Boolean constraints, a larger number of literals must be watched in order to be able to detect when a constraint becomes unsatisfied or unit.

Let W denote the set of **watched literals** in a pseudo-Boolean constraint ω and let $S(W)$ denote the sum of the watched literal coefficients:

$$S(W) = \sum_{l_j \in W} a_j \quad (28.5)$$

In order to detect that constraint ω becomes unsatisfied, it is only necessary to watch a set of literals W (unassigned or assigned value 1) such that $S(W) \geq b$, since it is still possible to satisfy ω by assigning value 1 to the unassigned watched literals. However, to make sure that a constraint does not imply a necessary assignment, one must watch a set of literals W such that:

$$S(W) \geq b + a_{max} \quad (28.6)$$

where a_{max} is greater than or equal to the largest coefficient of unassigned literals in the constraint. Note that if (28.6) is true, then there is no unassigned literal l_j such that $S(W) - a_j < b$. Hence, the constraint is not unit.

Whenever a watched literal $l_j \in W$ is assigned value 0, l_j is removed from W and unassigned or assigned value 1 literals are added to W until (28.6) holds. In this case, the constraint remains unresolved or becomes satisfied. However, if all non-value 0 literals are being watched and $S(W) < b$, then the constraint is unsatisfied. Otherwise, if $S(W) < b + a_{max}$ then the constraint is unit and the necessary assignments can be implied until (28.6) is true.

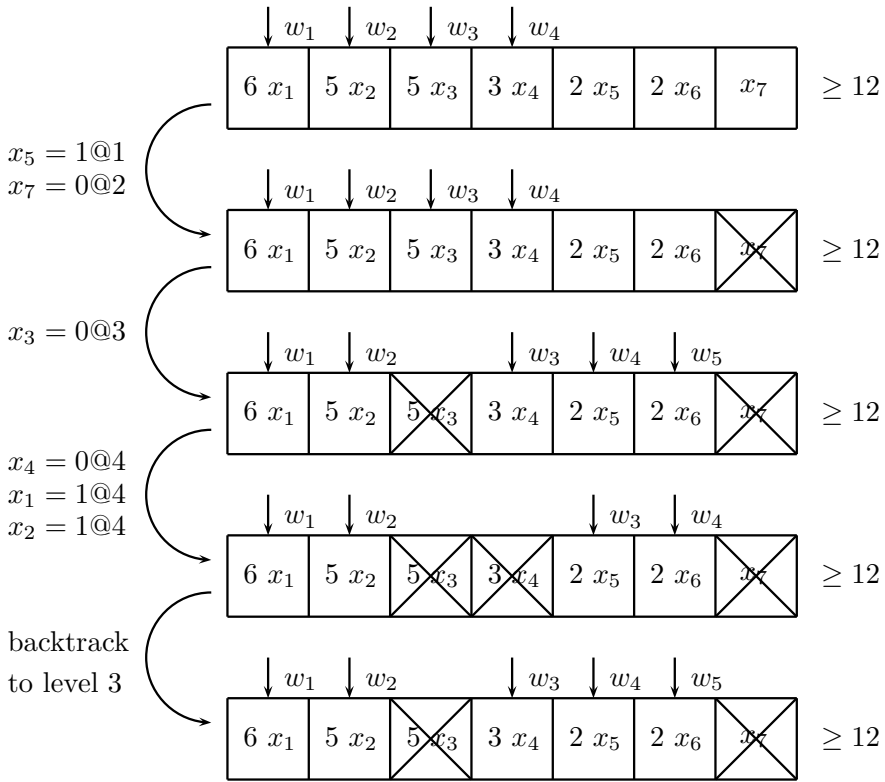

Figure 28.6. Example of lazy data structure for pseudo-Boolean constraints

Figure 28.6 presents an example of the use of lazy data structures in general pseudo-Boolean constraints. Consider the following pseudo-Boolean constraint:

$$6x_1 + 5x_2 + 5x_3 + 3x_4 + 2x_5 + 2x_6 + x_7 \geq 12 \tag{28.7}$$

and suppose that initially we have $W = \{x_1, x_2, x_3, x_4\}$. Note that watching only 3 literals would not satisfy (28.6) and consequently would not be enough to detect all situations of implication of necessary assignments.

As in the watched literals approach for propositional clauses, if non-watched literals are assigned, no update is necessary in the data structure. This is illustrated in Figure 28.6 if we start by assigning x_5 and x_7 . Afterwards, when x_3 is assigned value 0, the set of watched literals must be updated and we have $W = \{x_1, x_2, x_4, x_5, x_6\}$ such that (28.6) is satisfied. Next, if x_4 is assigned value 0, we can deduce value 1 to x_1 and x_2 . Afterwards, when search backtracks to level 3, no update to the watched literals is necessary.

One should note that for cardinality constraints, the number of watched literals in this approach is constant and the size of W is always $b + 1$. As expected,

for propositional clauses the size of W is always 2. However, as shown in our example, for general pseudo-Boolean constraints, the number of watched literals can vary since the value of a_{max} depends on which literals are assigned at any given moment.

The major drawback of this approach for handling general pseudo-Boolean constraints is the fact that most of the time is lost in updating the value of a_{max} [SS05]. Other options have already been proposed regarding the value of a_{max} to be used, as for example fixing the value of a_{max} to the value of the highest literal coefficient in the constraint [SS05]. With this approach, no update on the value of a_{max} is necessary. However, during the search process, more literals than necessary might be watched.

28.6.2. Conflict Analysis

Besides Boolean constraint propagation, other techniques from state of the art SAT algorithms can also be used in pseudo-Boolean algorithms. One of the most important is the **conflict analysis** procedure to be applied during search whenever a constraint becomes unsatisfied by the current partial assignment under consideration. As with SAT solving, it is possible to do non-chronological backtracking in a backtrack search pseudo-Boolean solver by using a sophisticated conflict analysis procedure.

The advantage of using non-chronological backtracking is that this technique might prevent the algorithm to waste a significant amount of time exploring a useless region of the search space only to discover that the region does not contain any satisfying assignment. Algorithms that perform non-chronological backtracks can jump directly from the current decision level d to another preceding decision level d' where $d - d' > 1$. The decision level d' where it is safe to backtrack to is determined by a conflict analysis procedure.

One approach to the conflict analysis procedure is to apply the same ideas as in SAT algorithms, in which an analysis of an **implication graph** represented as an directed acyclic graph (DAG) is made. The implication graph is defined as follows ($v(x)$ represents the value of variable x and $\delta(x)$ represents the decision level where x was assigned, notation $v(x_j)@ \delta(x_j)$ is used to indicate the value of the variable and the level at which it was assigned):

- Each vertex corresponds to a variable assignment $x_j = v(x_j)@ \delta(x_j)$
- The predecessors of a vertex $x_j = v(x_j)@ \delta(x_j)$ in the graph are the associated assignments to the literals assigned value 0 in the unit constraint ω that led to the implication of value $v(x_j)$ to x_j . The directed edges from the predecessors vertices to vertex $x_j = v(x_j)@ \delta(x_j)$ are all labeled with ω . Vertices that have no predecessors correspond to decision assignments.
- Special conflict vertices (κ) are added to the implication graph to indicate the occurrence of conflicts. The predecessors of a conflict vertex correspond to variable assignments that force a constraint ω to become unsatisfied. The directed edges are also all labeled with ω .

Figure 28.7 presents the implication graph produced after the assignment of value 1 to x_1 , assuming the set of constraints and truth assignments shown. The

Current Truth Assignment: $\{x_9 = 0@1, x_{12} = 1@2, x_{10} = 0@3, \dots\}$

Current Decision Assignment: $\{x_1 = 1@6\}$

- $\omega_1 : \overline{x_1} + x_2 + x_3 + x_9 \geq 2$
- $\omega_2 : 3\overline{x_4} + 2x_5 + 2x_6 + 4x_{10} \geq 4$
- $\omega_3 : 2\overline{x_2} + 3\overline{x_3} + 5x_4 \geq 5$
- $\omega_4 : \overline{x_5} + \overline{x_6} \geq 1$
- $\omega_5 : x_1 + x_7 + \overline{x_{12}} \geq 1$
- $\omega_6 : x_1 + x_8 \geq 1$
- $\omega_7 : \overline{x_7} + \overline{x_8} \geq 1$
- ...

Figure 28.7. Example of an implication graph

implication graph contains a conflict node κ that shows a conflict on constraint ω_4 since both variables x_5 and x_6 are assigned value 1. Note that unlike the implication graph of SAT algorithms, in pseudo-Boolean formulations, the same constraint can imply several assignments.

When a logical conflict arises, the implication sequence leading to a conflict vertex κ is analyzed to determine the variable assignments that are responsible for the conflict. The conjunction of these assignments is an implicant for the conflict and represents a sufficient condition for the conflict to arise. Therefore, the negation of this implicant yields an implicate for the function associated with the problem constraints that must be satisfied. This new implicate is known as *conflict-induced clause*².

Let $A(\kappa)$ denote the conflicting assignment associated with a conflict vertex κ . The conflicting assignment is determined by a backward traversal of the implication graph starting at κ . Besides the decision assignment at the current decision level, only those assignments that occurred at previous decision levels are included in $A(\kappa)$. Hence, the current decision assignment with assignments from previous decision levels is a sufficient explanation for the conflict. For the example presented in Figure 28.7, we would have:

$$A(\kappa) = \{x_9 = 0@1, x_{10} = 0@3, x_1 = 1@6\} \tag{28.8}$$

The associated conflict-induced clause $\omega(\kappa)$ would then be:

$$\omega(\kappa) : x_9 + x_{10} + \overline{x_1} \geq 1 \tag{28.9}$$

²Conditions similar to these implicates are referred to as "no-goods" in Reasoning [dK86, SS77] and in some algorithms for Constraint Satisfaction Problems (CSP) [SV93].

Figure 28.8. Implication graph after adding conflict-induced clause $\omega(\kappa)$ from (28.9)

After adding the new learned constraint $\omega(\kappa)$ to the list of the instance constraints to satisfy, the search backtracks to the decision level β determined by:

$$\beta = \max\{\delta(x_j) : (x_j = v(x_j)@ \delta(x_j)) \in A(\kappa) \wedge \delta(x_j) \neq \delta(\kappa)\} \tag{28.10}$$

where $\delta(\kappa)$ denotes the decision level of the conflict (current decision level). At decision level β either $\omega(\kappa)$ is used to imply a new assignment (the opposite value of the decision assignment at level β), or the conflict analysis procedure is executed again to determine a new backtracking decision level. In the example of Figure 28.7, the search would backtrack to decision level 3 and use $\omega(\kappa)$ to assert $x_1 = 0@3$. Observe that the assignment of value 0 to x_1 is not a decision assignment, but an implication from the conflict-induced clause. We refer to such assignments as *failure-driven assertions* (FDA) [MSS96], since they are implications of conflicts and not decision assignments.

Figure 28.8 shows the implication graph after adding the new learned constraint $\omega(\kappa)$ from (28.9). A new conflict arises and the conflict assignment $A(\kappa)$ associated with this conflict is:

$$A(\kappa) = \{x_9 = 0@1, x_{12} = 1@2, x_{10} = 0@3\} \tag{28.11}$$

Therefore, we would have a conflict-induced clause:

$$\omega(\kappa) : x_9 + x_{10} + \overline{x_{12}} \geq 1 \tag{28.12}$$

From (28.10) we can conclude that the search can backtrack directly to decision level 2 and propagate $x_{10} = 1@2$. This non-chronological backtrack avoids having to explore the opposite value of decision assignments made at intermediate decision levels.

28.6.3. Unique Implication Points

In an implication graph, a vertex a is said to *dominate* vertex b iff any path from the decision variable (or failure-driven assertion) of the decision level of a to b needs to go through a . A **Unique Implication Point** (UIP) [MSS96] is a vertex at the current decision level that dominates the conflict vertex κ in the implication graph at that decision level. For example, in Figure 28.7, vertex corresponding to the assignment $x_4 = 1$ dominates the conflict vertex κ . Hence, this vertex is an

Figure 28.9. Cuts in implication graph

UIP in the implication graph. One should note that the vertex associated with the last decision assignment (or failure-driven assertion) is always a UIP.

The identification of UIPs in the implication graph can be used as a learning procedure [MSS96] by generating stronger implicates, i.e. with fewer literals than conflict-induced clauses. Considering that the UIP provides a single reason that implies the conflict on the current decision level, the same approach for generating conflict-induced clauses based on the last decision variable can be used for generating new clauses through a backward traversal of the implication graph until a UIP is found. Therefore, considering the UIP associated with assignment $x_4 = 1$ in Figure 28.7, a new clause can be added to the set of problem constraints

$$\omega_{uip} : \overline{x_4} + x_{10} \geq 1 \tag{28.13}$$

since the assignments $x_4 = 1$ and $x_{10} = 0$ are sufficient explanations for the conflict. Note that the same procedure can be applied to all UIPs found during the backward traversal of the implication graph, generating a new clause for each UIP.

It has been noted that the conflict-induced clause is generated by a bipartition of the implication graph [ZMMM01]. This bipartition is called a *cut* where the side containing the conflict vertex is called the *conflict partition* while the side with all vertices associated with decision assignments is called the *reason partition*.

In Figure 28.9 we show different cuts that can occur in the implication graph of Figure 28.7. The set of vertices on the reason partition that have at least one edge to the conflict partition provide an explanation for the conflict. Therefore, choosing a different cut of the implication graph corresponds to choose another explanation for the conflict and hence a different clause will be learned. The cuts

in Figure 28.9 would correspond to the following implicates:

$$\begin{aligned} \text{cut 1 : } \bar{x}_1 + x_9 + x_{10} &\geq 1 \\ \text{cut 2 : } \bar{x}_2 + \bar{x}_3 + x_{10} &\geq 1 \\ \text{cut 3 : } \bar{x}_4 + x_{10} &\geq 1 \end{aligned} \tag{28.14}$$

Observe that after backtracking both clauses generated from cut 1 or cut 3 are unit. Therefore, these clauses provide a mechanism to deduce an assignment to avoid the same conflict. However, the clause generated from cut 2 becomes unresolved after backtracking. The difference, is that both clauses from cut 1 and 3 are provided when the backward traversal of the implication graph is at an UIP [ZMMM01]. Hence, these clauses will always be unit after backtracking and provide the deduction of a failure-driven assertion. Several learning schemes can be used [ZMMM01], but current state of the art solvers usually stop at the first UIP when generating the conflict-induced clause since there is no need to make the complete backward traversal.

The conflict analysis approach presented in this section directly adapts to pseudo-Boolean solving the techniques developed for SAT solvers. Next, we describe the generalization of the conflict analysis procedure where the conflict-induced constraints are not necessarily propositional clauses. The purpose is to generate more expressive constraints than propositional clauses in order to not only provide a mechanism to deduce failure-driven assertions, but also to prune the search tree.

28.6.4. Generalizing Conflict Analysis

The purpose of applying a conflict analysis procedure is not only to be able to backtrack non-chronologically in the search tree, but also to learn a new constraint that implies a failure-driven assertion. In SAT algorithms, the new constraint is built using a sequence of resolution steps combining several propositional clauses. In fact, the propositional clauses selected for resolution operations are those labeling the edges used in a backward traversal of the implication graph [MSS96]. As described in section 28.6.3, the backward traversal can stop at the first UIP of the implication graph.

In section 28.5, cutting plane rules on pseudo-Boolean constraints were introduced. The new constraint resulting from the application of these rules is also known as a **cutting plane**. In fact, a cutting plane can be defined as any constraint that is implied by the original set of constraints [Hoo00]. However, as a result of the generalized resolution rule it is possible to obtain a weaker constraint. Hence, the final result from replacing resolution by the generalized resolution rule might not result in a conflict-induced constraint able to deduce a failure-driven assertion in a conflict analysis procedure.

Consider the partial assignment $\{x_2 = 0, x_4 = 1, x_5 = 0\}$ and suppose we have the following problem constraints:

$$\begin{aligned} \omega_1 : 3x_1 + 2x_2 + x_3 + 2\bar{x}_4 &\geq 3 \\ \omega_2 : 3\bar{x}_1 + x_5 + x_6 + x_7 &\geq 3 \end{aligned} \tag{28.15}$$

These constraints are in conflict since ω_1 implies $x_1 = 1$ while from ω_2 we must have $x_1 = 0$. If we apply generalized resolution to eliminate x_1 , we get the new constraint:

$$\omega_3 : 2x_2 + x_3 + 2\bar{x}_4 + x_5 + x_6 + x_7 \geq 3 \quad (28.16)$$

Note that the original constraints ω_1 and ω_2 were in conflict, but the resulting constraint ω_3 is not. This occurs due to the fact that ω_3 does not have the same information as the original constraints in (28.15) [Wil76]. Nevertheless, it has already been observed that generalized resolution can be strengthened with reduction and rounding operations so that no information is lost [Wil76].

In this section, an approach for building a conflict-induced pseudo-Boolean constraint that enables a failure-driven assertion is presented [CK03]. The idea is to maintain the conflict information in building the conflict-induced constraint while making the backward traversal of the implication graph. For that, at each step, it is ensured that the conflict-induced constraint being built remains unsatisfiable until the backtrack step takes place. After backtracking, the constraint becomes unit and is able to infer a failure-driven assertion. This can be achieved by performing reduction operations followed by saturation on both constraints before the generalized resolution operation [CK03]. However, reduction operations on constraints can be made only on unassigned literals or literals assigned value 1. In our example, weakening constraint ω_2 by reducing x_6 and x_7 (remember the weakening operation from section 28.5) we get:

$$\omega_2' : \bar{x}_1 + x_5 \geq 1 \quad (28.17)$$

Now, when performing generalized resolution between ω_1 and ω_2' to eliminate variable x_1 we have

$$\begin{array}{l} \omega_1 : 3x_1 + 2x_2 + x_3 + 2\bar{x}_4 \geq 3 \\ \omega_2' : 3(\bar{x}_1 + x_5 \geq 1) \\ \hline \omega_3' : 2x_2 + x_3 + 2\bar{x}_4 + 3x_5 \geq 3 \end{array} \quad (28.18)$$

Note that ω_3' is unsatisfied for the considered partial assignment $\{x_2 = 0, x_4 = 1, x_5 = 0\}$.

Algorithm 28.2 presents the pseudo-code for computing the conflict-induced pseudo-Boolean constraint $\omega(\kappa)$. Starting from the unsatisfied constraint c , each step generates a new cutting plane (**Cut_Resolve**) with the antecedent constraint of the variable assignment implied at the current decision level, but in reverse order of the Boolean constraint propagation. The procedure ends whenever the conflict-induced constraint $\omega(\kappa)$ implies an assignment at a previous decision level.

It must be observed that the constraint resulting from the generalized resolution might be oversatisfied, i.e., is not unsatisfied at the current decision level. To avoid this, procedures **Reduce1** and **Reduce2** must apply a series of reduction operations on literals that are unassigned or have value 1, such that the resulting constraint remains unsatisfied (see example (28.17) and (28.18)).

Although the learning of a general pseudo-Boolean constraint might enable a better pruning of the search tree, the data structures to manipulate these constraints have a higher computational overhead than the data structures for propositional clauses or cardinality constraints. Hence, it has been noted that in some

Algorithm 28.2 Generalized Conflict Analysis

V is the set of assigned variables at current decision level in nodes preceding κ in conflict graph sorted in reverse order of BCP

ω_i is the antecedent constraint of variable x_i

A_d is the set of assignments made on decision levels from 1 to d

```

1: function CONFLICT_ANALYSIS( $c, P$ )
2:    $\omega(\kappa) \leftarrow c$ 
3:   while  $V \neq \emptyset$  do
4:      $x_i \leftarrow \text{Remove\_Next}(V)$ 
5:      $\omega(\kappa) \leftarrow \text{Reduce1}(\omega(\kappa))$ 
6:      $\omega'_i \leftarrow \text{Reduce2}(\omega_i)$ 
7:      $\omega(\kappa) \leftarrow \text{Cut\_Resolve}(\omega(\kappa), \omega'_i, x_i)$ 
8:     if  $A_d$  triggers a literal implication in  $\omega(\kappa)$  then
9:        $\omega(\kappa) \leftarrow \text{Reduce3}(\omega(\kappa))$ 
10:      Add  $\omega(\kappa)$  to  $P$ 
11:      Backtrack to smallest  $d$  such that  $A_d$  implies a literal in  $\omega(\kappa)$ 
12:      return NO_CONFLICT
13:     end if
14:   end while
15:   return CONFLICT
16: end function

```

cases, learning propositional clauses or cardinality constraints might be more effective [CK03, CK05, SS05, SS06]. Algorithm 28.2 can be easily adapted to learn propositional clauses (as explained in the previous section) just by changing the reduction procedures to always reduce the constraints to propositional clauses. In order for the conflict-induced constraint to be a cardinality constraint, the procedure `Reduce3` can apply a cardinality reduction algorithm [CK03, CK05]. Note that the cardinality reduction algorithm must preserve the properties of the conflict-induced constraint to imply a failure-driven assertion. Although this step weakens the resulting conflict-induced constraint, the subsequent processing of cardinality constraints is usually faster.

Due to the overhead associated with learning pseudo-Boolean constraints, a hybrid learning scheme has been proposed [SS05, SS06]. The idea is to apply the propositional clause learning scheme (section 28.6.3) and the generalized learning scheme. Afterwards, the solver decides if it is worth to keep the general pseudo-Boolean constraint instead of the propositional clause based on how strong the pseudo-Boolean constraint is and on the number of literals with coefficients larger than 1 [SS05, SS06].

28.6.5. Optimization and Lower Bounding

In Pseudo-Boolean Optimization, the goal is to find a set of assignments to the problem variables such that all constraints are satisfied and the value of the cost function is minimized. One can easily extend a pseudo-Boolean solver to deal with optimization instances by doing a small modification to Algorithm 28.1 described in section 28.6. Instead of stopping when a solution to all constraints is found, one can determine the value of the current solution and add a new constraint such that a new solution must improve on the best solution found so far [Bar95a].

Algorithm 28.3 presents the pseudo-code for this approach. The idea is to

Algorithm 28.3 Generic Pseudo-Boolean Optimization Algorithm

```

1: function PBO_SOLVER( $P$ )
2:    $ub \leftarrow +\infty$ 
3:   while true do
4:     if Solution_Found( $P$ ) then
5:        $ub \leftarrow \sum_{j \in N} c_j v(x_j)$ 
6:       add constraint  $\sum_{j \in N} c_j x_j \leq ub - 1$  to  $P$ 
7:     else
8:       Decide( $P$ )
9:     end if
10:    while Deduce( $P$ )=CONFLICT do
11:      if Diagnose( $P$ )=CONFLICT then
12:        return  $ub$ 
13:      end if
14:    end while
15:  end while
16: end function

```

perform a linear search on the possible values of the cost function starting from the highest, at each step requiring the next computed solution to have a cost lower than the previous one. If the resulting instance is not satisfiable, then the solution is given by the last recorded solution. Notice that all techniques previously described for the decision problem can be readily used for optimization instances.

Nevertheless, the classical approach for solving combinatorial optimization problems using backtrack search to exhaustively explore the search space is Branch and Bound [LW66]. In this approach, an **upper bound** on the value of the cost function is maintained and updated whenever a lower cost solution to the problem constraints is found. Additionally, at each node of the search tree, a **lower bound** on the value of the cost function is estimated considering the current partial assignment to problem variables. Whenever the lower bound estimate is higher than or equal to the upper bound, the search can be pruned since no better solution can be found by extending the current partial assignment. Hence, for optimization instances, the use of lower bound estimates can be a valuable pruning technique.

When solving a Pseudo-Boolean Optimization instance P , let $P.path$ denote the total cost of the partial assignment at some node in the search tree. Let $P.lower$ denote the lower bound estimate on the value of the cost function in order to satisfy all unresolved constraints at the same node. Clearly, at this node of the search tree, the lower bound value is given by the sum of $P.path$ and $P.lower$. Additionally, let $P.upper$ denote the cost of the best solution found so far. It is said that a **bound conflict** occurs when

$$P.path + P.lower \geq P.upper \quad (28.19)$$

in this case, a better solution than $P.upper$ cannot be found with the current partial assignment and the search can be pruned.

The most commonly used procedures to determine the $P.lower$ are based on finding a Maximum Independent Set of constraints [CM95] and Linear Programming Relaxation [LD97]. However, other methods can also be used namely

Lagrangian relaxation [AMO93] or the Log-approximation procedure [Cou96] initially proposed for Unate and Binate Covering Problems.

The effectiveness of lower bounding is usually determined by how tight the estimate is with respect to the optimum solution. The motivation is that with higher lower bound estimates, large portions of the search space can be pruned earlier. It has been shown that the Log-approximation procedure is able to determine a lower bound estimate that is log-approximable [Cou96] to the optimum value of the cost function, but it is dependent on being able to find a solution using a greedy algorithm. Although that is easy when solving Unate Covering instances, that is not the case for general case of Pseudo-Boolean Optimization.

28.6.5.1. Maximum Independent Set

The **maximum independent set** lower bounding procedure is a greedy method based on identifying an independent set of unresolved constraints. The objective of the greedy procedure is to determine a set of unresolved constraints with no literals in common such that the minimum cost to satisfy each constraint is non-zero.

First, in order to build a maximum independent set M , it is necessary to determine the minimum cost necessary to satisfy each unresolved constraint. Remember that a pseudo-Boolean constraint ω_i can be viewed as:

$$\omega_i = \sum_{j \in N} a_{i,j} l_j \geq b_i, \quad (28.20)$$

Suppose all no-cost literals from ω_i are true and let s_{nc} be the sum of the coefficients of all no-cost literals from ω_i . Let ω'_i be defined as:

$$\omega'_i = \sum_{j \in C} a_{i,j} x_j \geq b_i - s_{nc}, \quad (28.21)$$

where C is the set of literals from ω_i with positive cost. Finding the minimum cost for satisfying ω'_i provides the minimum cost to satisfy ω_i and that can be defined as:

$$\begin{aligned} & \text{minimize} && \sum_{j \in C} c_j \cdot x_j \\ & \text{subject to} && \omega'_i \end{aligned} \quad (28.22)$$

Observe that (28.22) is a special case of a PBO problem known as *knapsack 0-1* problem. Nevertheless, it is still an NP-Complete problem [Kar72] and it can be solved in pseudo-polynomial time using dynamic programming [Dan57].

Alternatively, one can use an approximation algorithm for the problem of finding the minimum cost of satisfying a pseudo-Boolean constraint by using a greedy algorithm. First, determine the minimum number of literals that need to be true in order to satisfy ω'_i by reducing ω'_i to a cardinality constraint [Bar95b]. This can be done by summing the sorted set of ω'_i coefficients, starting from the largest $a_{i,j}$ and checking if the sum of $\sum_{j=1}^k a_{i,j} < b_i - s_{nc}$ holds for each value of k . A more detailed description of the cardinality reduction algorithm can be found in [CK03].

Suppose that ω'_{ic} denotes the cardinality constraint obtained by the cardinality reduction algorithm applied to ω'_i

$$\omega'_{ic} = \sum_{j \in C} x_j \geq k \quad (28.23)$$

a lower bound on the minimum cost to satisfy ω'_i is given by accumulating the cost of the first k literals in a sorted set of literal coefficients in the problem cost function, starting with the lowest c_j .

Building the maximum independent set of constraints M is done by adding, at each step, a new constraint with no literal in common with any other constraint already in M . The minimum cost for satisfying the set of constraints M is a *lower bound* on the solution of the problem instance and is given by,

$$Cost(M) = \sum_{\omega_i \in M} MinCost(\omega_i) \quad (28.24)$$

where $MinCost(\omega_i)$ denotes the lower bound on the minimum cost to satisfy ω_i given by the approximation algorithm described in this section.

Although the lower bound provided by the maximum independent set of constraints can be arbitrarily far from the optimum, it is a simple and fast method to determine a lower bound on the problem instance. Linear programming relaxations [LD97] usually find tighter bounds, but are much more time consuming, in particular on highly constrained instances.

Some pruning techniques can be applied after the lower bound estimation when using the maximum independent set of constraints. One of these techniques is the *limit lower bound* first proposed in [CM95] which states that one can also prune the search tree by identifying some necessary assignments. That occurs whenever after calculating the lower bound estimation the following is true:

$$P.path + P.lower + Cost(x_j) \geq P.upper \quad (28.25)$$

when x_j is unassigned, but does not occur in any constraint $\omega_i \in M$, then $x_j = 0$ is a necessary assignment since otherwise a bound conflict would occur.

28.6.5.2. Linear Programming Relaxation

Although the approximation of a maximum independent set of constraints (MIS) is the most widely used lower bound procedure for the Binat Covering problem [Cou96, VKBSV97], **linear programming relaxation** (LPR) has also been used with success [LD97]. It is also often the case that the bound obtained with linear programming relaxation is higher than the one obtained with the MIS approach [LD97]. Moreover, linear programming relaxations have long been used for lower bounding estimation in branch and bound algorithms for solving integer linear programming problems [NW88].

The general formulation of the LPR for a pseudo-Boolean problem is obtained

from the original PBO instance as follows:

$$\begin{aligned}
 & \text{minimize} && z_{lpr} = \sum_{j=1}^n c_j \cdot x_j \\
 & \text{subject to} && \sum_{j=1}^n a_{i,j} x_j \geq b_i \\
 & && 0 \leq x_j \leq 1
 \end{aligned} \tag{28.26}$$

where c_j define the integer cost associated with every decision variable x_j , $a_{i,j}$ define the variable coefficients and b_i the right-hand side of every constraint. Notice that in the LPR formulation the decision variables are no longer Boolean values and can take a non-integer value between 0 and 1.

Let z_{lpr}^* denote the optimum value of the cost function of the LPR (28.26) and z_{pb}^* denote the optimum value of the cost function of the PBO instance. It is well-known that z_{lpr}^* is a lower bound on z_{pb}^* [NW88]. Basically, any solution of the original PBO problem is also a feasible solution of (28.26), but the converse is not true. Moreover, if the solution of (28.26) is integral (i.e. for all variables we have $x_j \in \{0, 1\}$), then we necessarily have $z_{pb}^* = z_{lpr}^*$. Furthermore, different linear programming algorithms can be used for solving (28.26), some with guaranteed worst-case polynomial run time [NW88].

In classical branch and bound algorithms, backtracking due to bound conflicts corresponds to a chronological backtrack in the search tree. However, current state-of-the-art PBO solvers are based on conflict-driven constraint learning algorithms. Therefore, whenever a bound conflict occurs, a new unsatisfied constraint must be added such that it *explains* the bound conflict. Since the explanation is represented as an unsatisfied constraint, it can be treated by the solver in the same way as a logical conflict. Hence, a conflict analysis procedure is carried out on the new constraint and the algorithm safely backtracks in the search tree. In order to establish an explanation for a bound conflict, it is necessary to take into account which lower bounding procedure is being used. Procedures to determine explanations for bound conflicts using the Maximum Independent Set [MMS04], Linear Programming Relaxations [MMS04] and Lagrangian Relaxations [MMS05] have already been established.

28.6.6. Cutting Planes

There are several techniques for pruning the search tree in PBO algorithms. One of the most well-known is the generation of cutting planes that are supposed to be able to readily exclude partial assignments that cannot be extended into a full assignment corresponding to a model [Hoo00]. However, these new cutting planes cannot exclude any model from the original pseudo-Boolean problem. In the context of optimization problems, the importance of cutting planes is on the ability to strengthen relaxations. In this section, the focus will be on the relation between Linear Programming Relaxation and cutting planes for PBO and refer to Hooker's work [Hoo00] for reference on cutting planes techniques and analysis.

Cutting plane techniques were first introduced for Integer Linear Programming and work on cutting planes can be traced back to Gomory [Gom58]. The original idea of Gomory's cutting planes was to derive new linear inequalities in

order to exclude some non-integer solutions when performing Linear Programming Relaxation (LPR) for lower bound estimation. However, the new linear inequalities are valid for the original integer linear program and so can be safely added to the original problem. Moreover, the LPR with the added inequalities may yield a tighter lower bound estimate. In spite of being first developed for Integer Linear Programming, Gomory's cutting planes can be readily used in Pseudo-Boolean Optimization.

Section 28.6.5.2 describes the utilization of linear programming relaxation (LPR) for estimating lower bounds in PBO. In simplex-based solutions for solving the LPR, the simplex method adds a set S of slack variables (one for each constraint) such that,

$$\begin{aligned} \text{minimize} \quad & z_{lpr} = \sum_{j=1}^n c_j \cdot x_j \\ \text{subject to} \quad & \sum_{j=1}^n a_{i,j} x_j - s_i = b_i \\ & 0 \leq x_j \leq 1, s_i \geq 0 \end{aligned} \tag{28.27}$$

This formulation is called the slack formulation and it is used to create the original simplex tableau [NW88].

Let x^* denote the optimal solution of the LPR. If the solution x^* is integral, then x^* provides the optimal solution to the original problem. Otherwise, in order to generate a new cutting plane, Gomory suggests to choose a basic³ variable x_j such that its value on the LPR solution is not integral. Since x_j is a basic variable, after the pivot operations performed by the simplex algorithm on (28.27), there is a row in the simplex tableau of the form,

$$x_j + \sum_{i \in P} \alpha_i x_i + \sum_{i \in Q} \beta_i s_i = x_j^* \tag{28.28}$$

where P and Q are the sets of indexes of non-basic variables (problem variables and slack variables, respectively). Gomory [Gom58] proves that the inequality,

$$\begin{aligned} \sum_{i \in P} f(\alpha_i) x_i + \sum_{i \in Q} f(\beta_i) s_i &\geq f(x_j^*) \\ \text{where } f(y) &= y - \lfloor y \rfloor, y \in \mathbb{R} \end{aligned} \tag{28.29}$$

is violated by the solution of the LPR, but satisfied by all non-negative integer solutions to (28.28). Hence, it is also satisfied by all solutions to the original PBO problem and can be added to the LPR. Solving the LPR with the new restriction (known as a Gomory *fractional cut*) will yield a tighter lower bound estimate on the value of the objective function.

Gomory fractional cuts were the first cutting planes proposed for Integer Linear Programming. However, several methods for strengthening these cuts have been proposed [BCCN96, BJ80, CCD95, Gom60, LL02]. In fact, Gomory [Gom60]

³See for example [NW88] for a definition of basic and non-basic variables.

himself proves that the cut

$$\sum_{i \in P} g(\alpha_i)x_i + \sum_{i \in Q} g(\beta_i)s_i \geq 1$$

$$\text{where } g(y) = \begin{cases} \frac{f(y)}{f(x_j^*)} & : f(y) \leq f(x_j^*) \\ \frac{1-f(y)}{1-f(x_j^*)} & : f(y) > f(x_j^*) \end{cases} \quad (28.30)$$

is stronger than (28.29) and satisfied by all solutions of (28.27). These cuts are known as Gomory *mixed-integer cuts*.

One should note that from (28.27) each slack variable depends only from the original problem variables and can be replaced in (28.29) by $s_i = \sum_{j \in N} a_{i,j}x_j - b_i$. Afterwards, if we apply the rounding operation on the non-integer coefficients we obtain a new pseudo-Boolean constraint valid for the original PBO instance, since the rounding operation will only weaken the constraint.

Since Gomory's original work, a large number of cutting plane techniques have been proposed [Bix94, Chv73, NW88]. For example, the Chvátal-Gomory cuts [Chv73] is another approach to produce cutting planes where the slack variables are not necessary. Chvátal proves that any Gomory cut can be generated using his approach by producing a new inequality through a weighted combination of inequalities (generalized resolution rule) followed by rounding. However, unlike Gomory, he does not present a systematic way for obtaining useful cuts.

In a modern Conflict-Driven algorithm, a conflict analysis procedure is carried out whenever a conflict arises [MSS96, MMZ⁺01]. Therefore, if a generated cutting plane is involved in the conflict analysis process, the algorithm must be able to determine the correct logical dependencies in order to backtrack to a valid node of the search tree. In order to do that, it is necessary to associate dependencies to the computed cutting plane [MMS06], thus enabling constraint learning and non-chronological backtracking from constraints inferred with cutting plane techniques.

28.6.7. Translation to SAT

Pseudo-Boolean constraints can be **translated to SAT** and surprisingly this approach can be quite efficient as first demonstrated by the minisat+ solver [ES06] in several evaluations of pseudo-Boolean solvers [MR07].

28.6.7.1. Translation of constraints

A naive approach is to translate a PB constraint as a set of clauses which is semantically equivalent and uses the same variables. Unfortunately, an exponential number of clauses can be generated (as is the case with cardinality constraints) and therefore this approach is unusable in the general case.

Other approaches will introduce extra variables to generate a short clausal formula F which is semantically equivalent to the PB formula P in an extended sense (all models of F restricted to the vocabulary of P are models of P and conversely, models of P can be extended to obtain models of F).

A very basic approach is to translate each PB constraint as a sequence of binary adders followed by a comparator. Let $\sum_j a_j x_j \geq b$ be the PB constraint to

translate. The first adder will sum the first two terms a_1x_1 and a_2x_2 to get partial sum S_2 . Successive adders will sum S_{i-1} and a_jx_j to obtain S_j . Notice that a_jx_j is simply obtained by replacing each 1 in the binary representation of a_j by the x_j variable. The last sum S_n is compared to b by a final comparator. The output of this comparator is constrained so that an inconsistency is generated when $S_n \geq b$ does not hold. A slightly refined version of this basic idea is detailed in [War98]. These adders and comparator can be encoded linearly as clauses by introducing extra variables and this encoding is obviously equivalent to the PB constraint. However, it does not let unit propagation maintain generalized arc consistency which means that unit propagation will not be able to infer that a variable must be assigned a value v whereas this is logically implied by the assignment of the other variables. The problem with this encoding lies in the sequence of adders. As soon as one single variable x_j is unassigned, each following partial sum is also undefined and the comparator cannot enforce any constraint. As an example, with constraint $x_1 + x_2 + x_3 + x_4 \geq 3$ and current assignment $x_1 = x_2 = 0$, no inconsistency will be detected until x_3 and x_4 are also assigned. This is of course a terrible source of inefficiency for a solver. On the same example, an encoding that would let unit propagation enforce generalized arc consistency would be able to infer that x_2, x_3 and x_4 must all be assigned true as soon as x_1 is assigned false.

To have unit propagation automatically enforce generalized arc consistency, a BDD-like (Binary Decision Diagram described in Part 1, Chapter 3) encoding may be used [ES06, BBR06]. The root of the BDD represents the constraint to encode: $\sum_{j=1}^n a_jx_j \geq b$. A node in the BDD will represent a constraint $\omega_{m,c}$ defined by $\sum_{j=m}^n a_jx_j \geq c$. A propositional variable $c_{m,c}$ is associated to each node to indicate if $\omega_{m,c}$ is satisfied. There are two possibilities to satisfy $\omega_{m,c}$ defined by $\sum_{j=m}^n a_jx_j \geq c$. The first possibility is that $x_m = 1$ and $\sum_{j=m+1}^n a_jx_j \geq c'$ with $c' = c - a_m$. The second one is that $x_m = 0$ and $\sum_{j=m+1}^n a_jx_j \geq c'$ with $c' = c$. Therefore, each node $\omega_{m,c}$ in the BDD will have at most two children: $\omega_{m+1,c-a_m}$ and $\omega_{m+1,c}$. Some nodes may have less than two children because some constraints are trivially false ($\omega_{m,c}$ for any $c > \sum_{j=m}^n a_j$) or trivially true ($\omega_{m,0}$ for any m) and the BDD is simplified. Besides, two nodes may share a child. For example, if $a_m = 1$ and $a_{m+1} = 1$, node $\omega_{m,c}$ will have two children $\omega_{m+1,b}$ and $\omega_{m+1,b-1}$ which will share a common child $\omega_{m+2,b-1}$. The relation between the truth of a node and the truth of its children is encoded in a few clauses which only depend on x_m and the propositional variables associated to both nodes. [ES06] used Tseitin transformation of BDD and [BBR06] uses a slightly different encoding. These encodings let unit-propagation maintain generalized arc consistency of the pseudo-Boolean constraint. Unfortunately, it generates encodings of exponential size for some constraints [BBR06].

The third encoding is founded on the unary representation of numbers [BB03, ES06]. In unary notation, a number between 0 and m will be represented by exactly m propositional variables. A number n is represented by exactly n variables set to true and all other variables set to false (the value of the number is the number of true variables). To represent that the left side of a constraint is currently comprised in $[a, b]$, a variables will be set to true, $m - b$ variables are set to false and the $b - a$ remaining variables are unassigned. Sorting networks can be

used and encoded as clauses to make sure that a number X will be represented by propositional variables x_1 to x_m such that each true variable precedes any unassigned variable and each unassigned variable comes before any false variable, i.e. $\exists a, b$ s.t. $\forall i \leq a, x_i = 1, \forall a < i \leq b, x_i$ is unassigned, $\forall i > b, x_i = 0$. With this normalized unary representation, the constraint $X \geq b$ is encoded by $x_b = 1$ and $X < b$ is encoded by $x_b = 0$ which are easily handled by a SAT solver. Unfortunately, unary representation of numbers is generally too large to be used in practice. [ES06] introduces another representation of numbers in a base represented by a sequence of positive integers denoted $\langle B_0, B_1, \dots, B_{n-1} \rangle$. Each B_i is a constant and $B_0 = 1$. A number is represented by a sequence of digits $\langle d_0, d_1, \dots, d_{n-1}, d_n \rangle$ such that $0 \leq d_i < B_i$ for $i < n$. The notation $\langle d_0, d_1, \dots, d_{n-1}, d_n \rangle$ represents the number $\sum_{i=0}^n d_i \cdot \prod_{j=0}^i B_j$. This representation is a generalization of the usual representation of numbers in a base B with the exception that the ratio of the weights of two successive digits is not a constant. In [ES06], each digit d_i is represented in unary notation. Therefore a number is represented by several blocks in unary notation and carries are used to propagate information between blocks. The strength of this encoding is that it is a drastic compression of the unary representation.

The solver minisat+ [ES06] chooses between these different representations (adder, BDD or unary-based representation) the most appropriate to encode each individual PB constraint.

28.6.7.2. Polynomial PB Encodings enforcing GAC by unit propagation

Until 2009, SAT encodings of PB constraints either did not allow unit propagation (UP) to maintain generalized arc consistency (GAC), or were exponential in the worst case. The first encoding which lets UP maintain GAC was proposed in [BBR09]. This encoding was not designed for efficiency, but rather as a proof of concept. We consider *less than* constraints $\sum_{j=1}^n a_j l_j < b$ that are non trivial ($\sum_{j=1}^n a_j \geq b$), and denote by $p + 1$ the number of bits required to encode the numbers a_j . A first step is to let unit propagation detect when this constraint is falsified. To this end, each coefficient is written in binary: $a_j = \sum_{i=0}^p a_j^i \cdot 2^i$. Next, to facilitate the comparison between the left and right side of the constraint, we add on both sides a constant t (the tare, which is also written in binary $t = \sum_{i=0}^p t^i 2^i$) such that $b + t$ is the smallest multiple of 2^p . Let m be the smallest integer such that $b + t = m 2^p$. The constraint is then written as $\sum_{i=0}^p 2^i (t^i + \sum_{j=1}^n a_j^i l_j) < m \cdot 2^p$. Terms with weight 2^i are grouped into a bucket $B_i = \langle t^i, a_0^i l_0, a_1^i l_1, \dots, a_n^i l_n \rangle$. These buckets only contain constants and literals and are easily sorted by unit propagation (by encoding a sorting network or a totalizer [BB03]) such that literals or constant set to 1 appear first in the bucket, unassigned literals appear next and literals or constant set to 0 appear last. Let B'_i be the sorted bucket corresponding to B_i . B'_i encodes in unary notation the current interval of possible values for the terms with weight 2^i . When bucket B'_i contains two consecutive 1s, a carry must be propagated to bucket B_{i+1} . To this end, we define the half of a sorted bucket $B'_i = \langle x_0, x_1, \dots, x_n \rangle$ as the bucket containing only variables with odd indexes: $\frac{1}{2} B'_i = \langle x_1, x_3, x_5, \dots, x_{2k+1}, \dots \rangle$. We can now redefine B_i as $\langle t^i, a_0^i l_0, a_1^i l_1, \dots, a_n^i l_n \rangle + \frac{1}{2} B'_{i-1}$ where $+$ on buckets represents both concatenation of contents and addition of the associated values, and

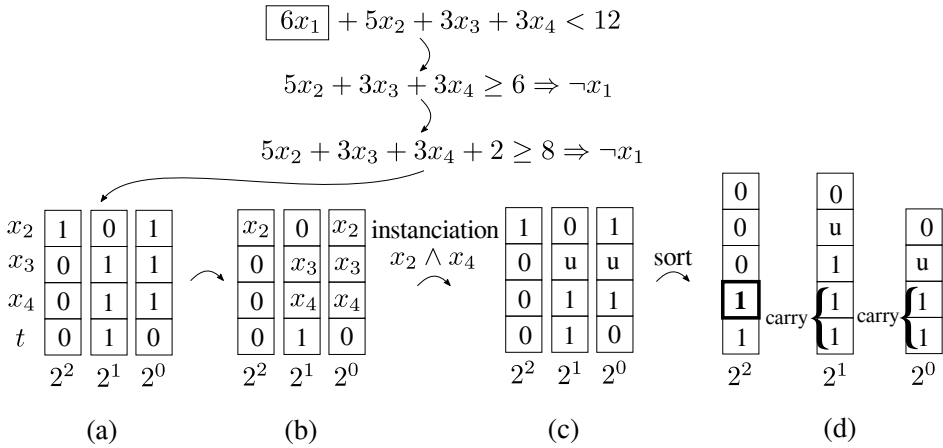

Figure 28.10. Example of propagation on the [BBR09] encoding. Given the constraint $6x_1 + 5x_2 + 3x_3 + 3x_4 < 12$, the example presents how it is detected if x_1 must be set to 0. Subfigure (a) presents the coefficients in binary and subfigure (b) presents the multiplication. Given an assignment $x_2 \wedge x_4$, subfigure (c) shows the instantiation of variables. Subfigure (d) presents the result after sorting and carry propagation. The 1 shown in bold (the m -th term of the last bucket) indicates that x_1 must be set to 0, because the left side of the bottom constraint is at least 8.

by convention B_{-1} is the empty bucket. With all this setup, a bucket B_i now represents in unary notation the sum of all terms with weight 2^j such that $j \leq i$. The constraint is falsified if and only if the left side of the rewritten constraint is equal to $m2^p$, which is true if and only if the m -th term of bucket B'_p is true, and this can be computed by unit propagation. This means that we can enforce the satisfaction on the constraint by setting the m -th term to 0. This encoding uses $O(n \log(n) \log(a_{max}))$ variables and $O(n^2 \log(n) \log(a_{max}))$ clauses, where a_{max} is the largest coefficient of the constraint.

The last step to enforce GAC with unit propagation is to consider each term of the constraint individually. As soon as $\sum_{j=1, j \neq i}^n a_j l_j \geq b - a_i$, l_i is necessarily false. In other words, l_i must be false whenever $\sum_{j=1, j \neq i}^n a_j l_j < b - a_i$ is falsified, which is detected by the above encoding when the m -th term of the last bucket is true. So for each literal l_i , we just have to encode $\sum_{j=1, j \neq i}^n a_j l_j < b - a_i$, identify the m -th term (x_m) of the last bucket and add the implication $x_m \Rightarrow \neg l_i$. This is sufficient to let unit propagation maintain GAC. Figure 28.10 illustrates unit propagation on this encoding.

28.6.8. Dealing with the Optimization Problem

Algorithm 28.3 presented in section 28.6.5 describes a generic approach for solving Pseudo-Boolean Optimization. In this case, a linear search on the possible values of the objective function is performed. The objective function $c(x_1, \dots, x_n)$ to be minimized is translated to a constraint $c(x_1, \dots, x_n) \leq ub - 1$ where ub is an inte-

Algorithm 28.4 Linear Search SAT-UNSAT

```

1: function LINEARSEARCH-SAT-UNSAT( $P, c$ )
2:    $ub \leftarrow \sum_{j \in N} c_j + 1$ 
3:   while true do
4:     if PBS( $P$ ) = SATISFIABLE then
5:        $ub \leftarrow \sum_{j \in N} c_j v(x_j)$ 
6:        $P \leftarrow P \cup \{\sum_{j \in N} c_j x_j \leq ub - 1\}$ 
7:     else
8:       return  $ub$ 
9:     end if
10:  end while
11: end function

```

ger which is modified at each iteration of the algorithm. Initially, ub is initialized with a value higher than the maximum value of the objective function. Each time a solution S is found, ub is set to $c(S)$ so that the constraint corresponding to the objective function imposes to find a strictly better solution than S . This process ends when the formula becomes unsatisfiable. Therefore, the last solution (if it exists) is an optimal solution.

The linear search approach can be viewed as a sequence of iterative calls to a Pseudo-Boolean Satisfiability (PBS) oracle that determines if a given Pseudo-Boolean formula P is satisfiable. Algorithm 28.4 summarizes this approach.

It should be noted that enforcing the constraint $c(x_1, \dots, x_n) \leq ub$ at each step of this algorithm does not necessarily require adding a new constraint to the formula. Some extra Boolean variables b_j can be introduced so that the single constraint $c(x_1, \dots, x_n) \leq ub - \sum_j 2^j b_j$ is introduced at the beginning of the algorithm. Initially, each b_j is set to false and for each new solution S , these variables are instantiated so that $ub - \sum_j 2^j b_j = c(S) - 1$. Furthermore, observe that the learned constraints in the PBS oracle remain valid between iterations. Hence, learned constraints from previous PBS calls can be used to cut the search space.

In the binary search approach, the objective function $c(x_1, \dots, x_n)$ is translated to the two constraints $lb \leq c(x_1, \dots, x_n)$ and $c(x_1, \dots, x_n) \leq ub$ where lb and ub are integers which are modified at each iteration of the algorithm. Initially, lb is set to the minimum value of the objective function (lower bound) and ub is set to a value higher than the maximum value of the objective function (upper bound). At each step, the middle M of interval $[lb, ub]$ is computed and solutions are searched in the interval $[lb, M]$. If a solution S is found, the search continues in the interval $[lb, c(S) - 1]$. Otherwise, the search is performed in the interval $[M + 1, ub]$ (this is mostly the usual binary search algorithm). Algorithm 28.5 summarizes this process using a PBS oracle. The last solution found by this algorithm (if any) is an optimal solution. This algorithm is known to converge faster toward the optimal solution, but will usually spend much more time than the linear search to find the first solutions. Moreover, when there is an unsatisfiable call to the PBS oracle, any learnt constraint which was inferred from the search bounds must be forgotten from one call of the PBS oracle to another, which may be difficult to implement.

Algorithm 28.5 Binary Search

```

1: function BINARYSEARCH( $P, c$ )
2:    $lb \leftarrow 0$ 
3:    $ub \leftarrow \sum_{j \in N} c_j + 1$ 
4:   while  $lb < ub$  do
5:      $M \leftarrow \frac{(lb+ub)}{2}$ 
6:     if  $\text{PBS}(P \cup \{lb \leq \sum_{j \in N} c_j x_j \leq M\}) = \text{SATISFIABLE}$  then
7:        $ub \leftarrow \sum_{j \in N} c_j v(x_j)$ 
8:     else
9:        $lb \leftarrow M + 1$ 
10:    end if
11:  end while
12:  return  $ub$ 
13: end function

```

28.6.8.1. Core-guided algorithms

Algorithm 28.4 is said to be a SAT-UNSAT linear search since the first calls to the PBS oracle are satisfiable, while the last call is unsatisfiable. However, one can also perform an UNSAT-SAT linear search on the value of the objective function. In this case, we define a lower bound lb (initially set to 0) and at each iteration a constraint $c(x_1, \dots, x_n) \leq lb$ is considered. If the PBS oracle call is unsatisfiable, then the lower bound is incremented and the constraint is replaced considering the new value for lb . The process is repeated until a satisfiable call is reached. When a satisfiable call is obtained, then an optimal solution was found, since all lower values of the objective function were already tried.

Observe that in this UNSAT-SAT algorithm, at each iteration, learned constraints that depend on the objective function constraint must be discarded. Moreover, all non-zero coefficients in the objective function must be considered in the constraint that limits the value of the objective function.

In the last decade, a plethora of new algorithms for Maximum Satisfiability (MaxSAT) have been proposed that resulted in a dramatic progress in MaxSAT solver performance for many real-world applications. Most of these algorithms perform an UNSAT-SAT search, but take advantage of the ability of SAT solvers to be able to identify a subset of clauses that are unsatisfiable (also known as unsatisfiable cores). Despite being proposed to solve MaxSAT, core-guided algorithms can also be used to solve Pseudo-Boolean Optimization.

There are several variants of MaxSAT. However, in the context of this chapter, MaxSAT refers to the more general weighted partial MaxSAT problem. Let (F_H, F_S) define a weighted partial MaxSAT problem such that F_H denotes the set of hard clauses and F_S denotes the set of soft clauses. For each soft clause ω_i there is a positive weight c_i that represents the cost of not satisfying ω_i . Given a MaxSAT instance (F_H, F_S) , the goal is to find an assignment such that it satisfies all hard clauses in F_H and minimizes the sum of the weights of unsatisfied soft clauses in F_S .

Weighted Boolean Optimization (WBO) is a generalization of MaxSAT. A WBO instance (F_H, F_S) is defined in the same way as MaxSAT, but hard constraints in F_H and soft constraints in F_S can be pseudo-Boolean constraints [MMSP09]. Given a pseudo-Boolean Optimization instance defined over a set

Algorithm 28.6 MSU3 for Weighted Boolean Optimization

```

1: function MSU3( $(F_H, F_S)$ )
2:    $lb \leftarrow 0$ 
3:    $V_R \leftarrow \emptyset$ 
4:    $P \leftarrow F_H \cup F_S$ 
5:   while true do
6:      $(st, v, C) \leftarrow \text{PBS}(P \cup \{\sum_{r_j \in V_R} c_j r_j \leq lb\})$ 
7:     if  $st = \text{SATISFIABLE}$  then
8:       return  $\sum_{r_j \in V_R} c_j v(r_j)$ 
9:     end if
10:    for all  $\omega_j \in (C \cap F_S)$  do
11:       $V_R \leftarrow V_R \cup \{r_j\}$ 
12:       $\omega_R \leftarrow \omega_j \vee r_j$ 
13:       $P \leftarrow (P \setminus \{\omega_j\}) \cup \{\omega_R\}$ 
14:    end for
15:     $lb \leftarrow lb + 1$ 
16:  end while
17: end function

```

of constraints P and an objective function $\sum_{j \in N} c_j x_j$, one can build the corresponding WBO (F_H, F_S) instance as follows: (i) define $F_H = P$ as the hard constraints and (ii) for each term $c_j x_j$ in the objective function, add $\bar{x}_j \geq 1$ with a weight of c_j to F_S . Clearly, an optimal solution of the WBO instance is also a solution of the pseudo-Boolean Optimization instance.

MaxSAT algorithms based on iterative calls to a SAT solver can be easily adapted to solve WBO (and pseudo-Boolean Optimization as a result). One just needs to replace each call to a SAT solver with a call to a PBS solver. However, in order to use a core-guided algorithm, the PBS solver to use must be able to identify an unsatisfiable core of the formula.

As an example of adaptation of MaxSAT algorithms, a generalization of the MSU3 [MP07] algorithm is presented to solve a WBO instance (F_H, F_S) . Algorithm 28.6 follows a core-guided linear UNSAT-SAT search. First, the algorithm starts by initializing the lower bound to 0 and building a pseudo-Boolean satisfiability formula joining both hard and soft constraints (line 4). Next, an iterative process starts by calling a PBS oracle (line 6). Note that at each call of the PBS oracle, a constraint is considered such that the total weight of unsatisfied soft constraints is not larger than lb .

In this algorithm, the PBS oracle returns a triple (st, v, C) where st denotes if the formula is satisfiable or unsatisfiable, v contains an assignment if the formula is satisfiable, and C contains an unsatisfiable core if the formula is unsatisfiable. Whenever the PBS oracle returns unsatisfiable, for each soft constraint ω_j in the unsatisfiable core C , a new relaxation variable r_j is created and added to V_R . The cost c_j of unsatisfying soft constraint ω_j is associated with variable r_j . Next, a new constraint ω_R is build such that r_j must be assigned to true if the original soft constraint ω_j is not satisfied (line 12), and ω_j is replaced by ω_R in P (line 13). Moreover, at each iteration, the lower bound is incremented ⁴ Finally, the algorithm ends when the PBS oracle returns a satisfiable assignment that

⁴Depending on the values for the weights of soft constraints, the lower bound can be increased by more than one [MHL⁺13].

corresponds to an optimal solution.

We refer to Chapter 23 and 24 for an extensive explanation of core-guided algorithms, as well as further details on these algorithms, such as different techniques of incremental implementation. Nevertheless, it should be noted that core-guided algorithms can also be adapted to pseudo-Boolean optimization (as exemplified in this section) or other optimization problems such as Maximum Satisfiability Modulo theories [BN15]. Moreover, many core-guided and linear search algorithms for MaxSAT rely on efficient usage of cardinality and pseudo-Boolean constraints. In fact, several current state of the art algorithms for MaxSAT rely on effective translations of cardinality and pseudo-Boolean constraints.

28.7. Conclusion

Pseudo-Boolean constraints offer a rich framework for knowledge representation and inference and still remain close enough to the well-known SAT problem and the integer linear programming paradigm to benefit from the experience in both fields. Pseudo-Boolean constraints are more expressive than clauses and optimization problems can be naturally expressed in this formalism. Proofs in the pseudo-Boolean formalism can be exponentially shorter than in the clausal formalism, and pseudo-Boolean encodings can be exponentially shorter than clausal encodings.

Pseudo-Boolean solvers integrate techniques from both the SAT and ILP community. Integer Linear Programming techniques usually focus on identifying the optimal non-integer solution and then will try to identify integral solutions close to this optimal non-integer solution. In contrast, SAT techniques focus on identifying integral solution and search for the optimal solution among them. The integration of these techniques is undoubtedly a promising method to solve a variety of problems (both decision and optimization problems).

At this time, it is hard to identify one kind of algorithm among the existing solvers as the most efficient to solve pseudo-Boolean problems. The pseudo-Boolean field has not yet reached the same maturity as SAT solving and a number of major improvements can be expected in the coming years. Solving pseudo-Boolean formulas raises new challenges, both from a theoretical and implementation point of view. Trade-offs between inference power and inference speed are often made in current algorithms and the right balance is still sought. We can expect that, once the right balance is found, pseudo-Boolean solvers will become a major tool in problem solving.

Chapter 29

Theory of Quantified Boolean Formulas

Hans Kleine Büning and Uwe Bubeck

29.1. Introduction

Quantified Boolean formulas are a natural extension of propositional formulas by allowing universal (\forall) and existential (\exists) quantifiers. Roughly speaking, a formula $\exists x\phi$ is true if there is a truth assignment to the variable x , such that ϕ is true for this truth value. Analogously, $(\forall x\phi)$ is true if ϕ is true for all truth values. The use of quantifiers results in a greater expressive power, but also in more complex problems. For instance, the satisfiability of a propositional formula ϕ over the variables x_1, \dots, x_n can be expressed by $\exists x_1 \dots \exists x_n \phi$ being true, and the question whether two propositional formulas α and β are logically equivalent can be represented as $\forall x_1 \dots \forall x_n (\alpha \leftrightarrow \beta)$ being true.

This chapter is devoted to foundations and the theory of quantified Boolean formulas and organized as follows: First, we introduce the syntax and the semantics of quantified Boolean formulas including various normal forms. Then we present some complexity results mainly for the satisfiability and the equivalence problem for the class of quantified Boolean formulas and some subclasses. Thereafter, we discuss the expressive power, and based on a more functional view of the valuation of formulas, we show some results on satisfiability and equivalence models. Then we introduce Q-resolution as an extension of the resolution calculus for propositional formulas. The last section is devoted to two special subclasses of quantified Boolean formulas.

29.2. Syntax and Semantics

We will now introduce quantified Boolean formulas. Formulas will be denoted by upper or lower Greek letters, and variables by lower case Latin letters. Besides the universal quantifier \forall and the existential quantifier \exists , the inductive definition makes use of the logical connectives \wedge (and), \vee (or), and the negation \neg . Additionally, for technical reasons, quantified Boolean formulas may contain the Boolean constants true (1) and false (0).

Definition 29.2.1. *Quantified Boolean formulas (QBF^{*})*

The set of *quantified Boolean formulas* is inductively defined as follows:

1. Propositional formulas and the Boolean constants 1 (true) and 0 (false) are quantified Boolean formulas.
2. If Φ is a quantified Boolean formula, then $\exists x\Phi$ and $\forall x\Phi$ are quantified Boolean formulas.
3. If Φ_1 and Φ_2 are quantified Boolean formulas, then $\neg\Phi_1$, $\Phi_1 \vee \Phi_2$ and $\Phi_1 \wedge \Phi_2$ are quantified Boolean formulas.
4. Only formulas given by (1) to (3) are quantified Boolean formulas.

A literal is a variable or a negated variable. We say, a literal L is positive if L is a variable, and a negative literal otherwise. The set of variables in a formula Φ is denoted as $var(\Phi)$. For $\forall x\phi$ (resp. $\exists x\phi$), the occurrence of x in $\forall x$ (resp. $\exists x$) is called a quantified occurrence, where ϕ is the scope of the quantified variable x . An occurrence of the variable x is bound if the occurrence is in the scope of $\forall x$ or $\exists x$. All the non-quantified occurrences of a variable, which are not in the scope of a quantification, are free occurrences. A variable is called *free* (resp. *bound*) in a formula Φ if there is a free (resp. bound) occurrence in Φ . A formula is termed *closed* if and only if the formula contains no free variables.

In the formula $\Phi = (\forall x(x \vee y)) \wedge (x \vee z)$, the first occurrence of x is a quantified occurrence, the second one is bound, and the third one is a free occurrence. The variable x is free and bound in the formula Φ . The variables y and z are free, but not bound. The scope of the variable x in the quantification $\forall x$ is the formula $(x \vee y)$.

The semantics is defined as an extension of the semantics of propositional formulas. Besides the truth assignment to the free variables, the evaluation of a formula is based on the structure of the formula. In addition to propositional formulas, we have to take into account the cases $\exists x$ and $\forall y$. The idea is that in case of a universal quantification, the formula $\forall x\phi$ is true if the formula ϕ is true for all truth assignments to x . An existential quantification $\exists x\phi$ should be true if there is some truth assignment to x , such that ϕ is true.

Definition 29.2.2. *Evaluation*

Let Φ be a quantified Boolean formula with free variables z_1, \dots, z_n . Then a truth assignment \mathfrak{S} is a mapping $\mathfrak{S}: \{z_1, \dots, z_n\} \rightarrow \{0, 1\}$ which satisfies the following conditions:

$$\begin{aligned}
 \Phi = z_i : & \quad \mathfrak{S}(\Phi) = \mathfrak{S}(z_i) \text{ for } 1 \leq i \leq n \\
 \Phi = 0 : & \quad \mathfrak{S}(\Phi) = 0 \\
 \Phi = 1 : & \quad \mathfrak{S}(\Phi) = 1 \\
 \Phi = \neg\Phi' : & \quad \mathfrak{S}(\neg\Phi') = 1 \iff \mathfrak{S}(\Phi') = 0 \\
 \Phi = \Phi_1 \vee \Phi_2 : & \quad \mathfrak{S}(\Phi_1 \vee \Phi_2) = 1 \iff \mathfrak{S}(\Phi_1) = 1 \text{ or } \mathfrak{S}(\Phi_2) = 1 \\
 \Phi = \Phi_1 \wedge \Phi_2 : & \quad \mathfrak{S}(\Phi_1 \wedge \Phi_2) = 1 \iff \mathfrak{S}(\Phi_1) = \mathfrak{S}(\Phi_2) = 1 \\
 \Phi = \exists y\Phi' : & \quad \mathfrak{S}(\exists y\Phi') = 1 \iff \mathfrak{S}(\Phi'[y/0]) = 1 \text{ or } \mathfrak{S}(\Phi'[y/1]) = 1 \\
 \Phi = \forall x\Phi' : & \quad \mathfrak{S}(\forall x\Phi') = 1 \iff \mathfrak{S}(\Phi'[x/0]) = \mathfrak{S}(\Phi'[x/1]) = 1.
 \end{aligned}$$

$\Phi'[z_1/a_1, \dots, z_n/a_n]$ denotes the simultaneous substitution of free occurrences of z_i by a_i in Φ' .

Example: Given is the formula $\Phi = \forall x \exists y ((x \vee y \vee z) \wedge (x \vee \neg y))$ and the truth assignment $\mathfrak{S}(z) = 1$ to the free variable z .

$$\mathfrak{S}(\Phi) = 1$$

$$\iff \mathfrak{S}(\exists y(\phi_1 \wedge \phi_2)[x/0]) = 1 \text{ and } \mathfrak{S}(\exists y(\phi_1 \wedge \phi_2)[x/1]) = 1$$

$$\iff (\mathfrak{S}((\phi_1 \wedge \phi_2)[x/0, y/0]) = 1 \text{ or } \mathfrak{S}((\phi_1 \wedge \phi_2)[x/0, y/1]) = 1) \text{ and} \\ (\mathfrak{S}((\phi_1 \wedge \phi_2)[x/1, y/0]) = 1 \text{ or } \mathfrak{S}((\phi_1 \wedge \phi_2)[x/1, y/1]) = 1)$$

$$\iff (\mathfrak{S}((0 \vee 0 \vee z) \wedge (0 \vee 1)) = 1 \text{ or } \mathfrak{S}((0 \vee 1 \vee z) \wedge (0 \vee 0)) = 1) \text{ and} \\ (\mathfrak{S}((1 \vee 0 \vee z) \wedge (1 \vee 1)) = 1 \text{ or } \mathfrak{S}((1 \vee 1 \vee z) \wedge (1 \vee 0)) = 1)$$

$$\iff (\mathfrak{S}(z) = 1 \text{ or } \mathfrak{S}(0) = 1) \text{ and } (\mathfrak{S}(1) = 1 \text{ or } \mathfrak{S}(1) = 1)$$

$$\iff \mathfrak{S}(z) = 1$$

The formula is true for the truth assignment $\mathfrak{S}(z) = 1$ and false for the truth assignment $\mathfrak{S}(z) = 0$.

Definition 29.2.3. A formula $\Phi \in QBF^*$ is *satisfiable* if and only if there is a truth assignment \mathfrak{S} with $\mathfrak{S}(\Phi) = 1$. Φ is termed *unsatisfiable* (or *inconsistent*) if and only if Φ is not satisfiable.

If Φ contains no free variables, we also say that Φ is *true* (respectively *false*) if Φ is satisfiable (respectively unsatisfiable).

A formula Φ_2 is a *consequence* of Φ_1 ($\Phi_1 \models \Phi_2$) if and only if for all truth assignments \mathfrak{S} we have $\mathfrak{S}(\Phi_1) = 1 \implies \mathfrak{S}(\Phi_2) = 1$. Φ_1 is *logically equivalent* to Φ_2 ($\Phi_1 \approx \Phi_2$) if and only if $\Phi_1 \models \Phi_2$ and $\Phi_2 \models \Phi_1$.

Two formulas Φ_1 and Φ_2 are called *satisfiability equivalent* (\approx_{sat}) if and only if (Φ_1 is satisfiable $\iff \Phi_2$ is satisfiable).

Since closed formulas do not contain free variables, two closed formulas are logically equivalent if and only if these formulas are satisfiability equivalent. Obviously, any quantified Boolean formula Φ with free variables z_1, \dots, z_n is satisfiable if and only if after binding the free variables by existential quantifiers the formula is true. That is, Φ is satisfiable if and only if $\exists z_1 \dots \exists z_n \Phi$ is true. The syntax of quantified Boolean formulas allows us to construct the following formulas:

$$\Phi_1 = (\forall x \phi_1) \wedge (\forall x \phi_2) \text{ and } \Phi_2 = (\forall x (\neg x)) \wedge (x \vee y).$$

In Φ_1 , two distinct occurrences of the quantifier \forall have the same variable x . In the second formula Φ_2 , the variable x is free and bound. In order to avoid distinct occurrences of quantifiers having the same variable name or variables occurring both free and bound, we can rename the quantified variables. For instance, in Φ_1 , we replace the first subformula $\forall x \phi_1$ with $\forall x' \phi'_1$, where x' is a new variable and ϕ'_1 is the result of substituting x' for all free occurrences of x . Similarly, we perform this on the formula Φ_2 , replacing $\forall x (\neg x)$ with $\forall x' (\neg x')$. It is straightforward to see that such renamings preserve the logical equivalence between the initial and the resulting formula. Moreover, we can delete quantifiers whose variables do not occur in the scope of the quantifier. For instance, the variable y is not in the scope $(x \vee z)$ of $\exists y$ in the formula $\forall x \exists y (x \vee z)$. So we can delete the quantification $\exists y$. The formulas satisfying the following two conditions are called *cleansed* or *polite*:

1. Two distinct occurrences of quantifiers have distinct quantification variables.

2. Let $Q \in \{\forall, \exists\}$ and $Qx\phi$ be a subformula in Φ , then x is free in ϕ and not free in Φ .

Any quantified Boolean formula can be transformed into a cleansed formula in linear time via renaming. Subsequently, we assume that all formulas satisfy the conditions. In case of formulas with a propositional constant 0 and/or 1, the following simplification rules can be used to reduce the formula

$$\neg 1 \approx 0, \neg 0 \approx 1, \Phi \wedge 0 \approx 0, \Phi \vee 0 \approx \Phi, \Phi \wedge 1 \approx \Phi, \Phi \vee 1 \approx 1$$

A formula Φ is in *negation normal form* (NNF) if and only if every negation symbol occurs immediately in front of a variable. For instance, $\forall x(\neg x \vee z)$ is in NNF, whereas $\neg(\exists x(x \vee z))$ and $\exists y(\neg\neg y)$ are not in negation normal form. In addition to De Morgan's law and the negation law, which are sufficient for propositional formulas, we have to switch the quantifiers. Any quantified Boolean formula can be transformed into a formula in NNF by the following rules:

$$\begin{aligned} \neg(\Phi_1 \vee \Phi_2) &\approx \neg\Phi_1 \wedge \neg\Phi_2 \text{ and } \neg(\Phi_1 \wedge \Phi_2) \approx \neg\Phi_1 \vee \neg\Phi_2 \\ \neg\neg\Phi &\approx \Phi \\ \neg(\exists x\phi) &\approx \forall x\neg\phi \\ \neg(\forall x\phi) &\approx \exists x\neg\phi \end{aligned}$$

A quantified Boolean formula Φ is in *prenex (normal) form* if the formula consists of a sequence of quantifiers (the *prefix*) followed by a quantifier-free propositional formula, the so-called *matrix* or kernel. A formula Φ in prenex form can be written as $\Phi = Q_1 z_1 \dots Q_n z_n \phi$, where $Q_i \in \{\forall, \exists\}$, z_i are variables and ϕ is the matrix. We sometimes use the notation $\Phi = Q\phi$, where Q is the prefix of the formula and ϕ is the matrix.

If the matrix of a quantified Boolean formula has a particular structure, the abbreviation BF in QBF is replaced with the abbreviation of that class. For example, QCNF* denotes the class of quantified Boolean formulas in prenex form with matrix in CNF. CNF is the class of propositional formulas in conjunctive normal form. HORN is the class of propositional Horn formulas, that means any clause contains at most one positive literal. k -CNF is the class of propositional formulas consisting of k -clauses. A k -clause is a disjunction of at most k literals. If we restrict ourselves to closed formulas, i.e. formulas without free variables, we omit the asterisk *. For instance, Q3-CNF is the class of closed formulas with matrix in 3-CNF.

The length of a quantified Boolean formula is the number of occurrences of variables. Please notice that this definition includes the variables in the prefix. We write $|\Phi|$ in order to denote the length of Φ .

Every quantified Boolean formula can be transformed into a logically equivalent formula in prenex form. For a formula Φ , we first construct a logically equivalent formula Φ' in negation normal form. In general, $(\forall x\phi_1) \vee (\forall x\phi_2)$ is not logically equivalent to $\forall x(\phi_1 \vee \phi_2)$. But that case cannot occur, because we are dealing with cleansed formulas. That is, distinct occurrences of quantifiers have distinct variable names.

In order to generate formulas in prenex form, we can apply the following rules to a formula Φ' :

$$\begin{aligned} (\forall x\phi) \vee \Phi &\approx \forall x(\phi \vee \Phi) \\ (\forall x\phi) \wedge \Phi &\approx \forall x(\phi \wedge \Phi) \\ (\exists x\phi) \wedge \Phi &\approx \exists x(\phi \wedge \Phi) \\ (\exists x\phi) \vee \Phi &\approx \exists x(\phi \vee \Phi) \end{aligned}$$

More sophisticated prenexing strategies can be borrowed from procedures well-known for first-order logic or can be found specially for QBFs for example in [EST⁺04].

Lemma 29.2.1. *Any quantified Boolean formula Φ can be transformed into a logically equivalent formula which is cleansed and in prenex form. The time required is linear in the length of Φ .*

It is well-known that any propositional formula in NNF can be transformed into a logically equivalent formula in CNF by means of the distributive laws $(\alpha \vee \beta) \wedge \sigma \approx (\alpha \wedge \sigma) \vee (\beta \wedge \sigma)$ and $(\alpha \wedge \beta) \vee \sigma \approx (\alpha \vee \sigma) \wedge (\beta \vee \sigma)$. We can apply these rules to the propositional matrix of a quantified Boolean formula in prenex form and obtain a formula in QCNF*. But the problem is the possibly exponential growth of the formula. In order to avoid this critical process, we make use of the well-known procedure introduced in [Tse70].

For propositional formulas in NNF, we replace subformulas of the form $\alpha \vee (\beta \wedge \gamma)$ with $((\alpha \vee \neg x) \wedge (\beta \vee x) \wedge (\gamma \vee x))$, where x is a new variable. Finally, we obtain a formula in CNF. Both formulas are satisfiability equivalent, but in general not logically equivalent. If we bind the new variable x by an existential quantifier, we have

$$\alpha \vee (\beta \vee \gamma) \approx \exists x((\alpha \vee \neg x) \wedge (\beta \vee x) \wedge (\gamma \vee x)).$$

Let $\Phi = Q\phi$ be a formula in prenex form, x_1, \dots, x_n the new variables introduced by the above procedure, and ϕ' the conjunction of the derived clauses. Then we have

$$\Phi \approx Q\exists x_1 \dots \exists x_n \phi' \text{ in QCNF*}.$$

Since three new literals are added for every subformula of the form $\alpha \vee (\beta \wedge \gamma)$ in Φ and the number of such subformulas is bounded by the length of Φ , the length of the resulting CNF formula is linear in the length of Φ .

Similar to the propositional case, we can transfer arbitrary QCNF* formulas into logically equivalent Q3-CNF* formulas in linear time as follows. Let $\Phi = Q\phi$ be a formula in QCNF*. We replace any clause $\varphi = (L_1 \vee \dots \vee L_n)$ containing more than three literals with the sequence of clauses $\varphi' = (L_1 \vee L_2 \vee x_1), (\neg x_1 \vee L_2 \vee x_2), (\neg x_2 \vee L_3 \vee x_3), \dots, (\neg x_{n-2} \vee L_{n-1} \vee L_n)$ for new variables x_1, \dots, x_{n-2} . Binding the newly introduced variables existentially, we obtain not only satisfiability equivalence, but also logical equivalence $\varphi \approx \exists x_1 \dots \exists x_{n-2} \varphi'$.

Let ϕ' be the result of replacing all clauses of length greater than 3 with the conjunction of 3-clauses, and let x_1, \dots, x_m be the new variables. Then we have

$$\Phi \approx Q\exists x_1 \dots \exists x_m \phi' \text{ in Q3-CNF*}.$$

Besides Q3-CNF*, for every fixed $k \geq 3$, we can generate a logically equivalent formula in Q k -CNF* by adapting the substitution to k -clauses. But for Q2-CNF*, no polynomial-time procedure is known, and assuming that PSPACE does not equal P, such a transformation cannot exist. We summarize the previous remarks on transformations in the following lemma.

Lemma 29.2.2. *For $k \geq 3$, any QBF* formula Φ can be transformed into a logically equivalent QCNF* and Q k -CNF*. The time is linear in the length of Φ .*

Besides the above mentioned simplifications and transformations, a formula in QCNF* can be reduced according to the following observations. Let Φ be a formula in QCNF*:

1. If Φ is not a tautology, all tautological clauses can be deleted preserving the logical equivalence.
2. If Φ contains a non-tautological clause with only universal variables, then the formula is unsatisfiable (false).
3. *Universal Reduction / ForAll Reduction:*

Suppose Φ contains a non-tautological clause $(\varphi \vee x)$, where x is a universally quantified variable and φ is a subclause. If there is no existentially quantified variable in φ , or if every existentially quantified variable in φ occurs in the prefix before the variable x , we can delete the variable x while preserving the logical equivalence.

An example is the formula $\exists y \forall x \exists y_1 ((\neg y \vee \neg x) \wedge (y \vee \neg x \vee y_1) \wedge (z \vee x))$. In the first clause, $\neg x$ can be deleted, because y occurs in the prefix before x . In the second clause, x is followed by y_1 . The clause remains unchanged. And in the last clause, we have the free variable z but no existentially quantified variable. We can remove x . The result is the formula $\exists y \forall x \exists y_1 ((\neg y) \wedge (y \vee \neg x \vee y_1) \wedge z)$.

4. *Unit Propagation:*

If Φ contains a clause $C = y^\epsilon$ with a single existential literal y^ϵ ($y^0 := \neg y$ and $y^1 := y$), then logical equivalence is preserved when we assign $y = \epsilon$ by replacing all occurrences of y^ϵ in ϕ with 1 and all occurrences of $y^{1-\epsilon}$ with 0. In the formula from above, $\neg y$ is an existential unit which can be propagated. We obtain the formula $\forall x \exists y_1 ((\neg x \vee y_1) \wedge z)$.

5. *Pure Literal Detection:*

If Φ contains a quantified variable v which occurs only positively or only negatively in ϕ , then logical equivalence is preserved in the following cases:

- (a) if v is existentially quantified and all clauses containing v are deleted from Φ .
- (b) or if v is universally quantified and the occurrences of v are removed from all clauses of ϕ .

In the previous example, y_1 occurs only positively, so we can delete the first clause. We can conclude that the formula is equivalent to just z .

29.3. Complexity Results

The satisfiability problem for quantified Boolean formulas, often denoted as QSAT, is the problem of deciding whether or not a quantified Boolean formula is satisfiable. It was shown in [MS73] that for quantified Boolean formulas without free variables, QSAT is solvable in polynomial space and complete for PSPACE. By the previous remarks on transformations of QBF* into QCNF* and Q3-CNF*, we see that the satisfiability problem for Q3-CNF* is PSPACE-complete, too. Since $\text{PSPACE} = \text{NPSPACE}$ [Sav70], that means problems solvable non-deterministically in polynomial space are also solvable deterministically in polynomial space, we immediately obtain the PSPACE-completeness of the complement of QSAT, the set of unsatisfiable formulas. According to this observation, we can conclude that the consequence and the equivalence problems are also PSPACE-complete. The consequence problem (respectively equivalence problem) is to decide whether for arbitrarily given formulas Φ_1 and Φ_2 we have $\Phi_1 \models \Phi_2$ (respectively $\Phi_1 \approx \Phi_2$).

Theorem 29.3.1. *The following problems are PSPACE-complete:*

1. *Satisfiability problem for QBF* and Q3-CNF**
2. *Consequence problem for QBF*.*
3. *Equivalence problem for QBF*.*

In contrast to propositional formulas, for which the satisfiability problem for formulas in disjunctive normal form (DNF) is solvable in polynomial time, the satisfiability problem for QDNF remains PSPACE-complete. That follows directly from the fact that the unsatisfiability problem for QCNFs remains PSPACE-complete, and a negation of formulas in QCNF can be transferred into a formula in QDNF by moving the negation symbols inside.

From an application perspective, it is interesting to notice that various verification problems are also PSPACE-complete, e.g. propositional linear temporal logic (LTL) satisfiability [SC85] or symbolic reachability in sequential circuits [Sav70]. Thus it seems quite natural to solve such problems by encoding them as quantified Boolean formulas.

The satisfiability problem for Q2-CNF* and for QHORN* is solvable in polynomial time, which will be discussed in Section 29.6. In order to reduce the worst-case complexity of the satisfiability problem, mainly two approaches have been considered. One is to restrict the matrix to certain subclasses of propositional formulas, and the second is to consider bounded alternations of quantifiers. Next, we introduce the prefix type of formulas in prenex form. Roughly speaking, Σ_n (respectively Π_n) is the set of formulas with an outermost existential (respectively universal) quantifier and n alternations.

Definition 29.3.1. *Prefix Type of Quantified Boolean Formulas*

Every propositional formula has the prefix type $\Sigma_0 = \Pi_0$ (empty prefix). Let Φ be a quantified Boolean formula with prefix type Σ_n (respectively Π_n), then the formula $\forall x_1 \cdots \forall x_n \Phi$ (respectively $\exists y_1 \cdots \exists y_n \Phi$) is of type Π_{n+1} (respectively Σ_{n+1}).

For instance, the formula $\Phi = \forall x \exists y \forall z \phi$ with matrix ϕ is in Π_3 , because ϕ is in Σ_0 , $\forall z \phi \in \Pi_1$, and $\exists y \forall z \phi \in \Sigma_2$. Please note that any closed quantified Boolean formula containing at least one variable is of prefix type Σ_k or Π_k with $k \geq 1$.

There is a strong connection to the polynomial-time hierarchy, introduced in [MS72]. The polynomial-time hierarchy is defined as follows ($k \geq 0$):

$$\Delta_0^P := \Sigma_0^P := \Pi_0^P := P$$

$$\Sigma_{k+1}^P := NP^{\Sigma_k^P}, \quad \Pi_{k+1}^P := co\Sigma_{k+1}^P, \quad \Delta_{k+1}^P := P^{\Sigma_k^P}$$

Δ_{k+1}^P (respectively Σ_{k+1}^P) is the class of all problems which can be decided deterministically (respectively non-deterministically) in polynomial time with the help of an oracle for a problem in Σ_k^P . An oracle is a subroutine which solves a problem in the complexity class Σ_k^P . This subroutine is called in the program, but it contributes only $O(1)$ to the complexity of this program. The class Π_{k+1}^P contains every problem whose complement is in Σ_{k+1}^P . We have $\Sigma_1^P = NP$, $\Pi_1^P = coNP$ and $\Delta_1^P = P$. For $k \geq 1$, we obtain $\Delta_k^P \subseteq \Sigma_k^P \cap \Pi_k^P$. The following theorem has been proved in [Sto76, Wra76].

Theorem 29.3.2. *For $k \geq 1$, the satisfiability problem for quantified Boolean formulas with prefix type Σ_k is Σ_k^P -complete, and for formulas with prefix type Π_k , it is Π_k^P -complete.*

Another approach to characterize classes of quantified Boolean formulas with respect to the complexity of the satisfiability problem is the so-called dichotomy theorem [Sch78]. Let C be a set of Boolean functions $\{f_1, \dots, f_n\}$, where the n_i -ary functions f_i are often called *constraints*. For $1 \leq i \leq n$ let \mathbf{x}_i be a n_i -tuple of not necessarily distinct variables. Then $f_i(\mathbf{x}_i)$ is called a constraint application, and a finite conjunction of constraint applications is denoted as $F(y_1, \dots, y_t)$, where y_1, \dots, y_t are the occurring variables.

We say, the expression $F(y_1, \dots, y_t)$ is satisfiable if and only if there is a truth assignment to the variables y_i , such that the expression is true. Obviously, the complexity of the satisfiability problem for such classes of expressions essentially depends on the set of Boolean functions C . A *quantified constraint expression* has the form

$$Q_1 y_1 \dots Q_n y_n F(y_1, \dots, y_n), \text{ where } Q_i \in \{\forall, \exists\}.$$

Let C be a finite set of constraints. QC is the set of quantified expressions $Q_1 y_1 \dots Q_n y_n F(y_1, \dots, y_n)$, where $Q_i \in \{\forall, \exists\}$ and $F(y_1, \dots, y_n)$ is a conjunction of constraint applications from C . If the constraint applications can include nullary functions (the propositional constants 0 and 1), the class is denoted as $Q_c(C)$. Please notice that QC as well as $Q_c(C)$ do not contain formulas with free variables.

We next classify constraints according to whether the constraints (Boolean functions) can be represented as propositional formulas of a special form.

Definition 29.3.2. Let f be a constraint.

1. f is *Horn* if and only if f is equivalent to a Horn formula.
2. f is *anti-Horn* if and only if f is equivalent to a conjunction of clauses which contain at most one negative literal.

3. f is *bijunctive* if and only if f is equivalent to a 2-CNF formula.
4. f is *affine* if and only if f is equivalent to a XOR-CNF formula, i.e. a conjunction of clauses of the form $(x_1 \oplus \dots \oplus x_n = 1)$ or $(x_1 \oplus \dots \oplus x_n = 0)$, where \oplus denotes addition modulo 2.

A finite set of constraints C is called Horn (anti-Horn, bijunctive, affine, respectively), if every constraint in C is Horn (anti-Horn, bijunctive, affine, respectively). The satisfiability problem for quantified constraint applications is denoted as QSAT(C), and in case of applications with constants as QSAT $_c$ (C).

Theorem 29.3.3. Dichotomy Theorem [Sch78, Dal97, CKS01]

Let C be a finite set of constraints. If C is Horn, anti-Horn, bijunctive, or affine, then QSAT(C) and QSAT $_c$ (C) are in P, otherwise QSAT(C) and QSAT $_c$ (C) are PSPACE-complete.

The Dichotomy Theorem immediately implies that the satisfiability problem for Q2-CNF is solvable in polynomial time. For instance, let $C_2 = \{f_1, f_2, f_3\}$ be the set of Boolean functions, where the functions are given as 2-clauses

$$f_1(x, y) = x \vee y, f_2(x, y) = (\neg x \vee y), \text{ and } f_3(x, y) = (\neg x \vee \neg y).$$

Every conjunction of constraint applications coincides to a formula in 2-CNF and vice versa. For instance,

$$f_1(x_1, x_3) \wedge f_1(x_2, x_2) \wedge f_2(x_3, x_2) \approx (x_1 \vee x_3) \wedge (x_2 \vee x_2) \wedge (\neg x_3 \vee x_2).$$

That shows that QSAT(C_2) is in P if and only if the satisfiability problem for Q2-CNF is polynomial-time solvable.

In QHORN, clauses may have an arbitrary length and can therefore not directly be represented by a finite set of constraints. But every formula in QHORN can be transformed into an equivalent Q3-HORN formula. To the possible types of 3-clauses, we can associate a finite set of constraints \mathcal{H} , which is Horn. For instance, for 3-clauses with one positive literal, we define $f(x_1, x_2, x_3) = (x_1 \vee \neg x_2 \vee \neg x_3)$. Since the satisfiability problem QSAT(\mathcal{H}) is in P, we obtain the polynomial-time solvability of the satisfiability problem for QHORN. In [Sch78], the dichotomy theorem has been shown for non-quantified expressions. For QSAT(C) and QSAT $_c$ (C), the theorem is presented, but no complete proof is given. More about the dichotomy theorem, including the proof of the theorem, can be found, among others, in [Dal97, CKS01, FK06]. Results for formulas with a fixed prefix type have been shown in [Hem04].

An example of a subclass of quantified Boolean formulas whose satisfiability problem is not covered by the Dichotomy Theorem is the set of formulas in which the matrix is a conjunction of prime implicates. A *prime implicate* of a CNF formula ϕ is a clause π such that $\phi \models \pi$, and for any proper subclause $\pi' \subset \pi$, we have $\phi \not\models \pi'$. A *prime implicate formula* is a CNF formula ϕ where every clause is a prime implicate and every prime implicate is a clause in ϕ . The set of prime implicate formulas is denoted as PI. The class PI can be decided in polynomial time, because a CNF formula ϕ is in PI if and only if the following conditions hold:

1. no clause in ϕ properly contains another clause in ϕ .
2. for every resolvent α from any two clauses in ϕ , there is a clause $\pi \in \phi$ with $\pi \subseteq \alpha$.

And since every unsatisfiable PI formula contains the empty clause, the satisfiability problem for PI is polynomial-time solvable.

The quantified extension of prime implicates formulas are formulas of the form $Q_1x_1 \dots Q_nx_n\phi$, where $Q_i \in \{\forall, \exists\}$ and ϕ is a prime implicates formula over the variables x_1, \dots, x_n . The set of these formulas is denoted as $Q(\text{PI})$. The satisfiability problem for $Q(\text{PI})$ is PSPACE-complete. That has been shown in [CMLBLM06] by a reduction from the satisfiability problem for QCNF.

It is well-known that every propositional formula can be represented as a graph. We now assume that graphs are DAGs (directed acyclic graphs). The leaves are labeled with literals x or $\neg x$ or with the propositional constants 1 or 0. The internal nodes are labeled with \wedge or \vee . Let C be a node, then $\text{var}(C)$ denotes the set of all variables that label the descendants of node C . If C is the root, $\text{var}(C)$ is the set of all variables occurring in the graph. For sake of simplicity, a graph is called a formula. Depending on the structure and on various constraints, special graphs and corresponding classes of propositional formulas have been investigated. Moreover, the graph representation allows us, for instance, to reason about the satisfiability problem and related problems for the quantified version of ordered binary decision diagrams (OBDDs) and free binary decision diagrams (FBDDs). Most proofs of the PSPACE-completeness of the satisfiability problem for the quantified classes are based on the NP-completeness of the satisfiability problem for the matrices. As an example, we present two classes of formulas:

Let DNNF be the class of decomposable formulas, which means the conjuncts of every \wedge -node C do not share variables. That is, if C_1, \dots, C_n are the successors of an \wedge -node C , then $\text{var}(C_i) \cap \text{var}(C_j)$ is empty for $i \neq j$.

The class d-DNNF is the set of formulas in DNNF with the additional condition of determinism. That is, for every \vee -node C , if C_i and C_j are successors of C , then $C_i \wedge C_j$ is inconsistent for $i \neq j$.

Let QDDNF (Qd-DNNF, QFBDD, QOBDD $_{<}$ respectively) be the set of quantified formulas in prenex form with matrix in DNNF (d-DNNF, FBDD, OBDD $_{<}$). Then the following result has been shown.

Theorem 29.3.4. [CMLBLM06]

The satisfiability problems for QDNNF, Qd-DNNF, QFBDD, and QOBDD $_{<}$ are PSPACE-complete.

29.4. Models and Expressive power

Besides the natural description of quantified propositions, QBF is a tool for short representations of propositional formulas and Boolean functions. Any quantified Boolean formula with free variables z_1, \dots, z_n is logically equivalent to a propositional formula and a Boolean function over these variables. In propositional logic, auxiliary variables are often used to reduce the length of a formula. For

example, the propositional formula $\phi = \bigwedge_{1 \leq i, j \leq n} (a_i \vee b_j)$ has length $2 \cdot n^2$. For a new variable y , the formula

$$\Phi = \exists y \left(\bigwedge_{1 \leq i \leq n} (a_i \vee y) \wedge \bigwedge_{1 \leq j \leq n} (\neg y \vee b_j) \right)$$

is logically equivalent to ϕ and of length $4 \cdot n$. In the best case, an exponential reduction can be obtained. A technique to reduce the length by means of a more complex prefix is based on the following idea. We use the universal variables to exclude some consequences. In the example above, suppose we want to exclude the clause $(a_1 \vee b_3)$ and the clause $(a_2 \vee b_2)$. Then we define $\Phi' = \forall x_1 \forall x_2 \exists y ((a_1 \vee x_1 \vee y) \wedge (a_2 \vee x_2 \vee y) \wedge (a_3 \vee y) \wedge (\neg y \vee b_1) \wedge (\neg x_2 \vee \neg y \vee b_2) \wedge (\neg x_1 \vee \neg y \vee b_3))$.

Since the clause $(a_1 \vee x_1 \vee y)$ contains x_1 , and $\neg x_1$ is in the clause $(\neg x_1 \vee \neg y \vee b_3)$, $(a_1 \vee b_3)$ is not a consequence of Φ' . Similarly, the second and the fifth clause contain the complementary pair of universal literals x_2 and $\neg x_2$. Therefore, $(a_2 \vee b_2)$ is not an implication. All the other consequences remain valid.

Any propositional formula and quantified Boolean formula is a representation of a Boolean function. The representation of Boolean functions and the compression of formulas have their limits. Not every n -ary Boolean function f can be described by a formula $\Phi \in \text{QBF}^*$ which is polynomial in the length of n . That is, there is no polynomial p , such that for every Boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ there exists a quantified Boolean formula $\Phi \in \text{QBF}^*$ with free variables z_1, \dots, z_n which satisfies

$$f \approx \Phi \text{ and } |\Phi| \leq p(n).$$

That can be shown straightforward by a counting argument, because the number of n -ary Boolean functions is 2^{2^n} , and the number of QBF^* formulas of length $p(n)$ is bound by $2^{q(n)}$ for some polynomial q .

In general, it is not necessarily a good idea to translate a quantified Boolean formula into a logically equivalent propositional formula. We will return to this approach later in the section on quantified Horn formulas.

A more functional view of the valuation of a quantified Boolean formula is based on the role of the existential variables. The value of an existential variable depends upon the current values of the dominating universal variables. For instance, the formula $\Phi = \forall x \exists y ((x \vee y) \wedge (\neg x \vee \neg y))$ is true. If $x = 0$, then we choose $y = 1$, and for $x = 1$ we assign $y = 0$. That can be expressed as a Boolean function $f : \{0, 1\} \rightarrow \{0, 1\}$ with $f(0) = 1$ and $f(1) = 0$, i.e. $f(x) = \neg x$. Replacing the variable y in Φ with the function $f(x)$, we obtain the formula $\Phi' = \forall x ((x \vee f(x)) \wedge (\neg x \vee \neg f(x))) \approx \forall x ((x \vee \neg x) \wedge (\neg x \vee x))$, which is true. In our example, the Boolean function has been represented as a propositional formula.

For sake of simplicity, we subsequently only deal with formulas in prenex form. Let $\Phi = \forall x_1 \exists y_1 \dots \forall x_k \exists y_k \phi$ be a quantified Boolean formula without free variables. Then Φ is true if and only if there exist Boolean functions $f_i : \{0, 1\}^i \rightarrow \{0, 1\}$ for $1 \leq i \leq k$, such that

$$\forall x_1 \dots \forall x_k \phi[y_1/f_1(x_1), \dots, y_k/f_k(x_1, \dots, x_k)] \text{ is true if and only if } \phi[y_1/f_1(x_1), \dots, y_k/f_k(x_1, \dots, x_k)] \text{ is a tautology.}$$

Definition 29.4.1. *Satisfiability Model*

Let $\Phi = \forall x_1 \exists y_1 \dots \forall x_k \exists y_k \phi$ be a quantified Boolean formula without free variables. A sequence of Boolean functions $M = (f_1, \dots, f_k)$ is denoted a *satisfiability model* if and only if $\Phi' = Q\phi[y_1/f_1(x_1), \dots, y_k/f_k(x_1, \dots, x_k)]$ is true.

The definition of satisfiability models can easily be extended to formulas with free variables. In that case, the Boolean functions substituting the free variables are the constants 0 or 1. The syntax of quantified Boolean formulas does not include function symbols for Boolean functions. Such an extension will be discussed later. In a first approach, we assume that the Boolean functions are given as propositional or quantified Boolean formulas. Then after the substitution of the functions, the formulas are again quantified Boolean formulas, but in case of functions given as QBFs, not necessarily in prenex form.

The length of satisfiability models represented as propositional formulas cannot be bound by a polynomial, assuming $\text{PSPACE} \neq \Sigma_2^P$. Suppose there is a polynomial p such that any satisfiable formula Φ has a satisfiability model $M = (f_1, \dots, f_n)$ with $|f_i| \leq p(|\Phi|)$. For a closed formula $\Phi = \forall x_1 \exists y_1 \dots \forall x_n \exists y_n \phi$, we obtain:

Φ is true if and only if $\forall x_1 \dots \forall x_n \phi[y_1/f_1, \dots, y_n/f_n]$ is true if and only if $\phi[y_1/f_1, \dots, y_n/f_n]$ is a tautology.

Moreover, $\Phi[y_1/f_1, \dots, y_n/f_n]$ is of length at most $O(|\Phi| \cdot p(|\Phi|))$. It follows that the truth of Φ can be decided by guessing propositional formulas f_i of length less than or equal to $p(|\Phi|)$ and solving the coNP-complete tautology problem. That implies the PSPACE-complete satisfiability problem for QCNF is in Σ_2^P , in contradiction to the widely believed conjecture $\text{PSPACE} \neq \Sigma_2^P$.

But if we represent the model functions as quantified Boolean formulas, then there is a polynomial p , such that the length of the satisfiability models is bound by the polynomial.

Models are of particular interest, because they provide a precise characterization of the behavior of the existentially quantified variables. Knowing (parts of) the model can be helpful when solving a quantified Boolean formula, because that process requires finding satisfying truth assignments to the existentials for different values of the universal variables. For example, a solver can use models as a formalism to represent information about the existentials which it has learned while traversing the search space. A popular example of this technique is the QBF solver sKizzo [Ben05], which is based on successively computing the model functions and storing them compactly as binary decision diagrams (BDDs).

Another reason for models being an interesting research topic is that there appears to be a close connection between the structure of QBF formulas and the structure of their models. From an application perspective, it is clear that the information that a given formula has models of a special structure can be very useful for a QBF solver to prune the search space. We now present some of these results on the relationship between formula classes and the structure of satisfiability models.

Definition 29.4.2. Let K be a class of propositional formulas and $X \subseteq \text{QCNF}$. Then $M = (f_1, \dots, f_n)$ is called a *K-model* for $\Phi \in X$ if M is a satisfiability model for Φ and the formula f_i is in K for every $1 \leq i \leq n$.

The satisfiability model problems we are interested in are defined as

K -Model Problem for X :

Instance: A formula $\Phi \in X$.

Query: Does there exist a K -model for Φ ?

K -Model Checking Problem for X :

Instance: A formula $\Phi \in X$ and $M = (f_1, \dots, f_n)$ a sequence of propositional formulas $f_i \in K$.

Query: Is M a K -model for Φ ?

Let K be the set of propositional formulas. Then the K -model problem for QCNF is PSPACE-complete, because the problem is equivalent to the satisfiability problem for QCNF. In contrast, the K -model checking problem for QCNF is in coNP, since after replacing the existential variables with the propositional formulas, we have to decide whether the resulting matrix is a tautology. The coNP-completeness follows easily by a reduction of the tautology problem for propositional formulas. For a more detailed analysis, we introduce the following sets K_0, K_1 , and K_2 of Boolean functions, where $x^0 := \neg x$ and $x^1 := x$.

$$K_0 = \{f \mid f \text{ is a constant } 0 \text{ or } 1\}$$

$$K_1 = \{f \mid \exists i \exists \epsilon \in \{0, 1\} : f(x_1, \dots, x_n) = x_i^\epsilon\} \cup K_0$$

$$K_2 = \{f \mid \exists I \subseteq \{1, \dots, n\} : f(x_1, \dots, x_n) = \bigwedge_{i \in I} x_i\} \cup K_0.$$

For the next theorem, we need the following notation. Let $\Phi = Q(\alpha_1 \wedge \dots \wedge \alpha_n)$ and $\Phi' = Q(\alpha'_1 \wedge \dots \wedge \alpha'_n)$ be two formulas in QCNF*. If α'_i is a subclause of α_i for every i , we write $\Phi' \subseteq_{cl} \Phi$. We say Φ' is a subclause-subformula of Φ .

Theorem 29.4.1. [KBSZ04]

1. Every satisfiable formula $\Phi \in \text{Q2-CNF}$ has a K_1 -satisfiability model.
2. A formula $\Phi \in \text{QCNF}$ has a K_1 -satisfiability model if and only if there is some $\Phi' \subseteq_{cl} \Phi$ with $\Phi' \in \text{Q2-CNF}$ and Φ' being satisfiable.
3. Every satisfiable formula $\Phi \in \text{QHORN}$ has a K_2 -satisfiability model.
4. A formula $\Phi \in \text{QCNF}$ has a K_2 -satisfiability model if and only if there is some $\Phi' \subseteq_{cl} \Phi$ with $\Phi' \in \text{QHORN}$ and Φ' being satisfiable.

Theorem 5 characterizes Q2-CNF and QHORN in terms of satisfiability models. We see that every satisfiable formula in Q2-CNF has a model in which every existential variable depends only on at most one universal variable. In case of formulas in QHORN, conjunctions of variables are sufficient (besides the constants). Similar to propositional Horn formulas, the satisfiability models for quantified Horn formulas are closed under intersection, which can be shown straightforward.

Lemma 29.4.2. Let $M_1 = (f_1, \dots, f_n)$ and $M_2 = (g_1, \dots, g_n)$ be two satisfiability models for the formula $\Phi \in \text{QHORN}$. Then $M_1 \cap M_2 := (f_1 \wedge g_1, \dots, f_n \wedge g_n)$ is a model for Φ .

For further subclasses, more results can be found in [KBSZ07]. Sometimes, the term *policy* or *strategy* is used instead of satisfiability model.

Instead of looking for satisfiability models, we may try to determine Boolean functions, such that after the substitution of the functions for the existential variables, the input formula is logically equivalent to the resulting formula. Take for example the formula

$$\Phi = \forall x \exists y ((x \vee y \vee z_1) \wedge (x \vee \neg y \vee z_2) \wedge (\neg x \vee \neg y \vee z_3)).$$

The formula is logically equivalent to $(z_1 \vee z_2)$. When we substitute the function $f(z_1, z_2, z_3, x) = (z_2 \wedge \neg x)$ for y , we obtain the formula $\forall x((x \vee (z_2 \wedge \neg x) \vee z_1) \wedge (x \vee \neg(z_2 \wedge \neg x) \vee z_2) \wedge (\neg x \vee \neg(z_2 \wedge \neg x) \vee z_3))$, and after simplifying the formula $\forall x((x \vee z_1 \vee z_2) \wedge (x \vee \neg z_2 \vee z_2) \wedge (\neg x \vee \neg z_2 \vee x \vee z_3))$. The last two clauses are tautological clauses, and by universal reduction on the first clause, we see that the formula is logically equivalent to the input formula. Please notice that in addition to the universally quantified variables, the Boolean functions now also depend on the free variables.

Definition 29.4.3. *Equivalence Model*

Let $\Phi = \forall x_1 \exists y_1 \dots \forall x_n \exists y_n \phi$ be a quantified Boolean formula with free variables $\mathbf{z} = z_1, \dots, z_t$. A sequence $M = (f_1, \dots, f_n)$ of Boolean functions $f_i \in K$ is called an *equivalence model* for Φ if and only if

$$\Phi \approx \forall x_1 \dots \forall x_n \phi[y_1/f_1(\mathbf{z}, x_1), \dots, y_n/f_n(\mathbf{z}, x_1, \dots, x_n)].$$

Let K be a set of Boolean functions. If every function f_i is in K , we say that M is a K -equivalence model.

The correspondence between formula classes and model structure is especially interesting for equivalence models. As mentioned before, QBF^* formulas can often represent propositional formulas exponentially shorter, and restrictions on the structure of the equivalence model translate to limits in the expressiveness (i.e. the ability to provide short representations for propositional formulas) of the corresponding class of QBF^* formulas.

The following two kinds of problems have been investigated for various subclasses of Boolean functions and quantified Boolean formulas.

K -Equivalence Model Problem for X :

Instance: A formula $\Phi \in X$.

Query: Does there exist a K -equivalence model for Φ ?

K -Equivalence Model Checking Problem for X :

Instance: A formula $\Phi \in X$ and $M = (f_1, \dots, f_n)$ a sequence of propositional formulas $f_i \in K$.

Query: Is M a K -equivalence model for Φ ?

It has been shown [KBZ05] that every quantified Boolean formula has an equivalence model. For closed formulas, any satisfiability model is an equivalence model, too. In general, equivalence models are more complex than satisfiability models.

Lemma 29.4.3. [KBZ05, BKBZ05]

1. Every $Q2$ -CNF * formula has an equivalence model where the functions can be represented as propositional formulas in $1\text{-CNF} \cup 1\text{-DNF} \cup \{0, 1\}$.
2. Every formula in $QHORN^*$ has an equivalence model where the Boolean functions can be represented as monotone propositional formulas.

For the test of whether a sequence of Boolean functions is an equivalence model, for instance the following propositions are known.

Lemma 29.4.4. [KBZ05]

1. The K_0 -equivalence model checking problem for arbitrary QCNF* formulas is PSPACE-complete.
2. Let K be the set of propositional formulas. Then the K -equivalence model checking problems for Q2-CNF* and QHORN* are coNP-complete.

We conclude the section with some remarks on an extension of quantified Boolean formulas. Suppose we have a formula $\Phi = \forall x_1 \forall x_2 \forall x_3 \exists y_1 \exists y_2 \exists y_3 \phi$, and we want to know whether Φ is true when y_1 only depends on x_1 and x_2 , y_2 on x_2 and x_3 , and y_3 on x_1 and x_3 . That is the question whether there are model functions $f_1(x_1, x_2)$, $f_2(x_2, x_3)$, and $f_3(x_1, x_3)$ such that after the substitution, the formula $\forall x_1 \forall x_2 \forall x_3 \phi[y_1/f_1(x_1, x_2), y_2/f_2(x_2, x_3), y_3/f_3(x_1, x_3)]$ is true. It is not clear how these requirements could directly be represented in a succinct QBF*, even if we allow non-prenex formulas. This kind of question can be expressed in an extension of quantified Boolean formulas, the so-called *Dependency Quantified Boolean Formulas* (DQBF).

The idea is based on partially ordered quantifiers introduced for first-order predicate logic [Hen61]. Instead of a total ordering on the quantifiers, we can directly express in a function-style notation on which universal variables an existential variable depends. For the formula above, we write

$$\forall x_1 \forall x_2 \forall x_3 \exists y_1(x_1, x_2) \exists y_2(x_2, x_3) \exists y_3(x_1, x_3) \phi.$$

These quantifiers are also called branching quantifiers or Henkin quantifiers. More formally, a dependency quantified Boolean formula $\Phi \in \text{DQBF}$ with universal variables x_1, \dots, x_n and existential variables y_1, \dots, y_m is a formula of the form

$$\Phi = \forall x_1 \dots \forall x_n \exists y_1(x_{d_{1,1}}, \dots, x_{d_{1,t_1}}) \dots \exists y_m(x_{d_{m,1}}, \dots, x_{d_{m,t_m}}) \phi$$

where $x_{d_{i,j}}$ points to the j^{th} variable on which y_i depends. The formula Φ is said to be true if and only if there are Boolean functions $f_i(x_{d_{i,1}}, \dots, x_{d_{i,t_i}})$ such that

$$\forall x_1 \dots \forall x_n \phi[y_1/f_1(x_{d_{1,1}}, \dots, x_{d_{1,t_1}}), \dots, y_m/f_m(x_{d_{m,1}}, \dots, x_{d_{m,t_m}})]$$

is true.

It has been shown in [PRA01] that the problem of deciding whether an arbitrarily given $\Phi \in \text{DQBF}$ is true is NEXPTIME-complete. Assuming that NEXPTIME does not equal PSPACE, this means that there are DQBF formulas for which no logically equivalent QBF* of polynomial length can be computed in polynomial space. For some subclasses, the satisfiability problem remains tractable. For instance, it has been shown in [BKB06] that any dependency quantified Horn formula $\Phi \in \text{DQHORN}^*$ of length $|\Phi|$ with free variables, $|\forall|$ universal variables, and an arbitrary number of existential variables can be transformed into a logically equivalent quantified Horn formula of length $O(|\forall| \cdot |\Phi|)$ which contains only existential quantifiers. Moreover, the satisfiability problem for DQHORN* is solvable in time $O(|\forall| \cdot |\Phi|)$.

29.5. Q-Resolution

We now extend the concept of resolution for propositional formulas to quantified Boolean formulas in conjunctive normal form. The idea of resolution is that two clauses are combined into a resolvent, so that the connecting literals disappear. In case of quantified Boolean formulas, these are existential or free literals, and additionally, any universally quantified variable that no longer dominates any existential variable can be deleted. This reduction provides a new possibility for generating the empty clause.

We first introduce the following terminology and notations. Subsequently, we assume that the formulas are in CNF, and therefore in prenex form, and do not contain the Boolean constants 1 and 0. A \forall -literal (universal literal) is a literal over a universally quantified variable. An \exists -literal is a literal over an existentially quantified or a free variable. A \forall -clause is a clause which only contains \forall -literals.

Definition 29.5.1. Ordering of Literals

Let Φ be a quantified Boolean formula, and let L_1 and L_2 be literals in Φ . Then L_1 is less than L_2 ($L_1 < L_2$) if the variable in L_1 occurs in the prefix before the variable of L_2 , or the variable of L_1 is free and the variable of L_2 is bound.

In order to motivate the definition of Q-resolution, we first summarize some observations.

1. If a non-tautological clause of a formula $\Phi \in \text{QCNF}^*$ is a \forall -clause, then Φ is unsatisfiable, and the clause can be replaced by the empty clause, which is false by definition.
2. An existentially quantified formula $\exists y_1 \dots \exists y_n \phi$ in QCNF^* is unsatisfiable if and only if the resolution for propositional formulas leads to the empty clause when only \exists -literals are resolved.
3. Let $(\dots \vee x)$ be a non-tautological clause with a universal variable x and an \exists -literal. If x does not dominate an existential variable, then x can be deleted.
4. Usually, the generation of tautological clauses is of no help in the process of deriving the empty clause, thus we explicitly exclude the generation and application of tautological clauses that are tautological because of \forall -literals.

A restriction of Q-resolution, the Q-unit-resolution, has been introduced in [KKBS87] and was later extended to Q-resolution in [FKKB95].

Definition 29.5.2. Q-Resolution

Let $\Phi = Q\phi$ be a formula in QCNF^* with matrix ϕ and prefix Q . Let ϕ_1 and ϕ_2 be non-tautological clauses of ϕ , where ϕ_1 contains the \exists -literal y , and ϕ_2 contains the literal $\neg y$. We obtain a Q -resolvent σ from ϕ_1 and ϕ_2 by applying the following steps (1) to (3):

1. Eliminate all occurrences of \forall -literals in ϕ_i which are not smaller than an \exists -literal which occurs in ϕ_i for $i = 1, 2$. The resulting clauses are denoted by ϕ'_1 and ϕ'_2 .
2. Eliminate the occurrences of y from ϕ'_1 and the occurrences of $\neg y$ from ϕ'_2 . We obtain ϕ''_1 and ϕ''_2 .

3. $\sigma := \phi_1'' \vee \phi_2''$. If σ is a non-tautological clause, then σ is a resolvent.

A single Q-resolution step is written as $\Phi \mid_{Q\text{-Res}}^1 Q(\phi \wedge \sigma)$ or $\phi \mid_{Q\text{-Res}}^1 \sigma$ or $\Phi \mid_{Q\text{-Res}}^1 \sigma$. We use $\mid_{Q\text{-Res}}^*$ to denote the derivability relation given by the reflexive and transitive closure of $\mid_{Q\text{-Res}}^1$.

Examples

1. $\Phi = \forall x_1 \forall x_2 \exists y((x_1 \vee y) \wedge (x_2 \vee \neg y))$

The formula is unsatisfiable, since the resolvent is a non-tautological \forall -clause: $(x_1 \vee y), (x_2 \vee \neg y) \mid_{Q\text{-Res}}^1 (x_1 \vee x_2)$

2. $\Phi = \forall x_1 \exists y_1 \exists y_2 \forall x_2 \exists y_3((y_1 \vee x_2 \vee y_3) \wedge (y_2 \vee \neg y_3) \wedge (x_1 \vee \neg y_1) \wedge (x_1 \vee \neg y_2))$

A Q-resolution refutation is as follows:

$$(y_2 \vee \neg y_3), (y_1 \vee x_2 \vee y_3) \mid_{Q\text{-Res}}^1 (y_1 \vee y_2 \vee x_2)$$

$$(y_1 \vee y_2 \vee x_2), (x_1 \vee \neg y_1) \mid_{Q\text{-Res}}^1 (x_1 \vee y_2)$$

$$(x_1 \vee y_2), (x_1 \vee \neg y_2) \mid_{Q\text{-Res}}^1 (x_1) \approx \perp.$$

3. $\Phi = \forall x \exists y((x \vee y) \wedge (\neg x \vee \neg y))$

There is no Q-resolvent, because resolution would produce a tautological \forall -clause $(x \vee \neg x)$.

The elimination of universals which do not dominate any existential in the same clause (Item 1. in Definition 29.5.2) has already been presented independently of Q-resolution as a general QBF* simplification rule called universal reduction. We must include it here, because Q-resolution is only refutation complete if universal reduction is applied in each resolution step. In the unsatisfiable formula

$$\Phi = \exists y_1 \forall x_1 \forall x_2 \exists y_2 ((y_1 \vee x_1 \vee y_2) \wedge (\neg y_1 \vee \neg x_1 \vee y_2) \wedge (x_2 \vee \neg y_2))$$

initial universal reduction cannot yield any simplifications, and we cannot resolve on y_1 due to the tautological occurrences of x_1 and $\neg x_1$. If we resolve on y_2 instead, we obtain the two resolvents $(y_1 \vee x_1 \vee x_2)$ and $(\neg y_1 \vee \neg x_1 \vee x_2)$. Now we can only resolve on y_1 if we first apply universal reduction on both resolvents, which produces the simplified clauses (y_1) and $(\neg y_1)$ that subsequently resolve to the empty clause.

The previous example also shows that the exchange lemma for resolution in propositional formulas [KBL99] no longer holds for QBF*. In the example, resolving first on y_2 and then on y_1 leads to the empty clause, whereas direct Q-resolution on y_1 leads to a tautological clause: the process is then *blocked*. Such blockages usually require a detour of several steps.

Lemma 29.5.1. *Let $\Phi = \Pi\phi$ be a formula in QCNF* with matrix ϕ and prefix Π . Suppose that $\Phi \mid_{Q\text{-Res}}^1 \sigma$ for a clause σ , then we have $\Phi \approx \Pi(\phi \wedge \sigma)$.*

Theorem 29.5.2. [FKKB95] *Let $\Phi \in \text{QCNF}^*$, then Φ is unsatisfiable (false) if and only if $\Phi \mid_{Q\text{-Res}}^* \sigma$ for a non-tautological \forall -clause σ .*

Idea of the proof: Proof by induction on k , the number of quantifiers in Φ . Without loss of generality, we consider only closed formulas. Otherwise, we can bind the free variables existentially.

1. $k = 1$ and $\Phi = \exists x\phi$. In that case, the Q-resolution is the same as the ordinary resolution for propositional formulas, and we obtain $\frac{*}{Q-Res} \sqcup$.

2. $k = 1$ and $\Phi = \forall y\phi$. Since Φ is closed and false, the formula contains a non-tautological \forall -clause. That is $\Phi \frac{*}{Q-Res} \sqcup$.

3. $k > 1$ and let $\Phi = \exists y \dots \phi$. Let Φ_0 (respectively Φ_1) be the formula we obtain when we substitute 0 for y (respectively $y = 1$) and reduce the formula accordingly. The formulas Φ_0 and Φ_1 are false. By the induction hypothesis for $k - 1$, it follows that $\Phi_0 \frac{*}{Q-Res} \sigma_0$ and $\Phi_1 \frac{*}{Q-Res} \sigma_1$ for some non-tautological \forall -clauses σ_0 and σ_1 . We obtain $\Phi \frac{*}{Q-Res} \sigma_0$ (respectively $\Phi \frac{*}{Q-Res} \sigma_1$) or simultaneously $\Phi \frac{*}{Q-Res} (y \vee \sigma_0)$ and $\Phi \frac{*}{Q-Res} (\neg y \vee \sigma_1)$. Since y is smaller than the universal variables in σ_0 and σ_1 , we obtain in one Q-resolution step the empty clause.

4. $k > 1$ and $\forall x Q\phi$. Since Φ is false, one of the formulas $\Phi_1 := Q\phi[x/1]$ and $\Phi_0 := Q\phi[x/0]$ must be false. Without loss of generality, suppose Φ_1 is false. By the induction hypothesis, we have $\Phi_1 \frac{*}{Q-Res} \sigma$ for some non-tautological \forall -clause σ . The Q-resolution steps can be carried out in Φ , since we only use clauses which contain neither x nor $\neg x$ or clauses with $\neg x$. That means a non-tautological \forall -clause is a Q-resolvent in Φ . That is, $\Phi \frac{*}{Q-Res} \sigma$ or $\Phi \frac{*}{Q-Res} (\neg x \vee \sigma)$. None of these clauses can be a tautological \forall -clause, since the variable x does not occur in σ .

Suppose $\Phi \frac{*}{Q-Res} \sigma$ for a non-tautological \forall -clause and $\Phi = Q\phi$. Then we have $\Phi \approx Q(\phi \wedge \sigma)$. The latter formula is false.

Most of the resolution restrictions known for propositional formulas can be adapted in a straightforward way to Q-resolution. For instance, unit resolution is refutation complete and correct for propositional Horn formulas. Now we extend the unit resolution to the so called Q-unit resolution. A clause of a quantified CNF formula is called a \exists -unit clause if the clause does not contain more than one \exists -literal (free or existentially quantified literal) besides some universal literals.

Definition 29.5.3. *Q-Unit-Resolution*

Q-unit resolution is Q-resolution, but with the restriction that one of the parent clauses is an \exists -unit clause. If σ is the resolvent from ϕ_1 and ϕ_2 , then we write $\phi_1, \phi_2 \frac{1}{Q-Unit-Res} \sigma$.

Obviously, Q-unit resolution is correct, but not refutation complete for QCNF* formulas. In case of an unsatisfiable formula without \exists -unit clauses, the Q-unit resolution cannot be applied to the formula. Since \exists -unit clauses only refer to the number of free and existential variables, we extend the class of quantified Horn formulas to the following class QEHORN*.

Definition 29.5.4. *QEHORN**

A formula $\Phi \in QCNF^*$ is a *quantified extended Horn formula* if, after eliminating the \forall -literals, the clauses are Horn clauses. The class of all such formulas is denoted by *QEHORN**.

An example of a QEHORN* formula which is not a quantified Horn formula is the following

$$\Phi = \forall x \exists y ((x \vee z \vee \neg y) \wedge (\neg x \vee y)).$$

In the first clause, two literals x and z occur positively. The clause is not a Horn clause. But the clause contains at most one positive \exists -literal (z). The second clause is an \exists -unit clause, because only one \exists -literal is given (y). It can be shown that Q-unit resolution is refutation complete for QEHORN* [FKKB90]. A more restricted version of Q-unit resolution is obtained by restricting Q-unit resolution to positive \exists -unit clauses. Here, the \exists -unit clause contains at most one positive free or existentially quantified literal. That means one of the parent clauses has the form $(w \vee y)$, where y is the free or existential variable and w is the (possibly empty) disjunction of universal literals.

Definition 29.5.5. *Q-Pos-Unit-Resolution (Q-PU-Res)*

Q-pos-unit-resolution is Q-unit-resolution with the additional restriction that in each Q-unit-resolution step, one of the parent clauses must be a positive \exists -unit clause.

Theorem 29.5.3. *Let $\Phi \in \text{QEHORN}^*$, then we have*

$$\Phi \text{ is unsatisfiable if and only if } \Phi \vdash_{\text{Q-Pos-Unit-Res}}^* \perp .$$

For propositional formulas in conjunctive normal form, the length of resolution refutations cannot be bound by a polynomial. That has been shown by a careful analysis of the so-called pigeon hole formulas. For extended quantified Horn formulas, there are also hard formulas for the Q-resolution. Let Φ_k be the following formula ($k \geq 1$):

$$\begin{aligned} \Phi_k = & \exists y_1 \exists y'_1 \forall x_1 \exists y_2 \exists y'_2 \forall x_2 \exists y_3 \exists y'_3 \dots \forall x_{k-1} \exists y_k \exists y'_k \forall x_k \exists y_{k+1} \dots \exists y_{k+k} \\ & ((\neg y_1 \vee \neg y'_1) \wedge \\ & (y_1 \leftarrow x_1, y_2, y'_2) \wedge (y'_1 \leftarrow \neg x_1, y_2, y'_2) \wedge \\ & (y_2 \leftarrow x_2, y_3, y'_3) \wedge (y'_2 \leftarrow \neg x_2, y_3, y'_3) \wedge \\ & \dots \dots \dots \\ & \dots \dots \dots \\ & (y_{k-1} \leftarrow x_{k-1}, y_k, y'_k) \wedge (y'_{k-1} \leftarrow \neg x_{k-1}, y_k, y'_k) \wedge \\ & (y_k \leftarrow x_k, y_{k+1}, \dots, y_{k+k}) \wedge (y'_k \leftarrow \neg x_k, y_{k+1}, \dots, y_{k+k}) \wedge \\ & (x_1 \vee y_{k+1}) \wedge \dots \wedge (x_k \vee y_{k+k}) \wedge (\neg x_1 \vee y_{k+1}) \wedge \dots \wedge (\neg x_k \vee y_{k+k}) \end{aligned}$$

With Q-unit-resolution, there is only a limited number of possible resolvents to choose initially. We can only resolve the clauses in the last row with the clauses in the second to last row. Some possible resolutions are blocked due to tautological occurrences of x_k . For example, we cannot resolve $(y_k \leftarrow x_k, y_{k+1}, \dots, y_{k+k})$ with $(x_k \vee y_{k+k})$, but with $(\neg x_k \vee y_{k+k})$. We obtain positive \exists -unit clauses of the form $(y_k \vee x_1^{\epsilon_1} \vee \dots \vee x_k^{\epsilon_k})$ (respectively $(y'_k \vee x_1^{\epsilon_1} \vee \dots \vee x_k^{\epsilon_k})$) where $x_j^{\epsilon_j} = x_j$ if $\epsilon_j = 1$ and $x_j^{\epsilon_j} = \neg x_j$ if $\epsilon_j = 0$. These can be simplified through universal reduction, because x_k occurs after y_k and y'_k in the prefix. We obtain $(y_k \vee x_1^{\epsilon_1} \vee \dots \vee x_{k-1}^{\epsilon_{k-1}})$ (respectively $(y'_k \vee x_1^{\epsilon_1} \vee \dots \vee x_{k-1}^{\epsilon_{k-1}})$), which can be resolved with the clauses in the third to last row in the formula above.

As the process continues, we can observe that every derivable positive \exists -unit clause with \exists -literal y_i (respectively y'_i) for $1 \leq i \leq k$ has the form $(y_i \vee x_1^{\epsilon_1} \vee \dots \vee x_{i-1}^{\epsilon_{i-1}})$ (respectively $(y'_i \vee x_1^{\epsilon_1} \vee \dots \vee x_{i-1}^{\epsilon_{i-1}})$). These \exists -unit clauses can only be derived in at least 2^{i-1} steps by means of Q-unit-resolution as discussed before. To see why the number of steps is exponential in i , consider the two clauses $\alpha = (y_i \leftarrow x_i, y_{i+1}, y'_{i+1})$ and $\beta = (y'_i \leftarrow \neg x_i, y_{i+1}, y'_{i+1})$. Since x_i occurs with different signs in α and β , different resolvents are blocked in both cases. α must be resolved with a clause $(y_{i+1} \vee x_1^{\epsilon_1} \vee \dots \vee x_{i-1}^{\epsilon_{i-1}} \vee \neg x_i)$, whereas β can only be resolved with a clause $(y_{i+1} \vee x_1^{\epsilon_1} \vee \dots \vee x_{i-1}^{\epsilon_{i-1}} \vee x_i)$, which means we need two different derivations of y_{i+1} as \exists -unit. An analogous observation can be made when resolving on y'_{i+1} . It follows that the derivation of y_1 and y'_1 requires at least 2^k steps. These steps cannot be shortened using Q-resolution.

Theorem 29.5.4. [Flö93] *For any $k \geq 1$, there is a formula $\Phi_k \in \text{QEHORN}$ of length $O(k)$ which is false, and the refutation requires at least 2^k Q-resolution steps.*

For propositional formulas in conjunctive normal form, unit propagation is a powerful technique to reduce the length of the formula. The previous example shows that for QCNF* formulas, propagating unit literals over existentially quantified or free variables may lead to an explosion of possible resolvents and potentially longer clauses. One of the reasons is that the \exists -units may contain universal variables which are not previously contained in the other parent clause.

The satisfiability problem for QEHORN* is PSPACE-complete [Flö93]. The proof of the PSPACE-completeness shows that for closed formulas, we need at most two existential literals per clause. Let QE2-HORN be the set of formulas in which the existential part of the clause is a 2-Horn clause. Then the satisfiability problem remains PSPACE-complete. But if we restrict ourselves to formulas with a fixed number of alternations in the prefix, then the satisfiability problem is coNP-complete. More formally, for $k \geq 2$, the satisfiability problem for QEHORN* formulas with prefix type Π_k (Σ_k respectively) is coNP-complete [FKKB90].

29.6. Quantified Horn Formulas and Q2-CNF

For propositional Horn formulas, the satisfiability problem can be solved in linear time. As we will see, the satisfiability problem for quantified Horn formulas (QHORN*) is also solvable in polynomial time, where the fastest known algorithm requires more than linear, but not more than quadratic time. The models for satisfiable QHORN formulas have a quite simple structure, i.e. they are constants or conjunctions of literals. Quantified Horn formulas with free variables are logically equivalent to propositional Horn formulas, but the length of the shortest Horn formula may be exponential in the length of the quantified formula. For example, let α_n be the following formula:

$$\alpha_n = \bigwedge_{1 \leq j_1, \dots, j_n \leq n} (z \leftarrow z_{1,j_1}, \dots, z_{n,j_n})$$

The formulas α_n have length $O(n^n)$. The length of the shortest CNF formula is not shorter than α_n . The following QHORN* formula is logically equivalent to α_n and has length $O(n^2)$:

$$\exists x_1 \dots \exists x_n ((z \leftarrow x_1, \dots, x_n) \wedge \bigwedge_{1 \leq i, j \leq n} (x_i \leftarrow z_{i,j}))$$

We next present the idea of testing formulas in QHORN* for satisfiability. Since a QHORN* formula with free variables is satisfiable if and only if the existential closure of the formula is true, we only consider closed formulas. Given is the formula

$$\Phi = \exists y_0 \forall x_1 \exists y_1 \dots \forall x_k \exists y_k \phi.$$

We assume that Φ contains no clause consisting only of universal literals and no tautological clause. Since the matrix ϕ is a Horn formula, every clause in Φ belongs to one of the following three classes:

1. P_Φ is the set of clauses with a positive \exists -literal.
2. N_Φ^+ is the set of clauses with a positive \forall -literal.
3. N_Φ is the set of clauses with only negated literals.

One can show that Φ is false if and only if there is a clause φ in $N_\Phi^+ \cup N_\Phi$ such that $\exists y_0 \forall x_1 \exists y_1 \dots \forall x_k \exists y_k (P_\Phi \wedge \varphi)$ is false. That is, clauses with one positive \exists -literal and one clause with only negated \exists -literals are sufficient to decide the satisfiability. We proceed with a case distinction:

Case 1: $\varphi \in N_\Phi$. Then every universal literal occurs only positively in $P_\Phi \wedge \varphi$. Therefore, we can remove all occurrences of universal variables without any effect on the satisfiability. The resulting formula is an existentially quantified formula and satisfiable if and only if the matrix, a propositional Horn formula, is satisfiable. We can apply the linear-time satisfiability algorithm for propositional Horn formulas to that formula.

Case 2: Let $\varphi \in N_\Phi^+$ and let x_i be the positive literal in φ . We can delete all other universal literals, because they occur only negatively in $N_\Phi^+ \cup P_\Phi$. Let $P(i)_\Phi$ be the reduced formula. If the clause φ contains existential literals $\neg y_j$ with $j < i$, then we test whether these variables are derivable units from $P(i)_\Phi$. That can be done by deleting the universal variable x_i in all the clauses of $P(i)_\Phi$ and applying unit propagation to the formula. If not all these \exists -literals y_j are derivable units, the formula Φ is satisfiable.

Otherwise, we remove these \exists -literals $\neg y_j$ from φ .

For the remaining \exists -literals $\neg y_t$ in φ , we have $i \leq t$. For y_t , at most two distinct positive \exists -unit clauses can be derived from $P(i)_\Phi$, namely y_t and $(\neg x_i \vee y_t)$. Because of the completeness of the positive Q-unit resolution for quantified Horn formulas, $\exists y_0 \forall x_1 \exists y_1 \dots \forall x_k \exists y_k (P_\Phi \wedge \varphi)$ is false if and only if all the literals y_t are derivable using positive Q-unit resolution. That can be decided in linear time.

Altogether, that leads to an algorithm for testing the satisfiability. The outline of the algorithm is as follows: At first, we decide whether $P_\Phi \cup N_\Phi$ is satisfiable. If that is not the case, we apply for every universal variable x_i which occurs positively in Φ the procedure explained above. Since the satisfiability problem for propositional Horn formulas is decidable in linear time and unit propagation is a linear-time procedure, we have the following result.

Theorem 29.6.1. [FKKB95] *The satisfiability problem for QHORN* can be decided in time $O(|\forall| \cdot n)$, where n is the length of the formula and $|\forall|$ is the number of universal variables which occur positively in the formula.*

Based on the observation that the satisfiability and equivalence models for formulas in QHORN* have a quite simple structure, the following theorem has been shown [BKBZ05].

Theorem 29.6.2. *Every formula $\Phi \in \text{QHORN}^*$ can be transformed into a logically equivalent and existentially quantified Horn formula in time $O(|\forall| \cdot n)$, where n is the length of the formula and $|\forall|$ is the number of universal variables.*

For propositional Horn formulas, the problem to decide whether two formulas are logically equivalent is solvable in quadratic time. In contrast to the propositional case, the equivalence problem for quantified Horn formulas with free variables is coNP-complete [KBL99].

Theorem 29.6.3. *The consequence problem*

$$\{(\Phi_1, \Phi_2) \mid \Phi_1 \models \Phi_2, \Phi_1, \Phi_2 \in \text{QHORN}^*\}$$

and the equivalence problem

$$\{(\Phi_1, \Phi_2) \mid \Phi_1 \approx \Phi_2, \Phi_1, \Phi_2 \in \text{QHORN}^*\}$$

are coNP-complete.

The proof of the coNP-completeness can be shown by a reduction from the complement of the NP-complete Monotone 3-SAT problem. A formula ϕ is in Monotone 3-SAT if and only if Φ is satisfiable, $\phi = \alpha \wedge \beta \in 3\text{-CNF}$, α contains only positive literals, and β has negative literals. Let be given

$$\begin{aligned} \alpha &= \{(L_{i,1} \vee L_{i,2} \vee L_{i,3}) \mid 1 \leq i \leq n\} \\ \beta &= \{(\neg K_{j,1} \vee \neg K_{j,2} \vee \neg K_{j,3}) \mid 1 \leq j \leq m\}. \end{aligned}$$

where $L_{i,s}$ and $K_{j,t}$ are variables. Now we introduce a new variable y and new variables $x_1, \dots, x_n, z_1, \dots, z_m$. We define

$$\begin{aligned} \Phi_1 &= \exists x_1 \dots \exists x_n \{(y \leftarrow x_1, \dots, x_n)\} \cup \{(x_i \leftarrow L_{i,p}) \mid 1 \leq p \leq 3, 1 \leq i \leq n\} \\ \Phi_2 &= \exists x_1 \dots \exists x_n \exists z_1 \dots \exists z_m \{(y \leftarrow x_1, \dots, x_n, z_j) \mid 1 \leq j \leq m\} \cup \\ &\quad \{(x_i \leftarrow L_{i,p}) \mid 1 \leq p \leq 3, 1 \leq i \leq n\} \cup \{(z_j \leftarrow K_{i,j}) \mid 1 \leq j \leq m\} \end{aligned}$$

Then we have: $\Phi_2 \approx \Phi_1$ if and only if $\Phi_2 \models \Phi_1$ if and only if $\alpha \wedge \beta$ is unsatisfiable. The construction shows that the problems remain coNP-complete for existentially quantified Horn formulas.

For a propositional formula ϕ over the variables x_1, \dots, x_n , a function $f : \text{literals}(\phi) \rightarrow \text{literals}(\phi)$ is called a *renaming* if and only if for all $L \in \text{literals}(\phi)$, we have $f(L) \in \{L, \neg L\}$ and $f(\neg L) \approx \neg f(L)$. The concept of renaming can be extended to quantified Boolean formulas. Let f be a renaming and Φ a QBF* formula, then $f(\Phi)$ is the result of applying the renaming to the matrix while the prefix remains unchanged. For example, let $f(x) = \neg x$, $f(y) = y$ and $\Phi = \forall x \exists y (x \vee y)$ be a formula not in QHORN*. Then we obtain $f(\Phi) = \forall x \exists y f((x \vee y)) = \forall x \exists y (\neg x \vee y)$. The resulting formula is now a quantified Horn formula. Obviously, a renaming preserves the satisfiability of the formulas. Whether a

quantified Boolean formula is renamable into a quantified Horn formula can be decided in linear time by applying the linear-time algorithm for propositional formulas in CNF. Moreover, for any satisfiable Q2-CNF* formula Φ , there is a renaming f with $f(\Phi) \in \text{Q2-HORN}^*$.

By means of renaming, we can decide as follows whether a Q2-CNF* formula is satisfiable. At first decide whether the formula is renamable into a quantified Horn formula. If that is not the case, then the formula is unsatisfiable. Otherwise, we apply the satisfiability algorithm for QHORN* formulas to the renamed formula. But this procedure is not the best one. An alternative algorithm deciding the satisfiability of Q2-CNF* formulas has been established in [APT79]. The idea of the satisfiability algorithm is based on a representation of formulas as graphs. We associate with a formula Φ the graph $G(\Phi)$ as follows:

1. If L is the literal of a unit clause in Φ , then $(\neg L) \rightarrow L$ is an edge in $G(\Phi)$
2. If $(L_1 \vee L_2)$ is a clause in Φ , then $(\neg L_1) \rightarrow L_2$ and $(\neg L_2) \rightarrow L_1$ are edges in $G(\Phi)$
3. Nothing else is an edge in $G(\Phi)$

Lemma 29.6.4. *Let $\Phi \in \text{Q2-CNF}^*$, and let $G(\Phi)$ be the associated graph. Then Φ is false if and only if one of the following conditions holds:*

1. *There is an \exists -variable y and a strongly connected component S of $G(\Phi)$ with $y, \neg y \in S$.*
2. *There is a \forall -variable x and an \exists -variable y with $y < x$, for which there exists a strongly connected component S of $G(\Phi)$ which contains both a literal over x and a literal over y .*
3. *There exist two \forall -literals L_1 and L_2 over distinct variables or one negated and the other unnegated, such that there is a path from L_1 to L_2 in the graph $G(\Phi)$.*

The first condition covers the propositional and the purely existentially quantified case. In condition (2), it is necessary that $y < x$, x does not dominate y in the prefix. The graphs of the formulas $\Phi_1 = \exists y \forall x ((y \vee x) \wedge (\neg y \vee \neg x))$ and $\Phi_2 = \forall x \exists y ((y \vee x) \wedge (\neg y \vee \neg x))$ are identical, but Φ_1 is false and Φ_2 is true. The third condition is necessary for formulas of the form $\Phi = \forall x_1 \forall x_2 \exists y ((\neg x_1 \vee y) \wedge (x_2 \vee \neg y))$. There is a path $\neg x_1 \rightarrow y, y \rightarrow x_2$ from $\neg x_1$ to x_2 .

There is an alternative formulation of condition (3) which is easier to implement.

Condition 3'. There is a strongly connected component S in $G(\Phi)$ which contains two \forall -literals L_1 and L_2 over distinct variables or one negated and the other not, or else there are two strongly connected components S_1 and S_2 in $G(\Phi)$ which are connected, each containing one \forall -literal.

The test for satisfiability can be carried out in linear time, since the computation of the strongly connected components and the test whether or not one of the conditions holds can be performed in linear time.

Theorem 29.6.5. [APT79] *The satisfiability problem for Q2-CNF* is decidable in linear time.*

Every formula in Q2-CNF* is logically equivalent to a propositional 2-CNF formula. The size of an equivalent formula is bound by $4 \cdot r^2$, where r is the

number of free variables, because there are at most this many 2-clauses over r variables.

Lemma 29.6.6. *For every satisfiable formula $\Phi \in \text{Q2-CNF}^*$, we can construct a logically equivalent formula $\Phi' \in \text{Q2-CNF}^*$ in $O((r+1) \cdot n)$ time and linear space such that $|\Phi'| = O(n)$ and Φ' contains no universal variables, where n is the length of Φ and r is the number of free variables.*

As a corollary we obtain the solvability of the equivalence and the consequence problem for Q2-CNF^* .

Lemma 29.6.7. [KBL99]

The consequence problem

$$\{(\Phi_1, \Phi_2) \mid \Phi_1 \models \Phi_2, \Phi_1, \Phi_2 \in \text{Q2-CNF}^*\}$$

and the equivalence problem

$$\{(\Phi_1, \Phi_2) \mid \Phi_1 \approx \Phi_2, \Phi_1, \Phi_2 \in \text{Q2-CNF}^*\}$$

are solvable in quadratic time.

Chapter 30

Reasoning with Quantified Boolean Formulas

Enrico Giunchiglia, Paolo Marin, and Massimo Narizzano

30.1. Introduction

The implementation of effective reasoning tools for deciding the satisfiability of Quantified Boolean Formulas (QBFs) is an important research issue in Artificial Intelligence and Computer Science. Indeed, QBF solvers have already been proposed for many reasoning tasks in knowledge representation and reasoning, in automated planning and in formal methods for computer aided design. Even more, since QBF reasoning is the prototypical PSPACE problem, the reduction of many other decision problems in PSPACE are readily available (see, e.g., [Pap94]). For these reasons, in the last few years several decision procedures for QBFs have been proposed and implemented, mostly based either on search or on variable elimination, or on a combination of the two.

In this chapter, after a brief recap of the basic terminology and notation about QBFs (Sec. 30.2, but see Part 2, Chapter 29 and 31 for a more extensive presentation), we briefly review various applications of QBF reasoning that have been recently proposed (Section 30.3), and then we focus on the description of the main approaches which are at the basis of currently available solvers for prenex QBFs in conjunctive normal form (CNF) (Section 30.4). Other approaches and extensions to non prenex, non CNF QBFs are briefly reviewed at the end of the chapter.

30.2. Quantified Boolean Logic

Consider a set P of symbols. A *variable* is an element of P . The set of *Quantified Boolean Formulas* (QBFs) is defined to be the smallest set such that

1. if z is a variable, then z is a QBF;
2. if $\varphi_1, \dots, \varphi_n$ are QBFs then also $(\varphi_1 \wedge \dots \wedge \varphi_n)$ and $(\varphi_1 \vee \dots \vee \varphi_n)$ are QBFs ($n \geq 0$);
3. if φ is a QBF then also $\neg\varphi$ is a QBF;

4. if φ is a QBF and z is a variable, then also $\forall z\varphi$ and $\exists z\varphi$ are QBFs.

Other popular propositional connectives, like implication and equivalence, can be defined on the basis of the given ones. In the following, we use TRUE and FALSE as abbreviations for the empty conjunction and the empty disjunction respectively.

In a QBF $Qz\varphi$ with $Q \in \{\forall, \exists\}$, φ is called the *scope* of Qz and Q is a *quantifier binding* z . An *occurrence of a variable z is free in a QBF φ* if it is not in the scope of a quantifier Q binding z . A *variable z is free in a QBF φ* if it has free occurrences. A QBF is *closed* if it has no free occurrences. For example, the QBF

$$\forall y\exists x_2((\neg x_1 \vee \neg y \vee x_2) \wedge (\neg y \vee \neg x_2) \wedge (x_2 \vee ((x_1 \vee \neg y) \wedge (y \vee x_2)))) \quad (30.1)$$

is not closed, since x_1 is free in it. From the above definitions, it is also clear that a QBF without quantifiers is a propositional formula.

A *valuation* is a mapping \mathcal{I} from the set P of variables to $\{\text{TRUE}, \text{FALSE}\}$. \mathcal{I} can be extended to an arbitrary QBF φ as follows:

1. If φ is a variable z , $\mathcal{I}(\varphi) = \mathcal{I}(z)$;
2. If φ is $\neg\psi$, $\mathcal{I}(\varphi) = \text{TRUE}$ iff $\mathcal{I}(\psi) = \text{FALSE}$;
3. If φ is $(\varphi_1 \wedge \dots \wedge \varphi_n)$, $\mathcal{I}(\varphi) = \text{TRUE}$ iff $\forall i : 1 \leq i \leq n, \mathcal{I}(\varphi_i) = \text{TRUE}$;
4. If φ is $(\varphi_1 \vee \dots \vee \varphi_n)$, $\mathcal{I}(\varphi) = \text{TRUE}$ iff $\exists i : 1 \leq i \leq n, \mathcal{I}(\varphi_i) = \text{TRUE}$;
5. If φ is $\exists x\psi$, $\mathcal{I}(\varphi) = \text{TRUE}$ iff $\mathcal{I}(\varphi_x) = \text{TRUE}$ or $\mathcal{I}(\varphi_{\neg x}) = \text{TRUE}$;
6. If φ is $\forall y\psi$, $\mathcal{I}(\varphi) = \text{TRUE}$ iff $\mathcal{I}(\psi_y) = \text{TRUE}$ and $\mathcal{I}(\psi_{\neg y}) = \text{TRUE}$.

If φ is a QBF and z is a variable, φ_z (resp. $\varphi_{\neg z}$) is the QBF obtained by substituting all the free occurrences of z in φ with TRUE (resp. FALSE).

A valuation \mathcal{I} *satisfies* a QBF φ if $\mathcal{I}(\varphi) = \text{TRUE}$. A QBF is *satisfiable* if there exists a valuation satisfying it. Two QBFs φ_1, φ_2 are (*logically*) *equivalent* if every valuation satisfies $((\neg\varphi_1 \vee \varphi_2) \wedge (\varphi_1 \vee \neg\varphi_2))$, and are *equisatisfiable* if they are both satisfiable or both unsatisfiable.

From the above definitions, it is clear that if φ is closed, any two valuations give the same value to φ . Thus, if φ_1 and φ_2 are both closed QBFs

1. φ_1 and φ_2 are satisfiable if and only if they are given the value TRUE by any valuation, and
2. φ_1 and φ_2 are equivalent if and only if they are equisatisfiable.

30.3. Applications of QBFs and QBF reasoning

Deciding the value of a QBF is the prototypical PSPACE complete problem. As such, many decision problems in PSPACE have been shown to be reducible to the task of deciding the satisfiability of a QBF (see, e.g., [Pap94]). Further, the availability of progressively more efficient QBF solvers has recently fostered the definition of effective encodings of various problems as QBFs, and the use of QBF solvers. In the following, we briefly review some of these recent proposals in the areas of automated planning, knowledge representation and reasoning, formal methods.

In the area of automated planning, QBF solvers are used to solve conformant and conditional planning problems in [Rin99a]. The work of [FG00] defines several

encodings of conformant planning problems and presents a procedure mimicking the computation of a search based QBF solver (see also [CGT03]). Turner [Tur02] shows how many other planning and reasoning tasks can be encoded as QBFs, but does not evaluate the effectiveness of the approach. In [GR04, AGS05], various encodings in QBFs of the famous "Connect4" and evader-pursuer problems on a fixed size checkerboard are presented. See also Part 2, Chapter 19 for details (including the presentation of some encodings) about how conditional planning problems can be casted in Quantified Boolean Logic.

In the area of knowledge representation and reasoning, [EETW00] defines the encoding of several reasoning tasks (including autoepistemic, default logic, disjunctive logic programming, and circumscription problems) in QBFs. [PV03] defines a translation of the modal logic K to QBF (see Part 2, Chapter 29 for more on this topic). [EST⁺03] shows how the problem of the evaluation of nested counterfactuals is reducible to a QBF. [DSTW04] shows that the task of modifying a knowledge base K in order to make the result satisfying and consistent with a set of formulas R and C respectively, can be encoded as a QBF φ such that the valuations satisfying φ correspond to belief change extensions in the original approach. In [BSTW05], the authors describe polynomial-time constructible encodings in QBFs of paraconsistent reasoning principles, and advocates the usage of QBF solvers. [Tom03] gives polynomial reductions mapping a given abduction problem into a QBF φ such that the valuations satisfying φ correspond to solutions of the original problem. [OSTW06] uses QBF solvers to check the equivalence of answer-set programs.

In the area of formal methods, the use of QBF for checking the equivalence of partial implementations has been proposed in [SB01, HBS06]. In [AB00] a similar technique is applied to check whether the structural and behavioral descriptions of protocols agree with each other. In [MS04, GNT07] QBF solvers are used to solve vertex eccentricity problems, while [KHD05, DHK05, JB07, MVB07] show how QBF could improve over SAT in various model checking and formal verification tasks. In [BLS03] QBF solvers are applied to verify pipeline processors. In [CKS05] QBF solvers are proposed for the formal verification of interleaving nondeterministic Boolean programs (see also Part 2, Chapter 18). In the area of Field Programmable Gate Array (FPGA) logic synthesis, [LSB05] uses QBFs for determining if a logic function can be implemented in a given programmable circuit.

30.4. QBF solvers

The development of solvers dedicated to the satisfiability problem of QBFs started with the seminal works of [KBKF95, CGS98] and has, since then, attracted more and more attention. Considering the currently available QBF solvers, the vast majority of them focuses on closed QBFs in prenex conjunctive normal form.

A QBF is in *prenex form* if it has the form

$$Q_1 z_1 Q_2 z_2 \dots Q_n z_n \Phi \quad (n \geq 0) \quad (30.2)$$

where

- every Q_i ($1 \leq i \leq n$) is a quantifier,
- z_1, \dots, z_n are distinct variables, and
- Φ is a propositional formula.

In (30.2), $Q_1 z_1 \dots Q_n z_n$ is the *prefix* and Φ is the *matrix*. (30.2) is in *Conjunctive Normal Form (CNF)* if Φ is a conjunction of clauses, where a *clause* is a disjunction of literals. A *literal* is a variable or its negation.

The motivation of this restriction is that any QBF φ can be in linear time transformed into a closed QBF φ' in CNF such that φ and φ' are equisatisfiable. A simple such procedure

1. renames variables in order to make sure that φ does not contain variables bounded by two distinct quantifier occurrences;
2. converts φ in prenex form by moving quantifiers in front of the formula: in the process, care has to be taken in order to ensure that if Qz occurs in the scope of $Q'z'$ in φ , then Qz occurs in the scope of $Q'z'$ also in the resulting formula (Q and Q' are quantifiers, z and z' are variables). In [EST⁺03], the authors define several polynomial prenexing strategies such that the resulting QBF is guaranteed to belong to the lowest possible complexity class in the polynomial hierarchy;
3. converts the matrix in CNF by using a procedure based on renaming, such as those described in [Tse70, PG86, JS04]: the additional variables introduced by the CNF transformation can be existentially quantified in the scope of all the other quantifiers in the formula;
4. assuming $\{x_1, \dots, x_n\}$ ($n \geq 0$) are the free variables in the QBF φ built so far, $\exists x_1 \dots \exists x_n \varphi$ is the final closed, prenex, CNF QBF.

Each of the above three steps can be performed in linear time, and an efficient procedure performs all the above steps with a single traversal of the input QBF (see Chapter 29 for a more detailed and formal discussion).

For example, using the procedure described in [JS04] for converting the matrix in CNF, it is easy to see that (30.1) is equisatisfiable to the QBF

$$\exists x_1 \forall y \exists x_2 \exists x_3 \{ \{ \bar{x}_1, \bar{y}, x_2 \}, \{ \bar{y}, \bar{x}_2 \}, \{ x_2, x_3 \}, \{ x_1, \bar{y}, \bar{x}_3 \}, \{ y, x_2, \bar{x}_3 \} \}, \quad (30.3)$$

in which

- the matrix is represented as a set of clauses (to be interpreted conjunctively),
- each clause is represented as a set of literals (to be interpreted disjunctively),
- \bar{z} stands for $\neg z$.

However, we have to mention that in the process of converting the formula in prenex and CNF form, some relevant information about the structure of both the matrix and the prefix of in input QBF is lost. Using such structural information (of the matrix and of the prefix) can greatly improve performances of the solvers, as shown in [Bie04, Ben05a, GNT07].

For sake of simplicity, in the following, we will restrict our attention to closed QBFs in CNF and prenex form, and keep the above conventions for representing

matrices, clauses and literals. We further assume that each clause in the matrix is non tautological, i.e., that a clause does not contain both a literal l and \bar{l} : Indeed, such clauses can be safely removed from the matrix without affecting the value of the QBF.

For a literal l ,

- $|l|$ is the variable occurring in l ; and
- \bar{l} is the negation of l if l is a variable, and it is $|l|$ otherwise.

We also say that a literal l is *existential* if $\exists|l|$ belongs to the prefix, and it is *universal* otherwise. With these assumptions, if φ is (30.2) and l is a literal with $|l| = z_i$, we redefine φ_l to be the QBF

- whose matrix is obtained from Φ by removing the clauses C with $l \in C$, and by removing \bar{l} from the other clauses; and
- whose prefix is $Q_1 z_1 Q_2 z_2 \dots Q_{i-1} z_{i-1} Q_{i+1} z_{i+1} \dots Q_n z_n$.

Further, we extend the notation to sequences of literals: If $\mu = l_1; l_2; \dots; l_m$ ($m \geq 0$), φ_μ is defined as $(\dots((\varphi_{l_1})_{l_2})\dots)_{l_m}$. For instance, if φ is (30.3), $\varphi_{x_1; x_3}$ is

$$\forall y \exists x_2 \{ \{ \bar{y}, x_2 \}, \{ \bar{y}, \bar{x}_2 \}, \{ y, x_2 \} \}.$$

30.4.1. Solvers based on search

A simple recursive procedure for determining the satisfiability of a QBF φ simplifies φ to φ_z and (or, respectively) $\varphi_{\bar{z}}$ if z is the leftmost variable in the prefix and z is universal (existential, respectively), till either an empty clause or the empty set of clauses are produced: On the basis of the satisfiability of φ_z and $\varphi_{\bar{z}}$, the satisfiability of φ can be determined according to the semantics of QBFs.

There are some simple improvements to this basic procedure.

Let φ be a QBF (30.2). Consider φ .

The first improvement is that we can directly conclude that φ is unsatisfiable if the matrix of φ contains a contradictory clause. A clause C is *contradictory* if it contains no existential literal. An example of a contradictory clause is the empty clause.

The second improvement is based on the fact that in a QBF we can swap two variables in the prefix if they have the same level. In (30.2), the *level of a variable* z_i is $1 +$ the number of expressions $Q_j z_j Q_{j+1} z_{j+1}$ in the prefix with $j \geq i$ and $Q_j \neq Q_{j+1}$. For example, in (30.3), x_2 and x_3 have level 1, \bar{y} has level 2, \bar{x}_1 has level 3. Thus, assuming that z_i and z_1 have the same level in (30.2), (30.2) is logically equivalent to

$$Q_i z_i Q_2 z_2 \dots Q_{i-1} z_{i-1} Q_1 z_1 Q_{i+1} z_{i+1} \dots Q_n z_n \Phi$$

and we can determine the satisfiability of φ on the basis of φ_{z_i} and/or $\varphi_{\bar{z}_i}$. This allows to introduce some heuristics in the choice of the literal for branching.

Finally, if a literal l is unit or monotone in φ , then φ is logically equivalent to φ_l . In (30.2), a literal l is

- *Unit* if l is existential, and, for some $m \geq 0$,

```

0 function Q-DLL( $\varphi, \mu$ )
1   if ((a contradictory clause is in the matrix of  $\varphi_\mu$ )) return FALSE;
2   if ((the matrix of  $\varphi_\mu$  is empty)) return TRUE;
3   if ( $l$  is unit in  $\varphi_\mu$ ) return Q-DLL( $\varphi, \mu; l$ );
4   if ( $l$  is monotone in  $\varphi_\mu$ ) return Q-DLL( $\varphi, \mu; l$ );
5    $l :=$  (a literal at the highest level in  $\varphi_\mu$ );
6   if ( $l$  is existential) return Q-DLL( $\varphi, \mu; l$ ) or Q-DLL( $\varphi, \mu; \bar{l}$ );
7   else return Q-DLL( $\varphi, \mu; l$ ) and Q-DLL( $\varphi, \mu; \bar{l}$ ).

```

Figure 30.1. The algorithm of Q-DLL.

- a clause (l, l_1, \dots, l_m) belongs to Φ , and
- each literal l_i ($1 \leq i \leq m$) is universal and has a lower level than l . The *level of a literal l* is the level of $|l|$.

For example, in a QBF of the form

$$\dots \exists x_1 \forall y_1 \exists x_2 \dots \{\{x_1, y_1\}, \{x_2\}, \dots\},$$

both x_1 and x_2 are unit.

- *Monotone* or *pure* if
 - either l is existential, \bar{l} does not belong to any clause in Φ , and l occurs in Φ ;
 - or l is universal, l does not belong to any clause in Φ , and \bar{l} occurs in Φ .
- For example, in the QBF

$$\forall y_1 \exists x_1 \forall y_2 \exists x_2 \{\{-y_1, y_2, x_2\}, \{x_1, \neg y_2 \neg x_2\}\},$$

the only monotone literals are y_1 and x_1 .

With such improvements, the resulting procedure, called Q-DLL, is essentially the one presented in the work of Cadoli, Giovanardi, and Schaerf [CGS98], which extends DLL in order to deal with QBFs. Figure 30.1 is a simple, recursive presentation of it. In the figure, given a QBF φ ,

1. FALSE is returned if a contradictory clause is in the matrix of φ_μ (line 1); otherwise
2. TRUE is returned if the matrix of φ_μ is empty (line 2); otherwise
3. at line 3, μ is recursively extended to $\mu; l$ if l is unit (and we say that l has been *assigned as unit*); otherwise
4. at line 4, μ is recursively extended to $\mu; l$ if l is monotone (and we say that l has been *assigned as monotone*); otherwise
5. a literal l at the highest level is chosen and
 - If l is existential (line 6), μ is extended to $\mu; l$ first (and we say that l has been *assigned as left split*). If the result is FALSE, $\mu; \bar{l}$ is tried and returned (and in this case we say that \bar{l} has been *assigned as right split*).
 - Otherwise (line 7), l is universal, μ is extended to $\mu; l$ first (and we say that l has been *assigned as left split*). If the result is TRUE, $\mu; \bar{l}$ is tried and returned (and in this case we say that \bar{l} has been *assigned as right split*).

Figure 30.2. The tree generated by $Q\text{-DLL}$ for (30.3). The matrix of (30.3) is shown at the root node, and the prefix is $\exists x_1 \forall y \exists x_2 \exists x_3$. U, P, L, R stand for “unit”, “pure”, “left split”, “right split” respectively, and have the obvious meaning.

Initially, φ is the input formula, and μ is the empty sequence of literals ϵ .

Theorem 1. $Q\text{-DLL}(\varphi, \epsilon)$ returns TRUE if φ is true, and FALSE otherwise.

Given what we have said so far, it is clear that $Q\text{-DLL}$ evaluates φ by generating a semantic tree [Rob68] in which each node corresponds to an invocation of $Q\text{-DLL}$ and thus to an assignment μ . For us,

- an *assignment* (for a QBF φ) is a possibly empty sequence $\mu = l_1; l_2; \dots; l_m$ ($m \geq 0$) of literals such that for each l_i in μ , l_i is unit, or monotone, or at the highest level in $\varphi_{l_1; l_2; \dots; l_{i-1}}$;
- the (*semantic*) *tree* representing a run of $Q\text{-DLL}$ on φ is the tree
 - having a node μ for each call to $Q\text{-DLL}(\varphi, \mu)$; and
 - an edge connecting any two nodes μ and $\mu; l$, where l is a literal.

Any tree representing a run of $Q\text{-DLL}$ has at least the node corresponding to the empty assignment ϵ .

As an example of a run of $Q\text{-DLL}$, consider the QBF (30.3). For simplicity, assume that the literal returned at line 5 in Figure 30.1 is the negation of the first variable in the prefix which occurs in the matrix of the QBF under consideration. Then, the tree searched by $Q\text{-DLL}$ when φ is (30.3) can be represented as in Figure 30.2. In the figure:

- Each node is labeled with the literal assigned by $Q\text{-DLL}$ in order to extend the assignment built so far. Thus, the assignment corresponding to a node is the sequence of labels in the path from the root to the node. For instance, the assignment corresponding to the node with label \bar{x}_3 is $\bar{x}_1; y; \bar{x}_3$.
- When literals are assigned as unit or monotone, the corresponding nodes are aligned one below the other. Further for each assigned literal l , we also show whether l has been assigned as unit, monotone, left or right split by marking it as U, P, L, R respectively.
- When l has been assigned as a left or right split, we also show the matrix of $\varphi_{\mu; l}$, where μ is the sequence of literals assigned before l .
- When the node μ is a leaf, then the matrix of φ_{μ} is either empty (in which case we write “ $\{\}$ ” below the node), or it contains a contradictory clause (in which case we write “ $\{\{\}\}$ ” below the node).

Figure 30.3. The clause resolution corresponding to the tree generated by *Q-DLL* for (30.3). The prefix is $\exists x_1 \forall y \exists x_2 \exists x_3$.

Considering Figure 30.2, it is easy to see that *Q-DLL* would correctly return FALSE, meaning that (30.3) is false.

As in SAT, there is a close correspondence between the search tree explored by *Q-DLL* and a resolution proof showing the (un)satisfiability of the input formula, and this correspondence lays down the foundations for incorporating nogood and good learning in *Q-DLL* [GNT06].

Consider a QBF φ . Assume φ is unsatisfiable and let Π be the search tree explored by *Q-DLL*(φ, ϵ). Then, we can restrict our attention to the *minimal false subtree* of Π , i.e., to the tree obtained from Π by deleting the subtrees starting with a left split on a universal literal: These subtrees are originated from “wrong choices” when deciding which branch to explore first. In the minimal false subtree Π' of Π , all the leaves terminate with the empty clause, and we can associate with each node of Π' a clause pretty much in the same way as in SAT: The leaves of the proof tree associated to the search tree are clauses that generated the empty clause, and the clauses associated to the internal nodes are obtained by resolving the clauses associated to children nodes in the search tree (a literal l assigned as unit can be considered as assigned as right split: performing a left split on \bar{l} would immediately generate the empty clause and this node would be a leaf of the search tree).

For instance, if φ is (30.3), Figure 30.3 shows the minimal false subtree of *Q-DLL*’s computation, and the clause associated to each node. In the figure,

- the clause associated with each node is written in gray and to the right of the node itself;
- when a node corresponds to the assignment of a unit literal l , a clause of φ which causes l to be unit at that node (used in the corresponding clause resolution) is written in gray and to the left of the node.

Indeed, the clause associated to the root node ϵ of the figure, is the empty one, meaning that (30.3) is unsatisfiable.

There are however two differences between the QBF and the SAT cases. The first one, is that Q (clause) resolution [KBKF95] is used instead of plain resolution.

Q (clause) resolution (on a literal l) is the rule

$$\frac{C_1 \quad C_2}{\min(C)} \quad (30.4)$$

where

- l is an existential literal;
- C_1, C_2 are two clauses such that $\{l, \bar{l}\} \subseteq (C_1 \cup C_2)$, and for no literal $l' \neq l$, $\{l', \bar{l}'\} \subseteq (C_1 \cup C_2)$;
- C is $(C_1 \cup C_2) \setminus \{l, \bar{l}\}$;
- $\min(C)$ is the clause obtained from C by removing the universal literals whose level is lower than the level of all the existential literals in C .

C_1 and C_2 are the *antecedents*, and $\min(C)$ is the *resolvent* of the rule.

The second difference is that the process of associating a clause to each node may require more than a single Q -resolution. Indeed, some clause resolutions can be blocked because of universal variables occurring both as y and \bar{y} in the clauses to be used for the resolution. Consider for instance the QBF:

$$\exists x_1 \exists x_2 \forall y \exists x_3 \{ \{x_1, \bar{x}_3\}, \{\bar{x}_2, \bar{y}, x_3\}, \{x_2, y, x_3\}, \{\bar{x}_1, x_3\} \}. \quad (30.5)$$

Then, Q -DLL may explore the following branch:

$$\begin{array}{l} \langle \bar{x}_1, L \rangle \\ \{x_1, \bar{x}_3\} \langle \bar{x}_3, U \rangle \\ \{\bar{x}_2, \bar{y}, x_3\} \langle \bar{x}_2, U \rangle \dots \\ \{\{\}\} \{x_2, y, x_3\} \end{array} \quad (30.6)$$

where it is not possible to perform the clause resolution associated with the node having label $\langle \bar{x}_2, U \rangle$. As in the example, a clause resolution (30.4) may be blocked only because of some “blocking” universal literal l

- with both l and \bar{l} not in μ , and
- with $l \in C_1$ and $\bar{l} \in C_2$.

Since both C_1 and C_2 are in minimal form, this is only possible if both C_1 and C_2 contain an existential literal l'

- having level less than or equal to the level of all the other literals in the clause; and
- assigned as unit.

Then, the obvious solution is to get rid of the blocking literals l in C_1 (or in C_2) by resolving away from C_1 (or from C_2) the existential literals with a level lower than the level of l .

In our example, if φ is (30.5) and with reference to the deduction in (30.6), the blocked clause resolution is the one associated with the node $\bar{x}_1; \bar{x}_3; \bar{x}_2$. Indeed, the two clauses $C_1 = \{x_2, y, x_3\}$ and $C_2 = \{\bar{x}_2, \bar{y}, x_3\}$ cannot be resolved on x_2 because of the occurrences of y and \bar{y} in the two clauses. Considering the first clause $\{x_2, y, x_3\}$, since the level of y is less than the level of x_2 and the clause is in minimal form, there must be another existential literal (in our case x_3) having

level less than the level of y and assigned as unit: By resolving $\{x_2, y, x_3\}$ with the clause $\{x_1, \bar{x}_3\}$ (which causes the assignment of \bar{x}_3 as unit) we get the resolvent $C_3 = \min(\{x_1, x_2, y\}) = \{x_1, x_2\}$ which can be now resolved with C_2 on x_2 . Thus, the clause associated with each node is:

$$\begin{array}{l} \langle \bar{x}_1, L \rangle \{x_1\} \\ \{x_1, \bar{x}_3\} \langle \bar{x}_3, U \rangle \{x_1\} \\ \{\bar{x}_2, \bar{y}, x_3\} \langle \bar{x}_2, U \rangle \{x_1, \bar{y}, x_3\} \\ \{\{\}\} \{x_1, x_2\} \text{ (From } \{x_2, y, x_3\} \{x_1, \bar{x}_3\}\text{)}. \end{array}$$

Notice that the choice of eliminating the blocking literal y in C_1 while keeping C_2 the same, is arbitrary. Indeed, we could eliminate the blocking literal \bar{y} in C_2 and keep C_1 . In the case of the deduction in (30.6), this amounts to eliminate the universal literal \bar{y} in $\{\bar{x}_2, \bar{y}, x_3\}$: By resolving this clause with $\{x_1, \bar{x}_3\}$ on x_3 , we get the resolvent $\{x_1, \bar{x}_2\}$, which leads to the following legal deduction:

$$\begin{array}{l} \langle \bar{x}_1, L \rangle \{x_1\} \\ \{x_1, \bar{x}_3\} \langle \bar{x}_3, U \rangle \{x_1\} \\ \text{(From } \{\bar{x}_2, \bar{y}, x_3\}, \{x_1, \bar{x}_3\}\text{)} \{x_1, \bar{x}_2\} \langle \bar{x}_2, U \rangle \{x_1, y, x_3\} \\ \{\{\}\} \{x_2, y, x_3\}. \end{array}$$

Variants of the above procedures are described in [GNT02, Let02, ZM02a]. In [GNT06], it is proved that we can always associate a clause C (resulting from a sequence of clause resolutions) to the node φ_μ of the minimal false subtree explored by $Q\text{-DLL}$: The clause C is such that for each existential literal $l \in C$, \bar{l} is in μ . Such clauses can be learned as nogoods, pretty much as in SAT.

If φ is satisfiable the situation is the dual one, except that we have to consider terms or cubes instead of clauses. A *term* or *cube* is a conjunction of literals. Terms are associated to the *minimal true subtree* Π' explored by $Q\text{-DLL}$, i.e., to the tree obtained from Π by deleting the subtrees starting with a left split on an existential literal. In more details, to each node φ_μ of Π' we associate a term T such that for each universal literal $l \in T$, \bar{l} is in μ . Such terms can be learned as goods, to be treated as in disjunction with the matrix of φ . Because of the learned goods, also universal literals can be assigned as unit at any point of the search tree. Assuming the current assignment is μ , a universal literal l can be assigned as *unit* if there exists a learned term T such that for each literal $l' \in T$, \bar{l}' is not in μ ; whose only unassigned universal literal is l while all the other unassigned literals have level lower than l . The process of associating terms to each node of Π' starts by associating the conjunction of the literals in μ when the matrix of φ_μ becomes empty. Then, the situation is analogous to the previous case, except that Q term resolution has to be used. *Term resolution (on a literal l)* is the rule

$$\frac{T_1 \quad T_2}{\min(T)}$$

where

- l is an universal literal;
- T_1, T_2 are two terms such that $\{l, \bar{l}\} \subseteq (T_1 \cup T_2)$, and for no literal $l' \neq l$, $\{l', \bar{l}'\} \subseteq (T_1 \cup T_2)$;

- T is $(T_1 \cup T_2) \setminus \{l, \bar{l}\}$;
- $\min(T)$ is the term obtained from T by removing the existential literals whose level is lower than the level of all the universal literals in T .

As before, some term resolution may be blocked, but this situation can be solved by getting rid of the existential blocking literals by performing term resolutions on one of the antecedents. See [GNT02, Let02, ZM02b, GNT06] for more details, and [GNT04] for a discussion about the interactions and problems related to the implementation of learning in the presence of monotone literal fixing.

Given the above, it is possible to associate a clause/term resolution deduction to each branch of the search tree explored by Q - DLL . The resolvents of such deductions can be learned as in SAT. Further, the Unique Implication Point (UIP) mechanism that has shown to be very effective in SAT (see [MSS96] for a presentation of UIP based learning and [ZMMM01] for a comparison of different UIP based learning mechanisms), can be generalized to the QBF case in a simple way. Assume that we are backtracking on a literal l assigned at decision level n , where the *decision level* of a literal is the number of branching nodes before l . The clause/term corresponding to the reason for the current conflict (resp. solution) is learned if and only if:

1. l is existential (resp. universal),
2. all the assigned literals in the reason except l , are at a decision level strictly smaller than n , and
3. there are no unassigned universal (resp. existential) literals in the reason that are before l in the prefix.

Under the above conditions, it is possible to backjump to the node at the maximum decision level among the literals in the reason, excluding l , and to assign l (resp. \bar{l}) as unit.

Also the ideas underlying the heuristic to be used for selecting the next literal to branch on, can be generalized from the SAT case. However, it is also clear that the effectiveness of any devised heuristic not only depends on the structure of the matrix of the QBFs, but also and in a crucial way, on the structure of the prefix. Indeed, QBFs range from formulas like

$$\exists x_1 \forall x_2 \exists x_3 \dots \forall x_{n-1} \exists x_n \Phi \quad (30.7)$$

to formulas like

$$\exists x_1 \exists x_2 \dots \exists x_m \Phi, \quad (30.8)$$

i.e., to SAT instance. If we consider QBFs of the type (30.7) then it is likely that the heuristic is almost useless: unless an atom $|l|$ is removed from the prefix because l is either unit or monotone, the atom to pick at each node is fixed. On the other hand, considering QBFs of the sort (30.8), we know from the SAT literature that nontrivial heuristics are essential to reduce the search space. In practice, QBF instances lay between the extremes marked by (30.7) and (30.8), and instances like (30.7) are fairly uncommon, particularly on QBFs encoding real-world problems. Because of this, the scoring mechanisms devised for SAT in order to decide which literal is best to branch on, are applied also to the QBF case. However, it is clear that the literal with the highest score can be selected

only if it has also the highest level among the unassigned literals. These ideas can be effectively implemented by arranging literals in a priority queue according to (i) the prefix level of the corresponding atom, and (ii) their score. In this way, atoms at prefix level i are always assigned before atoms at prefix level $j > i$ no matter the score, and atoms with the same prefix level are assigned according to their score.

The limitation to branch on literals at the highest level is one of the drawbacks of search based procedures. [Rin99b] proposed techniques based on the inversion of quantifiers, e.g., on assigning universal literals not at the highest level. Indeed, assigning a universal (resp. existential) literal not at the highest level corresponds to weakening (resp. strengthening) the satisfiability of the QBF: If the resulting QBF is unsatisfiable (resp. satisfiable), so it is the original one. These ideas have been proposed and used also in [CSGG02, SB05]. In [CSGG02] a SAT solver is called at each recursive call on the SAT formula obtained by removing all the universal literals from the matrix (this corresponds to consider the QBF in which all the universal quantifiers are pushed down the prefix till level 1): If the SAT formula is satisfiable, this is also the case for the original QBF. Along the same lines, [SB05] calls a SAT solver on the matrix of the QBF (this corresponds to consider the QBF in which all the universal quantifiers are changed to existential ones): If the SAT formula is unsatisfiable, so is also the QBF; in the case an assignment satisfying the matrix is found, such assignment is used to guide the search in the QBF solver.

Beside the above, [GN⁺04] presents lazy data structures for unit and monotone literal detection. [GNT01, GNT03] show how *Q-DLL* can be extended with conflict and solution backjumping. [GHR03] combines Conflict and Solution Directed Backjumping (CSBJ) with a Stochastic Local Search procedure: The result is a procedure which in some cases is unable to determine the (un)satisfiability of the QBF (in which cases it returns “Unknown”), but otherwise the result is guaranteed to be correct. [CMBL05] presents a branching heuristics promoting renamable Horn formulas. [SB06] proposes the use of binary clause reasoning and hyper-resolution.

30.4.2. Solvers based on variable elimination

An alternative approach consists in eliminating variables till the formula contains the empty clause or becomes empty. Elimination of variables can be performed in QBF on the basis that for any QBF (non necessarily in prenex CNF form) φ , $\exists x\varphi$ and $\forall y\varphi$ are logically equivalent to $(\varphi_x \vee \varphi_{\bar{x}})$ and $(\varphi_y \wedge \varphi_{\bar{y}})$ respectively.

The main problem of this approach is that at each step the formula can double its size. There are however several ways to address these issues. The first one, is that if a variable is unit or monotone then it can be simplified as we have seen in the previous section.

Further, in the case of universal variables, each clause C can be replaced with $\min(C)$, and we can avoid the duplication of the clauses not in their minimal scope. Given a universal variable y , a clause C is in the *minimal scope of y* if y occurs in C , or if C is y -connected to a clause already determined to be in the minimal scope of y . Two clauses are y -connected if there exists an existential

variable with level lower than y occurring in both clauses. For example, in (30.3) the minimal scope of y consists of all the clauses in the matrix. In other cases however, the minimal scope can be (significantly) smaller, as in

$$\forall y \exists x_1 \exists x_2 \exists x_3 \{ \{y, x_1\}, \{\bar{y}, \bar{x}_1\}, \{x_2, x_3\}, \{\bar{x}_2, \bar{x}_3\} \}$$

in which the minimal scope of y are just the first two clauses in the matrix. The expansion of a variable y is obtained by

1. adding a variable z' for each variable z with level lower than the level of y and occurring in minimal scope of y ,
2. quantifying each variable z' in the same way and at the same level of the variable z ,
3. for each C in the minimal scope of y , adding a new clause C' obtained from C by substituting the newly introduced variables z' to z ,
4. considering the newly introduced clauses, those containing \bar{y} are eliminated and y is eliminated from the others.
5. considering the clauses in the original minimal scope of y , those containing y are eliminated and \bar{y} is eliminated from the others.

For example, the expansion of the universal variable y in (30.3) yields the SAT formula:

$$\exists x_1 \exists x_2 \exists x_3 \exists x'_2 \exists x'_3 \{ \{x_2, x_3\}, \{x_2, \bar{x}_3\}, \{\bar{x}_1, x'_2\}, \{\bar{x}'_2\}, \{x'_2, x'_3\}, \{x_1, \bar{x}'_3\} \}.$$

which can be determined to be unsatisfiable by a call to a SAT solver. In order to determine the cost of such expansion, for a literal l let S_l be the set of clauses C with $l \in C$, $o(l)$ be $|S_l|$ and $s(l)$ be the sum of the sizes of the clauses in S_l (i.e., $\sum_{C \in S_l} |C|$). Then, if $\text{minscope}(y)$ is the size of the clauses in the minimal scope of y , after y expansion, the size of the matrix of the QBF increases or decreases by

$$\text{minscope}(y) - (s(y) + s(\bar{y}) + o(y) + o(\bar{y})). \quad (30.9)$$

Notice that when the variable y occurs in all the clauses in its minimal scope, then $\text{minscope}(y) = s(y) + s(\bar{y})$ and (30.9) is negative, i.e., the matrix of the QBF shrinks after the expansion.

Alternatively to the expansion of a universal variable y , we can eliminate the existential variables in its minimal scope. In general, the elimination of an existential variable x is performed only when x occurs in clauses in which all the other literals have level greater than or equal to the level of x . If this is the case, we say that x is an *innermost* variable (notice that all the variables with level 1 are innermost). If x is an innermost variable, we can eliminate x by replacing S_x and $S_{\bar{x}}$ with the clauses obtained by resolving each clause in S_x with each clause in $S_{\bar{x}}$ on x , i.e., with the clauses in

$$\{C \cup C' : C \cup \{x\} \in S_x, x \notin C, C' \cup \{\bar{x}\} \in S_{\bar{x}}, \bar{x} \notin C'\}.$$

For example, the elimination of the innermost variable x_3 from (30.3) yields the QBF:

$$\exists x_1 \forall y \exists x_2 \{ \{\bar{x}_1, \bar{y}, x_2\}, \{\bar{y}, \bar{x}_2\}, \{x_1, \bar{y}, x_2\}, \{y, x_2\} \}. \quad (30.10)$$

```

0 function Q-DP( $\varphi$ )
1   if ((a contradictory clause is in the matrix of  $\varphi$ ) return FALSE;
2   if ((the matrix of  $\varphi$  is empty)) return TRUE;
3   if ( $l$  is unit in  $\varphi$ ) return Q-DP( $\varphi_l$ );
4   if ( $l$  is monotone in  $\varphi$ ) return Q-DP( $\varphi_l$ );
5    $z :=$  (a variable in  $\varphi$  having level  $\leq 2$ );
6   if ( $z$  is existential) return Q-DP(resolve( $z, \varphi$ ));
7   else return Q-DP(expand( $z, \varphi$ )).

```

Figure 30.4. The algorithm of Q-DP.

After the elimination of a variable x , the size of the resulting formula can increase or decrease by

$$o(x) \times (s(\bar{x}) - o(\bar{x})) + o(\bar{x}) \times (s(x) - o(x)) - (s(x) + s(\bar{x})), \quad (30.11)$$

where

1. the first (resp. second) addendum takes into account the fact that each clause containing x (resp. \bar{x}) has to be resolved with all the clauses in $S_{\bar{x}}$ (resp. S_x); and
2. the last addendum takes into account the fact that all the clauses in S_x and $S_{\bar{x}}$ can be removed.

From (30.11) it is easy to see that there are cases in which the formula can shrink, i.e., in which (30.11) is negative. This is always the case, e.g., when $o(x) = 1$ and $s(x) = 2$, as it is the case for x_3 in (30.3). Further, in practice the size of the resulting formula may result to be smaller than the one predicted by (30.11). For instance, the size of matrix of (30.10) is 10, while the one predicted by (30.11) is 11. It is however easy to have cases in which (30.11) is positive and the size of the resulting formula is exactly the one predicted by (30.11), e.g., when $o(x) > 1$, $s(x) > 2$ and the variables in S_x are distinct from the variables in $S_{\bar{x}}$.

Figure 30.4 presents a high level description of a recursive procedure incorporating the above ideas. In the figure, given a QBF φ , lines (1)-(4) are analogous to the ones in Figure 30.1, while at line (5)

1. either an existential variable z at level 1 is chosen and then the call $resolve(z, \varphi)$ eliminates z by resolution (line (6)).
2. or a universal variable z at level 2 is chosen and then the call $expand(z, \varphi)$ eliminates z by expansion (line (7)).

If φ is a SAT formula, Q-DP behaves as the Davis Putnam procedure [DP60].

Theorem 2. Q-DP(φ) returns TRUE if φ is true, and FALSE otherwise.

For example, if φ is (30.3), Q-DP(φ) will return FALSE by, e.g., eliminating x_3 and obtaining (30.10), and then eliminating x_2 and obtaining

$$\exists x_1 \forall y \{ \{ \bar{x}_1, \bar{y} \}, \{ x_1, \bar{y} \} \},$$

equivalent to

$$\exists x_1 \{ \{ \bar{x}_1 \}, \{ x_1 \} \},$$

which is obviously unsatisfiable.

Alternatively, the expansion of y in (30.3) yields the SAT formula:

$$\exists x_1 \exists x_2 \exists x_3 \exists x'_2 \exists x'_3 \{ \{x_2, x_3\}, \{x_2, \bar{x}_3\}, \{\bar{x}_1, x'_2\}, \{\bar{x}'_2\}, \{x'_2, x'_3\}, \{x_1, \bar{x}'_3\} \}$$

which can be determined to be unsatisfiable by a call to a SAT solver, or by repeated applications of variable eliminations till the empty clause is produced.

As for Q - DLL , there are many variable elimination procedures which are variations to the above presented procedure. For example, in Figure 30.4, only universal variables y at level ≤ 2 are chosen for expansion: The restriction to level ≤ 2 is not necessary and in [BKB07] it is shown that variables z which occur only negatively or only positively within clauses in the minimal scope of y do not need to be duplicated and therefore do not propagate y -connectivity. In [Ben04, Bie04] a SAT solver is called as soon as the formula does not contain universal variables. In [Ben04, Bie04], existential variables get first eliminated if they are detected to appear in a binary equivalence: Indeed, if two clauses $\{\bar{l}, x\}$ and $\{l, \bar{x}\}$ are in the matrix of QBF, assuming x has a level not greater than the level of l , x can be safely substituted by l . In [Ben04, Bie04, PV04], simplification mechanisms are defined and used in order to remove subsumed clauses: a clause C is *subsumed* if there exists another clause C' with $C' \subset C$. Considering the way variables are selected for elimination, in [Ben04, Bie04] the choice takes into account the size of the resulting formula as estimated by equations (30.9) and (30.11); in [PV04], universal variables are never expanded since the variables being eliminated are always at level 1. Further, these procedures differ also for the way they represent the matrix. In [Ben04] the QBF is first Skolemized: Each clause corresponds to a disjunction of Boolean functions and is represented via Binary Decision Diagrams (BDDs) [Bry92]. In [PV04] clauses are represented and manipulated as BDDs and ZDDs. In [Bie04] a clause is represented as a set of literals.

The procedure described in [PBZ03] is somehow different from Q - DP though it is based on the elimination of variables from the matrix of the QBF. Given a QBF φ , the basic idea of the procedure is to replace a quantified subformula φ' of φ with a logically equivalent formula φ'' without quantifiers: φ''

1. is in CNF since it corresponds to the conjunction of the negation of the valuations falsifying φ' ; and
2. can be computed using a SAT solver as back-engine if all the quantifiers in φ' are of the same type, or using a QBF solver as back-engine in the general case.

Thus, in [PBZ03], more than a variable can be eliminated in a single step, and these variables can be of different type. Indeed, the selection of the subformula φ' which corresponds to the set V of variables to be eliminated is crucial: If S is the union of the minimal scopes of the variables in V , the intuition for the selection of V is to

1. try to minimize the set of variables in S and not in V , and, at the same time,
2. try to maintain V reasonably small in order to be able to enumerate the valuations falsifying φ' .

30.5. Other approaches, extensions and conclusions

Given a QBF, it is indeed possible to combine the techniques described in the previous sections for solving it. This is what it has been proposed in [Ben05b], where variable elimination and search techniques can be alternated inside one solver. In [PT07] a portfolio of solvers is considered, and the best one is selected using machine learning techniques. [DLMS02] shows how it is possible to encode QBFs in the language of the model checker NuSMV [CCG⁺02], and then use it as engine.

Extensions to the above procedures in order to deal with non prenex, non CNF QBFs have been proposed. When dealing with solvers based on variable elimination, we already mentioned that it is useful to compute the minimal scope of variables and this indeed corresponds to deal with non prenex QBFs, see [Bie04, Ben05a, PV04, PBZ03]. In [GNT07] it is shown that basic *Q-DLL* search procedures can be extended to take into account the quantifier structure, and that substantial speed ups can be obtained. Finally, non prenex QBFs are naturally handled by solvers based on Skolemization of the input QBF, which naturally allow for handling the more general Henkin's branching quantifiers [Hen61].

Non clausal QBF solvers have been proposed in [Zha06, SAG⁺06, ESW06]. In more details, the first two papers show that non clausal formulas can be more naturally encoded in both conjunctive and disjunctive normal forms allowing at the same time for substantial speed ups. The last paper presents a procedure which can be directly applied to formulas in negation normal form.

Chapter 31

Quantified Boolean Formulas

Olaf Beyersdorff, Mikoláš Janota, Florian Lonsing, Martina Seidl

31.1. Introduction

Motivated by the success achieved in practical SAT solving, *quantified Boolean formulas* (QBFs), the extension of propositional formulas with existential and universal quantifiers over the propositional variables, have become subject of intensive research (cf. Chapter 29 and Chapter 30). Over the last two decades, many different solving approaches have been presented forming a wide, heterogenous landscape of solving paradigms. While in SAT solving the conflict-driven clause learning (CDCL) is clearly the predominant solving paradigm (cf. Chapter 4), the picture for QBFs is less obvious. Two paradigms together with preprocessing have particularly impacted the progress in QBF research over the last years: search-based QBF solving and expansion-based solving.

From empirical evaluations [LSVG16, JJK⁺14], it has become evident that search-based solvers (which have variants of Q-resolution as underlying proof systems) and expansion-based solvers (which are based on the the $\forall\text{Exp}+\text{Res}$ proof system) often show orthogonal behavior. This observation could be concisely captured by the means of proof theory. In particular, separation and simulation results between the the different variants of Q-resolution and $\forall\text{Exp}+\text{Res}$ give a detailed picture of the relations between the different proof systems. For such proof-theoretical characterizations, however, it turned out that propositional techniques are insufficient for QBFs. To this end, novel separation techniques—for example, based on strategy extraction—have been introduced that provide an elegant tool for comparing proof systems.

In practical QBF solving proofs play another important role. Proofs that are polynomially checkable can be used to certify the correctness of the result of a QBF solver. In addition, they can be used to extract strategies in terms of so-called Skolem and Herbrand functions. For example, in the case of a synthesis problem, such a function represents the required implementation, or in the case of planning such a function represents the plan.

To obtain certification and strategy extraction also if preprocessing is used, the QRAT proof system has been introduced. It generalizes the RAT proof system

for SAT which is currently the formal foundation of the certificates produced by recent SAT solvers (see Chapter 15).

Currently, we see a strong interaction between proof theory and solving. In this chapter, we survey this connection between theory and practice. In Section 31.3 QCDCL and Q-resolution are presented and in Section 31.4 we show how expansion-based solving and $\forall\text{Exp}+\text{Res}$ are related. In Section 31.5 we discuss proofs for recent preprocessing techniques. Strategy extraction from proofs is shortly presented in Section 31.6. Section 31.7 compares different proof systems used in solving and introduces powerful proof systems that are currently not implemented in any solvers.

31.2. Preliminaries

A *literal* l is a Boolean variable x or its negation \bar{x} and $\text{var}(l) = x$. By $\bar{\bar{l}}$, we denote the complementary literal of l , i.e., if $l = x$ then $\bar{\bar{l}} = \bar{x}$ and if $l = \bar{x}$ then $\bar{\bar{l}} = x$. A *clause* is a disjunction of literals (sometimes also interpreted as set of literals) and a *term* is a conjunction of literals. The empty clause is denoted by \perp . A propositional formula in *conjunctive normal form* (CNF) is a conjunction of clauses. We sometimes write a formula as a set of clauses. By $\text{var}(\psi)$ we denote the set of variables that occur in a formula ψ .

The *quantified Boolean formulas* (QBFs) considered in this chapter are in closed prenex conjunctive normal form (PCNF). A QBF $\Pi\psi$ consists of a matrix ψ and a prefix $\Pi = \mathcal{Q}_1X_1 \dots \mathcal{Q}_kX_k$ where $\mathcal{Q}_i \in \{\exists, \forall\}$, $\mathcal{Q}_i \neq \mathcal{Q}_{i+1}$, and X_i are pairwise disjoint sets of variables. Furthermore, $\text{var}(\psi) \subseteq \text{var}(\Pi)$ where $\text{var}(\Pi)$ denotes the union of the X_i . If $x \in X_i$, we say that x is quantified at level i and write $\text{lv}(x) = i$; we write $\text{lv}(l)$ for $\text{lv}(\text{var}(l))$. If $\text{lv}(l) = i$, $\text{quant}(\Pi, l) = \mathcal{Q}_i$. We call \mathcal{Q}_iX_i a *quantifier block*; \mathcal{Q}_1X_1 is the *outermost* quantifier block and \mathcal{Q}_kX_k is the *innermost* quantifier block. For two variables x, y , we have $x \leq_\Pi y$ iff $x \in X_i$ and $y \in X_j$ and $i \leq j$. We use the standard QBF semantics: a QBF $\forall x\Pi\psi$ is true if $\Pi\psi[0/x]$ and $\Pi\psi[1/x]$ are true ($\Pi\psi[t/x]$ denotes the replacement of x by t). Further $\exists x\Pi\psi$ is true if $\Pi\psi[0/x]$ or $\Pi\psi[1/x]$ is true. We also write 1 for true and 0 for false. Often the evaluation of a QBF $\mathcal{Q}_1X_1 \dots \mathcal{Q}_kX_k(\psi)$ is seen as a *game* between the *universal* and the *existential player*. In the i -th step of the game, the player \mathcal{Q}_i assigns values to all the variables X_i . The existential player wins the game iff the matrix ψ evaluates to true under the assignment constructed in the game. The universal player wins iff the matrix ψ evaluates to false. For a universal variable u (an existential variable e), a *strategy* is a Boolean function over the existential (universal) variables that occur to the left of u (e) in the prefix. A QBF is (false) iff there exists a *winning strategy* for the existential (universal) player, i.e. if the existential (universal) player has a strategy for all existential (universal) variables such that this player wins any game when assigning the variable according to this strategy. The Boolean functions forming a winning strategy of the existential (universal) player are often called *Skolem functions* (*Herbrand functions*). Note that given a QBF, a winning strategy always exists for one and only one of the players.

A *proof system* for a language L over an alphabet Γ (usually binary) is a polynomial-time computable partial function $f : \Gamma^* \rightarrow \Gamma^*$ with $\text{rng}(f) = L$. If

$f(x) = y$ then x is called an f -proof for y . If L consists of all propositional tautologies, then f is called a *propositional proof system*, and proof systems for the language TQBF of true QBFs are called *QBF proof systems*. Equivalently, we can consider refutation proof systems where we start with the negation of the formula that we want to prove and derive a contradiction. A proof system S for L *simulates* a proof system P for L if there exists a polynomial p such that for all P -proofs π of x there is an S -proof π' of x with $|\pi'| \leq p(|\pi|)$. If such a proof π' can even be computed from π in polynomial time we say that S *p-simulates* P .

31.3. Proof Systems Based on Q-Resolution

Since the 1960s, the resolution principle [Rob65] has become a state-of-the-art approach in various domains of automated reasoning, cf. [BG01]. In the field of propositional satisfiability testing (SAT), groundbreaking technology to leverage the power of resolution in CDCL SAT solvers was developed in the late 1990s [MSS99] and early 2000s [MMZ⁺01, ZMMM01], cf. Chapter 4. Almost 20 years later, resolution still is the basic paradigm that underlies modern SAT solvers, which selectively integrate resolution with more powerful proof systems to potentially generate shorter proofs [WHHJ14, HKB17].

The resolution principle has been lifted to the QBF setting [KBKF95], along with the CDCL approach called QCDCL [GNT06, Let02, ZM02a]. In the following, we present the *Q-resolution calculus* and variants of it as the formal foundation of QCDCL. Additionally, we point out how the workflow of QCDCL interacts with the rules of the Q-resolution calculus.

31.3.1. The Q-Resolution Calculus

Resolution is one of the best studied propositional proof systems (cf. Chapter 7). It is a refutational proof system manipulating unsatisfiable CNFs as sets of clauses. The only inference rule *propres* is defined by

$$\frac{C \cup \{p\} \quad D \cup \{\bar{p}\}}{C \cup D} \quad (\text{propres})$$

where C, D are clauses and p is a literal. A *resolution refutation* derives the empty clause \emptyset . The generalization to QBF is shown in Figure 31.1.

We refer to a clause containing complementary literals as being *tautological* or a *tautology*. Non-tautological clauses occurring in the CNF of the given QBF ϕ are selected by applications of the axiom rule *cl-init*. The resolution rule *res* is similar to the resolution rule in propositional logic. However, the *pivot variable* p is restricted to existential variables and derived clauses must not be tautological.

The main distinguishing feature between propositional resolution and Q-resolution (Q-Res) is the rule *red*, the *reduction* operation. *Universal reduction* eliminates *trailing* universal literals locally from a non-tautological clause C with respect to the linear quantifier ordering. A universal literal l is trailing in a clause C if all existential literals $l' \in C$ are smaller than l . Note that universal reduction is the only rule in the calculus that allows to eliminate universal literals from

$\frac{C \cup \{l\}}{C} \quad \text{for all } x \in \text{vars}(\Pi) : \{x, \bar{x}\} \not\subseteq (C \cup \{l\}), \text{ quant}(\Pi, l) = \forall, \text{ and } l' <_{\Pi} l \text{ for all } l' \in C \text{ with } \text{quant}(\Pi, l') = \exists$	(red)
$\frac{C_1 \cup \{p\} \quad C_2 \cup \{\bar{p}\}}{C_1 \cup C_2} \quad \text{for all } x \in \text{vars}(\Pi) : \{x, \bar{x}\} \not\subseteq (C_1 \cup C_2), \bar{p} \notin C_1, p \notin C_2, \text{ and } \text{quant}(\Pi, p) = \exists$	(res)
$\frac{}{C} \quad \text{for all } x \in \text{vars}(\Pi) : \{x, \bar{x}\} \not\subseteq C \text{ and } C \in \psi$	(cl-init)

Figure 31.1. The rules of the Q-Resolution Calculus (Q-Res) [KBKF95]: $\phi = \Pi\psi$ is a PCNF, C a clause, and x, l and p are literals.

clauses. As such, it is crucial to obtain the empty clause in refutations of PCNFs. In a more general setting, it was shown that a QBF proof system can be obtained [BBC16] by combining the universal reduction rule with propositional proof systems.

Example 1. Consider the PCNF $\phi = \exists x_1, x_3, x_4 \forall y_5 \exists x_2. (\bar{x}_1 \vee x_2) \wedge (x_3 \vee y_5 \vee \bar{x}_2) \wedge (x_4 \vee \bar{y}_5 \vee \bar{x}_2) \wedge (\bar{x}_3 \vee \bar{x}_4)$. We resolve $(\bar{x}_3 \vee \bar{x}_4)$ and $(x_4 \vee \bar{y}_5 \vee \bar{x}_2)$ on the existential variable x_4 to obtain $C_0 := (\bar{x}_3 \vee \bar{y}_5 \vee \bar{x}_2)$. Note that the universal literal \bar{y}_5 cannot be reduced by universal reduction due to literal \bar{x}_2 . We resolve $C_0 = (\bar{x}_3 \vee \bar{y}_5 \vee \bar{x}_2)$ and $(\bar{x}_1 \vee x_2)$ on x_2 and get $C_1 := (\bar{x}_1 \vee \bar{x}_3 \vee \bar{y}_5)$. Now literal \bar{y}_5 is trailing in C_1 and can be reduced, which produces the clause $C_2 := (\bar{x}_1 \vee \bar{x}_3)$.

The above rules in Figure 31.1 define the common variant of Q-resolution, which is sound and refutational-complete for QBFs in PCNF [KBKF95]. The advantage of imposing restrictions in the side conditions of the rules of the calculus is that the search for a possible proof is made easier because the number of possible proof steps is reduced. However, lifting these restrictions, either individually or in combined ways, results in more powerful variants of Q-resolution.

In the following, we discuss variants of Q-resolution that result from lifting restrictions or from defining rules that provide additional reasoning capabilities.

31.3.2. Extensions of Q-Resolution

Long-Distance Q-resolution. The CDCL paradigm for SAT solving was lifted to the QBF level soon after its inception [GNT06, Let02, ZM02a]. When deriving a learned clause C in QCDCL analogously to CDCL following the *first unique implication point (1-UIP)* principle, C might end up being a tautology caused by a pair of complementary universal literals [ZM02a]. Resolution steps producing tautologies are called *long-distance resolution* steps because the tautology is produced by resolving two clauses that contain two literals that appear positively in one clause and negatively in the other. In general, deriving and using tautological clauses as part of refutations is unsound, as the following example shows.

Example 2. Consider the satisfiable PCNF $\phi := \forall x \exists y. (x \vee \bar{y}) \wedge (\bar{x} \vee y)$ which is obviously satisfiable. In an attempt to produce a *wrong* refutation, we resolve

$\frac{C \cup \{l\}}{C}$	$l \in \{y, \bar{y}, y^*\}, \text{quant}(\Pi, l) = \forall, \text{ and}$ $l' <_{\Pi} l \text{ for all } l' \in C \text{ with } \text{quant}(\Pi, l') = \exists$	$(ldqres)$
$\frac{C_1 \cup \{p\} \cup X_1 \quad C_2 \cup \{\bar{p}\} \cup X_2}{C_1 \cup C_2 \cup X^*}$	$\bar{p} \notin C_1, p \notin C_2, \text{quant}(\Pi, p) = \exists, \text{ and}$ $p <_{\Pi} l \text{ for all } l \in X_2$	$(ldqres)$

Figure 31.2. The long-distance Q-resolution calculus (LD-Q-Res) [ZM02a, BJ12] consists of the rules shown above in addition to the axiom rule *cl-init* from Figure 31.1. Let $\phi = \Pi\psi$ be a formula in PCNF, C a clause, and l and p literals. The sets X_1, X_2 , and X^* in rule *ldqres* contain (merged or unmerged) universal literals such that the following conditions hold. For each $y \in X_1$, if y is not a merged literal, then either $\bar{y} \in X_2$ or $y^* \in X_2$, and otherwise either $y \in X_2, \bar{y} \in X_2$ or $y^* \in X_2$. The set X^* contains the merged literal of each literal in X_1 .

the two clauses on variable y by neglecting the side condition of rule *res*, which produces the clause $(x \vee \bar{x})$. From that clause, we derive the empty clause by universal reduction.

In contrast to the observation made in Example 2, tautologies derived during learning in QCDCL can be used in the same way as ordinary, non-tautological learned clauses to prune the search space. In related work [BJ12], long-distance resolution (LD-Q-Res) was formulated as a calculus shown in Figure 31.2. In the following, we use the common notation y^* to denote the occurrence of the pair $y \vee \bar{y}$ of complementary universal literals in a clause. This special literal y^* is called a *merged literal*.

Tautologies resulting from resolution steps according to rule *ldqres* are always caused by complementary universal literals and never by existential ones. Furthermore, for the soundness of the calculus, it is necessary to respect the quantification level restriction of the pivot variable and the merged universal literals. Under that restriction, the wrong refutation in Example 2 cannot be produced. Furthermore, the QCDCL framework by construction guarantees that any tautologies derived during learning are derived under that restriction. Universal reduction by rule *ldqred* also allows the elimination of merged literals. The ability to produce certain tautological resolvents makes LD-Q-Res stronger than Q-Res [ELW13], cf. Section 31.7.

Example 3. Consider the PCNF $\phi = \exists x_1, x_3, x_4 \forall y_5 \exists x_2. (\bar{x}_1 \vee x_2) \wedge (x_3 \vee y_5 \vee \bar{x}_2) \wedge (x_4 \vee \bar{y}_5 \vee \bar{x}_2) \wedge (\bar{x}_3 \vee \bar{x}_4)$ and the first resolvent $C_0 := (\bar{x}_3 \vee \bar{y}_5 \vee \bar{x}_2)$ from Example 1. We carry out a long-distance resolution step on C_0 using the clause $(x_3 \vee y_5 \vee \bar{x}_2)$ and the pivot variable x_3 , which results in $C_1 := (y_5^* \vee \bar{x}_2)$. Note that the pivot variable x_3 has a smaller quantification level than the literals y_5 and \bar{y}_5 that result in the merged literal y_5^* according to rule *ldqres*.

Universal Pivots, Long-Distance Q-Resolution, and Combinations. The restriction of the quantifier type of pivot variables in Q-Res shown in Figure 31.1 can be relaxed to allow both existential and universal pivots in resolution steps. The resulting variant is called QU-resolution (QU-Res) and was shown to be stronger than Q-Res [VG12a]. Despite the possibility to eliminate universal literals

from clauses by resolving on them when constructing a resolution refutation, the universal reduction rule is still crucial for the completeness of QU-Res.

Further variants of Q-resolution were obtained by combining the relaxation of the quantifier type restriction of pivot variables and the generation of certain tautological resolvents [BWJ14]. LQU-resolution extends long-distance Q-resolution by also admitting universal pivot variables like in QU-resolution. However, resolution steps on universal pivots must not produce tautological resolvents. This restriction is relaxed in LQU⁺-resolution (LQU⁺-Res), which is thus a generalization of LQU-resolution.

Regarding proof complexity, both QU-Res and LD-Q-Res are stronger than Q-Res while being incomparable [BWJ14] to each other. LQU⁺-Res is stronger than both QU-Res and LD-Q-Res (cf. Section 31.7).

Enhanced Universal Reduction: Dependency Schemes. The linear ordering of the quantifier prefix of PCNFs has to be taken into account in practical QBF solving as well as in the theoretical context of QBF calculi, e.g., in the side condition of the universal reduction rule *red* in the Q-resolution calculus. The quantifier ordering imposes restrictions as it both limits the freedom of a QBF solver to assign variables and the potential number of universal literals eliminated by universal reduction. As a way to overcome these restrictions, *dependency schemes* [Sam08, SS09] were introduced to relax the linear quantifier ordering.

Informally, a dependency scheme is a binary relation D over the set of the variables of a QBF that expresses variable *independence*. Given two variables x and y , if $(x, y) \notin D$ then a QBF solver may safely assume that the values of x and y can be chosen independently from each other. Otherwise, if $(x, y) \in D$, then it has to assume that the value of one depends on the value of the other. Neglecting the dependency of the values of variables, e.g., bears the risk of unsound results in solving.

Dependency schemes can be regarded as an approximate representation of the *actual* independence of variables. For two variables, actual independence means that their values can be chosen independently from each other without affecting the result of a semantical evaluation of a QBF. Checking whether two variables in a QBF are independent is as hard as solving the QBF itself, i.e., PSPACE-complete. Therefore, dependency schemes represent sound approximations of the actual independence of variables in a QBF. These approximations result in the presence of *spurious dependency pairs*. A dependency scheme D may contain spurious dependency pairs (x, y) such that $(x, y) \in D$ but still the values of x and y can be chosen independently. A dependency scheme D is considered to be more refined than some other scheme D' if D contains fewer spurious dependency pairs than D' . The potential amount of spurious dependency pairs present in a dependency scheme is expressed by a hierarchy of schemes defined by different levels of refinement. For practical applications, only dependency schemes are of interest that can be computed in polynomial time such as the *standard dependency scheme* [SS09] or the resolution path dependency scheme [VG11, SS12], the latter being the most refined, practically relevant scheme currently known. In contrast to that, the *trivial dependency scheme* exactly represents the linear ordering of the quantifier prefix and thus is least refined.

With respect to Q-resolution calculi, dependency schemes are relevant in that they can be used to strengthen the universal reduction rule as follows.

Definition 1 (Dependency-Aware Reduction [LB10]). Let $\phi = \Pi\psi$ be a PCNF and D be a dependency relation represented by a dependency scheme.

$$\frac{C \cup \{l\}}{C} \quad C \text{ is a clause, } \text{quant}(\Pi, l) = \forall, \text{ and,} \quad (dep\text{-red}) \\ (l, l') \notin D \text{ for all } l' \in C \text{ with } \text{quant}(\Pi, l') = \exists$$

Dependency-aware universal reduction by rule *dep-red* generalizes the traditional universal reduction rule *red* of the Q-resolution calculus (Figure 31.1). Instead of the linear ordering of variables (\leq_{Π}) in the prefix of the PCNF ϕ , rule *dep-red* makes use of a dependency relation D . A universal literal l can be eliminated from a clause C if the variable of l is independent from the variables of all existential literals l' in C .

Note that rule *dep-red* indeed generalizes traditional universal reduction by rule *red* since it can be instantiated by the trivial dependency scheme. With dependency-aware universal reduction, it is possible to potentially reduce universal literals that cannot be reduced by traditional universal reduction, depending on the actual dependency relation used in rule *dep-red*.

Q-resolution calculi can be equipped with the dependency-aware universal reduction rule based on tractable dependency schemes. Using the reflexive resolution path scheme, e.g., a variant of Q-resolution is obtained that is stronger than traditional Q-resolution [BB17] (cf. Section 31.7.5). Certain theoretical properties of dependency schemes were studied that are sufficient to prove the soundness of combining these schemes with universal reduction in Q-resolution calculi, including long-distance Q-resolution [BB16, PSS16, SS16, PSS18].

The benefits of exploiting variable independence were also empirically observed in the context of solving. Early approaches are based on exploiting quantifier structure that is present in the parse tree of a given QBF [GNT07]. Alternatively, such structure can be (partially) reconstructed from a PCNF by shifting quantifiers inside the CNF part [AB02, Ben05], which is also called *mini-scoping*. For example, the expansion-based solver Quantor [Bie04] applies a limited form of mini-scoping to allow for a better scheduling of expansion steps. Dependency schemes can be regarded as a generalization of mini-scoping. Already the standard dependency scheme [SS09], which is less refined than the resolution path scheme [VG11, SS12], potentially allows to identify more independent variables than mini-scoping [LB09].

Since QCDCL solvers rely on Q-resolution, dependency-aware universal reduction can be applied to leverage variable independence in QCDCL. The QCDCL solver DepQBF [LE17] tightly integrates dependency-aware universal reduction via the standard dependency scheme in the QCDCL workflow [LB10]. Additionally, it employs variable independence to generate assignments in QCDCL on a more flexible basis than in traditional QCDCL, which operates with the linear quantifier order. The approach implemented in DepQBF was generalized in the QCDCL solver Qute [PSS17], which starts with an empty dependency relation and learns dependency pairs on demand.

Q-Resolution with Symmetries. Another powerful extension of the basic Q-Resolution Calculus (cf. Figure 31.1) exploits symmetries [KS18b] of a given formula. A symmetry for a QBF $\Pi\psi$ is a bijective map $\sigma: L \rightarrow L$ where $L = \{x, \bar{x} \mid x \in \text{var}(\Pi)\}$ such that for all $x \in \text{var}(\Pi)$ $\sigma(\bar{x}) = \overline{\sigma(x)}$ and $x, \sigma(x)$ belong to the same quantifier block. Further, if σ is applied to all literals in ψ , then ψ maps to itself.

Definition 2 (Symmetry Rule [KS18a]). Let $\phi = \Pi\psi$ be a PCNF.

$$\frac{C}{\sigma(C)} \quad C \text{ is a clause, } \sigma \text{ is a symmetry of } \Pi\psi \quad (\text{sym})$$

With the symmetry rule formula families hard for Q-Res such as $QParity_n$ or $KBKF_n$ have polynomial-size proofs [KS18a] (cf. Section 31.7.5).

31.3.3. Solving with Q-Resolution: QCDCL

Conflict-driven clause learning, called QCDCL [GNT06, Let02, ZM02a, ZM02b], is a generalization of the CDCL approach for SAT solving, cf. Chapter 4. A QCDCL solver derives new learned clauses during the search with the purpose to prune the search space. Depending on the variable assignments that are successively generated, the solver may also produce *learned cubes*. Dual to clauses, a cube is a conjunction of literals. While learned clauses prune parts of the search space that contain falsifying assignments, learned cubes prune parts that contain satisfying assignments. Propositional resolution and Q-resolution [KBKF95] are the proof systems that underlie CDCL and QCDCL. For unsatisfiable and satisfiable QBFs, a QCDCL solver can produce clause and cube proofs, respectively. Cube proofs are formulated in a calculus that is dual to Q-resolution of clauses.

Despite the similarity between CDCL and QCDCL on a theoretical level, clause learning in a QCDCL solver is more complex than in a CDCL solver. This is due to the interaction between the QCDCL workflow and the rules of the Q-resolution calculus. In the following, we point out this interaction on an abstract level. In particular, we do not give a comprehensive presentation of QCDCL. Instead, we refer to Chapter 30, where clause learning based on Q-resolution is presented in the framework of DPLL-based backtracking search, called *Q-DLL* or, alternatively, *QDPLL* [CGS98a, GNT06]. In terms of the effects of clause learning, QDPLL and QCDCL are similar. However, we find the QCDCL framework more suitable for our purposes due to its immediate relation to CDCL. Moreover, for simplicity we focus on clause learning and hence omit cube learning in our presentation of QCDCL.

Figure 31.3 shows a high-level flowchart of the QCDCL workflow. The building blocks are similar to CDCL: propagation in stage QBCP (quantified Boolean constraint propagation), decision making, learning, and backtracking. Given a PCNF $\phi = \Pi\psi$, variable assignments are successively enumerated by means of QBCP and decision making. The formula is simplified under the current assignment A to obtain the formula ϕ' . If ϕ' is not reduced to a syntactic truth constant \perp or \top then the current assignment is further extended by decision making and successive application of QBCP.

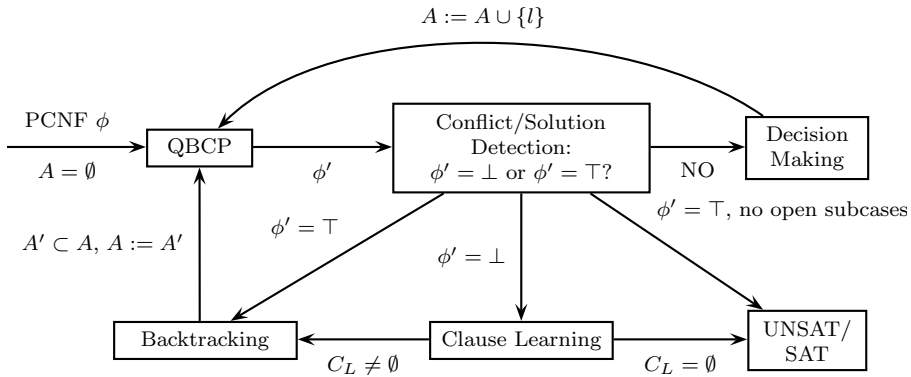

Figure 31.3. Flowchart of QCDCL. For simplicity of the presentation, cube learning is not shown. Instead, we assume that backtracking is carried out immediately after a satisfiable subcase has been detected ($\psi' = \top$).

Otherwise, if $\phi' = \top$ then a satisfiable subcase has been determined and closed. In this case, if there are no more open subcases remaining to be explored, then QCDCL terminates with the result that the input formula ϕ is satisfiable. If there are open subcases remaining, then a certain part A' of the current assignment A is retracted during backtracking, and a new assignment A is generated. In implementations of QCDCL, determining whether there are open subcases left and backtracking after finding satisfiable subcases is driven by cube learning, which we omit in our presentation. Instead, we assume that backtracking is carried out immediately after a satisfiable subcase has been detected.

Case $\phi' = \perp$ designates an unsatisfiable subcase, which triggers clause learning. A new learned clause C_L is derived by Q-resolution using clauses depending on assignment A . If C_L is empty ($C_L = \emptyset$), then QCDCL terminates with the result that the input formula ϕ is unsatisfiable. In this case, a Q-resolution proof of ϕ can be obtained by considering the derivations of the learned clauses. Otherwise, if C_L is non-empty ($C_L \neq \emptyset$) then it is added to formula ϕ , backtracking is driven depending on C_L , and a new assignment A is generated.

In the following, we describe the interaction of universal reduction and Q-resolution with the workflow of QCDCL. The universal reduction rule *red* of the Q-resolution calculus (Figure 31.1) is crucial not only for the derivation of clauses, but also in the generation of assignments by propagation in QBCP. Similar to BCP in CDCL, QBCP in QCDCL consists of unit literal detection. In addition to BCP, QBCP also applies universal reduction to shorten clauses under assignment A that is currently being generated. The combination of unit literal detection and universal reduction potentially detects more assignments and shortens more clauses than unit literal detection alone. In the following, we represent a variable assignment A as a set of literals such that $v \in A$ if variable v is assigned true, and $\neg v \in A$ if v is assigned false, and $v \notin A$ and $\neg v \notin A$ if v is unassigned. For a PCNF ϕ and an assignment A , $\phi[A]$ is the formula simplified under A .

Definition 3 (Unit Literal Detection [CGS98b]).

Given a QBF ϕ , a clause $C \in \phi$ is *unit* iff $C = (l)$ and $q(l) = \exists$. The existential literal l in C is called a *unit literal*. *Unit literal detection (UL)* collects the assignment $\{l\}$ from the unit clause $C = (l)$. Unit literal detection applied to a QBF ϕ collects the respective assignments from all unit clauses in ϕ .

Learned clauses C_L generated in QCDCL have the property that they become unit after backtracking. Similar to clause learning in CDCL, such clauses are *asserting* clauses. Note that the variables of unit literals are restricted to existential ones. This is necessary for the combination of unit literal detection and universal reduction in QBCP.

Definition 4 (QBCP). Given a PCNF ϕ and the empty assignment $A = \{\}$, i.e. $\psi[A] = \phi$.

1. Apply universal reduction (UR) to $\phi[A]$ to obtain $\phi[A]'$.
2. Apply unit literal detection (UL) to $\phi[A]'$ to collect new assignments.
3. Add assignments found by UL to A and repeat steps 1-2.
4. Stop if A does not change anymore or if $\phi[A] = \top$ or $\phi[A] = \perp$.

The result of QBCP applied to ϕ is an extended assignment A and a simplified formula $\phi[A]'$ obtained from $\phi[A]$ by UR.

Pure literal detection [CGS98b] is another approach to generate assignments in QBCP in addition to unit literal detection. It can further increase the capability of QBCP to generate assignments and shorten clauses. For simplicity of the presentation, however, we do not present pure literal detection.

Example 4. Let ϕ be a PCNF as follows:

$$\forall y_5 \exists x_1 \forall y_2 \exists x_3, x_4. (\bar{y}_5 \vee x_4) \wedge (y_5 \vee \bar{x}_4) \wedge (x_1 \vee y_2 \vee \bar{x}_4) \wedge (\bar{x}_1 \vee x_3 \vee \bar{x}_4) \wedge (\bar{y}_2 \vee \bar{x}_3)$$

Initially, no simplifications of ϕ by QBCP are possible. We assign y_5 by decision making to obtain assignment $A = \{y_5\}$. The formula simplifies to

$$\phi[y_5] = \exists x_1 \forall y_2 \exists x_3, x_4. (x_4) \wedge (x_1 \vee y_2 \vee \bar{x}_4) \wedge (\bar{x}_1 \vee x_3 \vee \bar{x}_4) \wedge (\bar{y}_2 \vee \bar{x}_3)$$

By UL and UR, we obtain the following assignments and simplified formulas.

- By UL: $\phi[y_5, x_4] = \exists x_1 \forall y_2 \exists x_3. (x_1 \vee y_2) \wedge (\bar{x}_1 \vee x_3) \wedge (\bar{y}_2 \vee \bar{x}_3)$.
- By UR: $\phi[y_5, x_4] = \exists x_1 \forall y_2 \exists x_3. (x_1) \wedge (\bar{x}_1 \vee x_3) \wedge (\bar{y}_2 \vee \bar{x}_3)$.
- By UL: $\phi[y_5, x_4, x_1] = \forall y_2 \exists x_3. (x_3) \wedge (\bar{y}_2 \vee \bar{x}_3)$.
- By UL: $\phi[y_5, x_4, x_1, x_3] = \forall y_2. (\bar{y}_2)$.
- By UR: $\phi[y_5, x_4, x_1, x_3] = \emptyset$

Since a conflict (i.e., empty clause) is derived in the last step, by QBCP we have shown that $\phi[y_5]$ and $\phi[y_5, x_4, x_1, x_3]$ are satisfiability-equivalent, i.e., $\phi[y_5]$ is unsatisfiable. Since the decision variable y_5 is universal, also ϕ is unsatisfiable. Note that in this example, universal reduction is crucial to determine the unsatisfiability of ϕ because unit literal detection alone cannot derive a conflict.

Figure 31.4. Implication graph related to the application of QBCP in Example 4. Variable y_5 is assigned as a decision.

For every assignment l collected by unit literal detection in QBCP the corresponding *antecedent clause* is recorded. The antecedent clause of assignment l is the clause of the original PCNF ϕ that became unit in QBCP. Given a conflict as in Example 4 and the set of antecedent clauses of unit literals in the current assignment, new learned clauses can be derived in QCDCL in a similar but more complex way as in CDCL. We illustrate the derivation of clauses from antecedent clauses in the following example.

Example 5. Let ϕ be the PCNF from Example 4:

$$\forall y_5 \exists x_1 \forall y_2 \exists x_3, x_4. (\bar{y}_5 \vee x_4) \wedge (y_5 \vee \bar{x}_4) \wedge (x_1 \vee y_2 \vee \bar{x}_4) \wedge (\bar{x}_1 \vee x_3 \vee \bar{x}_4) \wedge (\bar{y}_2 \vee \bar{x}_3)$$

The assignment generated by decision making and QBCP in Example 4 is $A := \{y_5, x_4, x_1, x_3\}$, with variables assigned in that ordering. The antecedent clauses of the assignments $\{x_4\}$, $\{x_1\}$, and $\{x_3\}$ are $C_{x_4} := (\bar{y}_5 \vee x_4)$, $C_{x_1} := (x_1 \vee y_2 \vee \bar{x}_4)$, and $C_{x_3} := (\bar{x}_1 \vee x_3 \vee \bar{x}_4)$, respectively. We resolve C_{x_1} and C_{x_4} and obtain $C_1 := (\bar{y}_5 \vee x_1)$ after universal reduction. Further, we resolve C_1 with C_{x_3} and obtain $C_2 := (\bar{y}_5 \vee x_3 \vee \bar{x}_4)$, which we resolve with C_{x_4} to get $C_3 := (\bar{y}_5 \vee x_3)$. Finally, by resolving the clause $(\bar{y}_2 \vee \bar{x}_3)$ that became empty during QBCP in Example 4 and C_3 , we obtain the empty clause by universal reduction.

In Example 5, we constructed a Q-resolution proof of the given PCNF by making what appears as an *ad-hoc* selection of clauses to be resolved. QCDCL solvers use information gathered in QBCP in a *systematic* way to carry out resolution steps to derive learned clauses. Pivot selection in QCDCL is crucial as it determines whether a Q-resolution or a long-distance Q-resolution derivation of the learned clause is obtained. In practical terms, a wrong pivot selection may result in failure to derive a learned clause.

In the following, we illustrate how the pivot selection influences the derivation of a learned clause in QCDCL. To this end, we informally introduce the concept of *implication graphs*.

Example 6. An implication graph related to the application of QBCP in Example 4 is shown in Figure 31.4. The implication graph contains a vertex for every decision variable and variable assigned by unit literal detection. It also contains a special vertex representing the empty clause. We add an edge (x, y) if y was assigned by unit literal detection and \bar{x} appears in the antecedent clause of y . For example, $C_{x_3} := (\bar{x}_1 \vee x_3 \vee \bar{x}_4)$ is the antecedent clause of assignment $\{x_3\}$ and the edges (x_1, x_3) and (x_4, x_3) indicate that \bar{x}_1 and \bar{x}_4 appear in C_{x_3} .

Implication graphs generated in QBCP are very similar to the ones generated by BCP in CDCL. However, universal literals eliminated by universal reduction

Figure 31.5. Implication graph related to the application of QBCP in Example 7. Variable x_1 is assigned as a decision.

Figure 31.6. Derivation related to Example 7.

are not explicitly represented by an edge. Hence, for example, the clause $(\bar{y}_2 \vee \bar{x}_3)$ that becomes empty in Example 4 has two literals but in the implication graph in Figure 31.4 there is only one edge from x_3 to the special vertex \emptyset . We illustrate the selection of pivot variables and its importance for the derivation of learned clauses by the following example.

Example 7. Let ϕ be a PCNF as follows:

$$\exists x_1, x_3, x_4 \forall y_5 \exists x_2. (\bar{x}_1 \vee x_2) \wedge (x_3 \vee y_5 \vee \bar{x}_2) \wedge (x_4 \vee \bar{y}_5 \vee \bar{x}_2) \wedge (\bar{x}_3 \vee \bar{x}_4)$$

Suppose that we assign x_1 to true as a decision variable. Then we obtain the assignment $A := \{x_1, x_2, x_3, x_4\}$, in that ordering, by QBCP. Figure 31.5 shows the corresponding implication graph. The antecedent clauses of assignments $\{x_2\}$, $\{x_3\}$, and $\{x_4\}$ are $C_{x_2} := (\bar{x}_1 \vee x_2)$, $C_{x_3} := (x_3 \vee y_5 \vee \bar{x}_2)$, and $C_{x_4} := (x_4 \vee \bar{y}_5 \vee \bar{x}_2)$, respectively, and $C_\emptyset := (\bar{x}_3 \vee \bar{x}_4)$ is the clause that becomes empty in QBCP.

Traditional QCDCL solvers derive learned clauses using Q-resolution (Figure 31.1). To this end, pivot variables are selected in reverse assignment ordering. This approach is similar to the pivot selection in CDCL SAT solvers. In our example, we first resolve the falsified clause C_\emptyset with C_{x_4} , which was assigned last, and the resulting clause with C_{x_3} . However, this results in a tautology, as shown in Figure 31.6.

To obtain a legal Q-resolution derivation of a learned clause, tautologies must be avoided. The reason for the tautology produced in Example 7 is that complementary universal literals appearing in relevant antecedent clauses were eliminated by universal reduction in QBCP. To avoid tautologies, such universal literals must be eliminated by universal reduction during the derivation of the learned clause. This can be achieved by selecting existential literals as pivots that block the universal literals from being eliminated. To this end, pivots must be selected in a more flexible way, i.e., not in strict reverse assignment ordering.

Example 8. Referring to Example 7 and Figure 31.6, the tautology can be avoided by first resolving the intermediate clause $(\bar{x}_3 \vee \bar{y}_5 \vee \bar{x}_2)$ with C_{x_2} on

Figure 31.7. Derivation related to Example 8. Nodes having one parent represent the result of universal reduction steps.

variable x_2 to obtain $(\bar{x}_1 \vee \bar{x}_3)$ after eliminating \bar{y}_5 by universal reduction. Note that the pivot variable x_2 is larger than the variable of the universal literal \bar{y}_5 in the quantifier ordering. The clause $(\bar{x}_1 \vee \bar{x}_3)$ is further resolved with C_{x_3} , resulting in $(\bar{x}_1 \vee y_5 \vee \bar{x}_2)$. A final resolution step with C_{x_2} on variable x_2 produces the learned clause (x_1) . The complete Q-resolution derivation is shown in Figure 31.7.

The approach illustrated in Example 8 guarantees that tautologies in the derivation of learned clauses are always avoided [GNT06]. Note that pivot variables were selected in the ordering x_4, x_2, x_3, x_2 , which is in contrast to the reverse assignment ordering x_4, x_3, x_2 . However, this approach has an exponential worst case [VG12a]. The size of the derivation of a single learned clause may be exponential in the size of the implication graph because universal literals eliminated in parts of the derivation may later be reintroduced.

As a remedy to the exponential worst case, *long-distance Q-resolution derivations* of learned clauses can be produced. With this approach, pivots can always be selected in reverse assignment ordering [ELW13], which is similar to the pivot variables selection in CDCL SAT solvers. Moreover, the size of the long-distance Q-resolution derivation of a learned clause is linear in the size of the respective implication graph. Quaffle [ZM02a] was among the first solvers that applied long-distance Q-resolution for clause learning. Figure 31.8 shows a long-distance Q-resolution derivation of the learned clause (x_1) related to Examples 7, and 8.

As an alternative to long-distance Q-resolution derivations, traditional Q-resolution derivations of learned clauses can be generated based on QPUP (QBF pseudo unit propagation) clauses [LEVG13]. In this approach, resolution steps are carried out starting from certain points in the implication graph, and the resolution process proceeds towards the falsified clause. This is in contrast to traditional QCDCL and CDCL SAT solvers, where the resolution process starts at the falsified clause and proceeds towards a unique implication point. In Example 5, we actually constructed a refutation following the QPUP approach (see also the related implication graph in Figure 31.4). QPUP-based learning allows

Figure 31.8. Long-distance Q-resolution derivation of the learned clause (x_1) related to Examples 7, and 8. The derivation continues the one shown in Figure 31.6.

to generate Q-resolution derivations that are linear in the size of the implication graph.

We presented several ways to enhance the traditional Q-resolution calculus (Figure 31.1). These include stronger Q-resolution variants, i.e., variants of rule *res*, and stronger variants of universal reduction (rule *red*) based on dependency schemes. The Q-resolution calculus can also be strengthened by a more general variant of the axiom rule *cl-init*. This general variant employs assignments generated in QCDCL and calls to a QBF oracle.

Definition 5 (Generalized Axiom [LBB⁺15, LES16]). Let $\phi = \Pi\psi$ be a PCNF. The *generalized axiom* is defined as follows.

$$\frac{A \text{ is a (partial) assignment generated in QCDCL,} \quad \phi[A] \text{ is unsatisfiable,} \quad (\textit{gen-cl-init})}{C \quad \text{and } C = (\bigvee_{l \in A} \bar{l}) \text{ is a clause}$$

The generalized axiom *gen-cl-init* can be added to the Q-resolution calculus in addition to the traditional axiom *cl-init* in Figure 31.1. Furthermore, it can be combined with any variants of the Q-resolution and universal reduction rules. Applications of the axiom rule require to check the satisfiability of $\phi[A]$. Since this problem is PSPACE-complete in general, for practical applications these satisfiability checks must be bounded and hence are incomplete. If $\phi[A]$ is found unsatisfiable, then the clause C can be derived and used as an ordinary learned clause in QCDCL. Note that learning C is sound only if A is an assignment generated in QCDCL.

Any QBF decision procedure can be used as an oracle to carry out the satisfiability test in the side condition of axiom *gen-cl-init*. Due to this property, the general axiom acts as an interface to integrate arbitrary decision procedures, and hence proof systems, in QCDCL. This way, it is possible to benefit from the combination of proof systems such as Q-resolution and, e.g., bounded expansion by means of clause learning. The resulting variant of QCDCL has the potential to produce proofs that are exponentially shorter than the proofs produced by traditional QCDCL.

Similar to the clause-based variant in Definition 5, a dual, cube-based variant can be formulated [LBB⁺15] for enhanced cube learning.

31.4. Expansion-Based Proof Systems

Taking a different approach than QCDCL, a number of solvers reduce QBF to SAT. Most commonly, they rely on iterative elimination of quantified variables until only one type of quantifier is left. Once the formula contains a single type of quantifier, an off-the-shelf SAT solver is invoked.

One of the first solvers taking this approach is the solver QUBOS [AB02], presented in 2002, which eliminates quantifiers inside-out. Considering some quantifier prefix Π , a QBF $\Pi\exists x\phi$ rewrites to $\Pi(\phi[0/x] \vee \phi[1/x])$ and $\Pi\forall x\phi$ to $\Pi(\phi[0/x] \wedge \phi[1/x])$. We say that the quantifier is *expanded*.

A similar approach is taken in the solver Quantor [Bie04] with the difference that the solver is designed to work on PCNF. That is not straightforward since a disjunction of CNF is no longer CNF. Quantor, in order to preserve PCNF, eliminates existential variables differently from the universal ones. Similarly to the Davis-Putnam procedure (also known as variable elimination, see Chapter 9), existentially quantified variables are exhaustively resolved out of the formula. The solver QMRES [PV04] follows a similar approach but tries to mitigate the size of the expansion by representing sets of clauses as ZBDDs.

A different take on elimination is adopted in the solver sKizzo [Ben04], which operates on a PCNF input and eliminates only universal variables. This, however, requires introduction of fresh existential variables. The reason for such is that if the variable x is eliminated from a formula $\forall x\exists y\dots\phi$, the result is no longer prenex: $(\exists y\dots\phi[0/x])\wedge(\exists y\dots\phi[1/x])$. To get back to prenex form, fresh variables are introduced: $\exists y^0y^1\dots(\phi[0/x,y^0/y] \wedge \phi[1/x,y^1/y])$. In sKizzo the process of introducing fresh variables is referred to as propositional Skolemization because effectively the fresh variables correspond to the individual points of a Skolem function for the original existential variable.

Solvers relying on full expansion of quantifiers inherently suffer from large memory consumption. Some solvers counter this issue by expanding quantifiers gradually but at the cost of multiple SAT calls. This approach was pioneered by the solver RAReQS and followed by QELL [THJ15] and Ijtihad [BBH⁺18b].

At the proof level, solving by expansion corresponds to the proof system $\forall\text{Exp}+\text{Res}$ [JMS13, JM15] discussed in Section 31.4.1. Sections 31.4.2 and 31.4.4 describe the algorithms AReQS and RAReQS, where AReQS accepts only 2QBF inputs and RAReQS extends AReQS by recursion to an arbitrary number of levels. The algorithms are related to the $\forall\text{Exp}+\text{Res}$ system in Sections 31.4.3 and 31.4.5.

31.4.1. The Calculus $\forall\text{Exp}+\text{Res}$

The $\forall\text{Exp}+\text{Res}$ calculus provides a transformation that enables refuting QBF by classical propositional resolution [JMS13, JM15]. This transformation stems from the idea that the existential player needs to respond to any assignment to the universal variables, but, the player may respond differently to different assignments. To represent the different choices of the existential player, $\forall\text{Exp}+\text{Res}$ annotates existential variables by the relevant assignments to the universals.

The calculus is defined in Figure 31.9. It comprises two rules. The *Axiom rule* introduces new annotated clauses into the proof and the *Res rule* enables

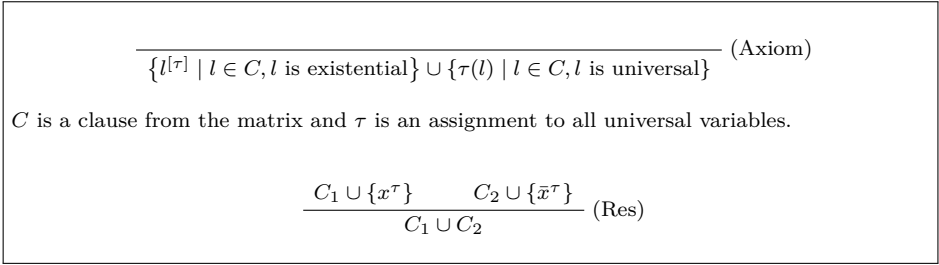

Figure 31.9. The rules of $\forall\text{Exp}+\text{Res}$ (adapted from [JM15]). The annotation $x^{[\tau]}$ considers only the universal variables that precede x in the prefix.

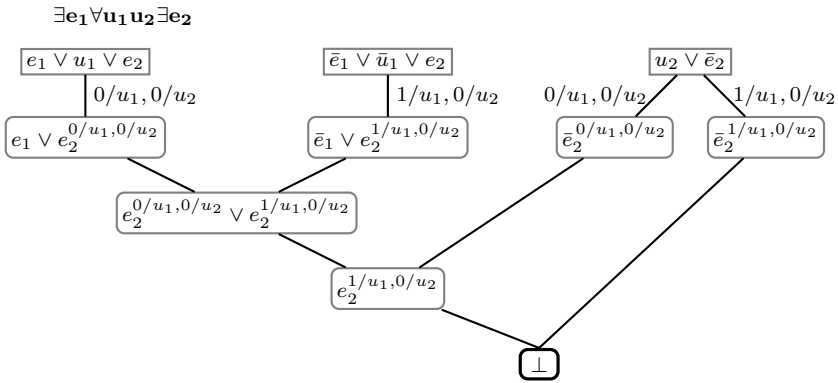

Figure 31.10. An example refutation in $\forall\text{Exp}+\text{Res}$

resolving them. An *annotated clause* is obtained by choosing a clause C from the matrix and an assignment τ to all the universal variables. The clause C is then transformed by applying τ to it and annotating each existential variable by $[\tau]$. The operation $x^{[\tau]}$ annotates x with the assignment τ restricted to the universal variables preceding x in the quantifier prefix. The rest of the proof is carried out by resolving the annotated clauses. A proof in $\forall\text{Exp}+\text{Res}$ that derives the empty clause, is called a *refutation*.

Note that the Axiom rule of the calculus potentially enables introducing an exponential number of annotated clauses. However, if the rule is applied to some assignment τ and clause C such that τ assigns some of the literals of C to true, the clause is reduced to true, denoted as \top ; such clause is useless for the rest of the proof. Observe also that since τ always assigns all universal variables, there are no universal literals in the annotated clauses. At the end of this chapter, Section 31.7 discusses more general proof systems that enable assigning only some universal variables.

Example 9. Figure 31.10 represents a possible refutation $\forall\text{Exp}+\text{Res}$ of the formula

$$\exists e_1 \forall u_1 u_2 \exists e_2 ((e_1 \vee u_1 \vee e_2) \wedge (\bar{e}_1 \vee \bar{u}_1 \vee e_2) \wedge (e_2))$$

The matrix clauses are depicted as rectangles and the annotated clauses as rectangles with rounded corners. The example demonstrates some distinctive features of the calculus. The clause $u_2 \vee \bar{e}_2$ is expanded in two different ways. The annotated clause $e_2^{0/u_1,0/u_2} \vee e_2^{1/u_1,0/u_2}$ contains two versions of the variable e_2 . Intuitively, this clause tells us that e_2 should be true in one of the two places, when both u_1 and u_2 are false or if u_1 is true and u_2 is false.

31.4.2. AReQS: Expansion-based solving for 2-level QBF

This section presents the algorithm AReQS [JMS11], which decides formulas with two levels of quantification, i.e., $\forall X \exists Y \phi$ or $\exists X \forall Y \phi$. The algorithm enables natively solving formulas whose matrix is not necessarily in CNF and we present it as such. However, in order to connect to the proof system $\forall \text{Exp} + \text{Res}$, we restrict ourselves to PCNF formulas.

To simplify the presentation we will only be looking at formulas of the form $\forall X \exists Y \phi$. The case $\exists X \forall Y$ is symmetric since $\forall X \exists Y \phi$ is true if and only if $\exists X \forall Y \neg \phi$ is false. In some scenarios, we need to call a SAT solver with non-CNF input. While SAT solvers in practice often require CNF input, this represents only a minor obstacle as CNF can be achieved by the addition of fresh variables, cf. [Tse68, PG86].

The algorithm AReQS is presented as a search for the winning move for the given formula anchored in the game perspective (see Section 31.2). Finding a winning move for a prefix of the form $\forall \exists$ shows the formula to be false, conversely, demonstrating the absence of such move shows the formula true.

Definition 6 (winning move). An assignment τ to variables X is a *winning move* for a QBF $\forall X \Phi$ if $\Phi[\tau]$ is false and it is a *winning move* for $\exists X \Phi$ if $\Phi[\tau]$ is true.

Calculating a winning move is conceptually simple when given a formula with a single quantifier block. Such formulas represent a 1-move game, where only one of the players is allowed to make a single move upon which the game terminates. Deciding such game translates naturally to propositional satisfiability. In particular, there exists a winning move for the formula $\exists X \phi$ if and only if ϕ is satisfiable. Analogously, there exists a winning move for the \forall -player for the formula $\forall X \phi$ if and only if $\neg \phi$ is satisfiable. Further, the satisfying assignments of the respective propositional formula are winning moves of the original formula.

This observation motivates the following approach to solving QBF. Start eliminating quantifiers until only one type of quantifier is left, at which point invoke a SAT solver. The question is how to eliminate quantifiers. The approach taken here is by *expansion* into Boolean connectives. This is enabled by the observation that the formula $\forall X \exists y \Phi$ has the same set of winning moves as the formula $\forall X (\Phi[0/y] \vee \Phi[1/y])$.

A key insight is that a full expansion is not necessarily needed and that a *partial expansions* may decide the formula. This is possible because assigning a variable to a specific value *reduces* the set of winning moves, cf. [JKMC16, Sec. 3].

Example 10. Let $\phi = (u \vee e_1) \wedge (\bar{u} \vee e_2) \wedge (\bar{e}_1 \vee \bar{e}_2)$ and consider $\forall u \exists e_1 e_2 \phi$. The formula is true and therefore there is no winning move for the \forall player. One

Algorithm 1: CEGAR Algorithm for 2QBF

```

input   :  $\forall X \exists Y (\phi)$ 
output :  $\tau$  if there exists a winning move  $\tau$  for  $\forall X$ ,  $\perp$  otherwise
1  $\omega \leftarrow \emptyset$ 
2 while true do
3    $\alpha \leftarrow \bigvee_{\mu \in \omega} \phi[\mu]$  // build abstraction
4    $\tau \leftarrow \text{SAT}(\neg \alpha)$  // find a candidate
5   if  $\tau = \perp$  then return  $\perp$  // no winning move, formula true
6    $\mu \leftarrow \text{SAT}(\phi[\tau])$  // find a countermove
7   if  $\mu = \perp$  then return  $\tau$  // no countermove, formula false
8    $\omega \leftarrow \omega \cup \{\mu\}$  // refine

```

could expand e_1 and e_2 with all the 4 possible assignments to e_1 and e_2 . However, considering only two is sufficient. Expanding by the assignments $\{1/e_1, 0/e_2\}$ and $\{e_1/0, e_2/1\}$ yields $\forall u(\phi[1/e_1, 0/e_2] \vee \phi[0/e_1, 1/e_2]) = \forall u(\bar{u} \vee u) = \forall u(1)$. Since $\forall u(1)$ has no winning moves, the original formula also does not have any and therefore it is true.

The idea of partial expansions is formalized in the following definition as an ω -abstraction.

Definition 7 (ω -abstraction). Let X, Y be finite sets of variables and ω be a set of assignments to Y . The ω -abstraction of a closed QBF $\forall X \exists Y \phi$ is $\forall X \bigvee_{\mu \in \omega} \phi[\mu]$.

The algorithm AREQS starts by an empty abstraction and strengthens it gradually using the *Counterexample Guided Abstraction Refinement* paradigm (CEGAR) [CGJ⁺03]. The ω -abstraction is an abstraction in the sense that its set of winning moves is a superset of the winning moves of the original formula. Adding more assignments to the set ω restricts the set of winning moves, i.e. it *refines* the abstraction.

Algorithm 1 shows the AREQS ideas in pseudocode. It consists of a loop, which in each iteration first finds a winning move for the current ω -abstraction and then it tests whether that move is also a winning move of the formula being solved. If it is, we are done. If, however, the winning move for the abstraction is *not* a winning move of the original formula, the abstraction is refined.

A winning move of the abstraction is referred to as a *candidate*. A candidate τ is a winning move of the original $\forall X \exists Y \phi$ if and only if $\exists Y \phi[\tau]$ is false. Equivalently, if $\phi[\tau]$ is unsatisfiable. Consequently, if τ is *not* a winning move, there exists an assignment μ satisfying $\phi[\tau]$; the assignment μ is called a *countermove* to the candidate move τ .

The algorithm maintains a set of countermoves ω , initialized to the empty set (line 1). In each iteration of the loop it first constructs an abstraction according to Definition 7 (line 3). Note that upon initialization, the set ω is empty and therefore $\alpha = 0$ when first entering the loop. Subsequently, the algorithm tries to find a winning move for the abstraction (line 4). If no candidate is found, it means that there is no winning move for the given formula and the algorithm terminates. If a candidate τ is found, a SAT solver is used to find a countermove to it (line 6). If there is no countermove, then τ is indeed a winning move and

the algorithm terminates. If there is a countermove μ , this countermove is added to the set ω (line 8).

Example 11. Consider the prefix $\forall u_1 u_2 u_3 \exists e_1 e_2 e_3$ and the following matrix

$$\begin{aligned} u_1 \vee u_2 \vee e_1 \vee e_2 \\ u_1 \vee u_3 \vee \bar{e}_1 \vee e_2 \\ \bar{u}_1 \vee u_2 \vee e_3 \\ \bar{u}_2 \vee u_3 \vee \bar{e}_1 \vee e_3 \end{aligned}$$

The following is a possible run of the algorithm. Let $\tau_1 = \{0/u_1, 0/u_2, 0/u_3\}$ be the first candidate with $\phi[\tau_1] = \{e_1 \vee e_2, \bar{e}_1 \vee e_2\}$. The assignment $\mu_1 = \{0/e_1, 1/e_2, 0/e_3\}$ is a countermove to τ_1 . The ω -abstraction refined by τ_1 is $\forall u_1 u_2 u_3 (\bar{u}_1 \vee u_2)$. The assignment $\tau_2 = \{1/u_1, 0/u_2, 0/u_3\}$ is a winning move for the abstraction and is chosen as the next candidate. We have $\phi[\tau_2] = \{e_3\}$, satisfiable by $\mu_2 = \{0/e_1, 0/e_2, 1/e_3\}$ chosen as the countermove.

Refining by μ_2 yields the ω -abstraction $\forall u_1 u_2 u_3 ((\bar{u}_1 \vee u_2) \vee (u_1 \vee u_2))$ which has no winning moves as its matrix is a tautology. This means that the original formula also has no winning moves and therefore it is true.

Example 11 uncovers an interesting property of AReQS in CNF. The assignments to the universal variables effectively select or deselect clauses for the existential quantifier to satisfy. The solvers QESTO [Jan18b] and CAQE [RT15] develop this idea for arbitrary number of levels. The solvers QuAbs [Ten16] and CQESTO [Jan18a] develop the ideas even further to non-CNF.

Since the winning moves of the ω -abstraction over-approximate the winning moves of the original formula, and the algorithm deems the formula true only if the abstraction has no winning moves, the original formula in such case must also be true. Termination follows from the observation that no candidates may repeat. Indeed, if μ is a countermove to τ , after the refinement the abstraction is of the form $\forall X(\alpha' \vee \phi[\mu])$. Consequently, any subsequent candidate τ' must falsify $\phi[\mu]$. This means that τ' cannot be τ as τ together with μ satisfy ϕ . By a similar argument we can show that countermoves also do not repeat.

31.4.3. Connecting AReQS to $\forall\text{Exp}+\text{Res}$

In order to relate AReQS to $\forall\text{Exp}+\text{Res}$, we focus only on the refutation of formulas of the form $\forall X \exists Y \phi$ where ϕ is in CNF. If $\forall X \exists Y \phi$ is false, there must be a winning move for the universal player. This means that AReQS finds an assignment τ to the first block such that there is no countermove to it. More specifically, $\phi[\tau]$ is unsatisfiable. Since $\phi[\tau]$ is unsatisfiable in purely propositional sense, there also exists a propositional resolution refutation π for it. The $\forall\text{Exp}+\text{Res}$ refutation for the original formula $\forall X \exists Y \phi$ is constructed by following the structure of π .

Each leaf of the resolution refutation π is a clause $C' \in \phi[\tau]$ obtained from some clause $C \in \phi$. Construct a clause C^τ by invoking the Axiom rule on C using the assignment τ . The Axiom rule removes all universal variables from C and annotates each existential variable with τ . The rest of the proof is constructed by applying the same resolution steps as in π : whenever there is a resolution step on x in π , perform a resolution step on x^τ .

Applying the Axiom rule parameterized by the substitution τ to the clauses of the matrix, yields annotated clauses corresponding to the clauses in $\phi[\tau]$, where each existential variable is annotated by τ .

Example 12. Consider the clauses $C_1 = u_1 \vee e_1$, $C_2 = u_2 \vee \bar{e}_1$, and $C_3 = \bar{u}_1 \vee e_2$ under the prefix $\forall u_1 u_2 \exists e_1 e_2$. The matrix becomes unsatisfiable under the assignment $\tau = \{0/u_1, 0/u_2\}$. Substituting τ into the matrix gives $C'_1 = e_1$, $C'_2 = \bar{e}_1$, and $C'_3 = \top$, where unsatisfiability is obtained by resolving C'_1 and C'_2 . The corresponding $\forall\text{Exp}+\text{Res}$ proof applies the Axiom rule on C_1 and C_2 yielding $C_1^\tau = e_1^\tau$, $C_2^\tau = \bar{e}_1^\tau$, which are then resolved into \perp .

31.4.4. RReQS: Expansion-based QBF Solving

This section presents the algorithm RReQS [JKMSC12], which generalizes AReQS to an arbitrary number of quantification levels by recursion. The algorithm tries to find a winning move for the given formula but rather than calling a SAT solver, it uses recursive calls as a subroutine. The base case, with one quantifier block left, is handled by a SAT solver.

Analogously to AReQS quantifiers are expanded into a propositional operator (disjunction of conjunction) and a partial expansion lets us approximate a set of winning moves. An abstraction of a QBF with at least two quantifier blocks is obtained by partially expanding the second quantifier block. Just as before, a *candidate* refers to a winning move of an abstraction.

Applying expansion to arbitrary quantifiers requires additional care. Consider for instance $\exists x \forall y \exists z \phi$. Expanding the middle quantifier $\forall y$ into a conjunction yields a QBF in non-prenex form: $\exists x (\exists z \phi[0/y] \wedge \exists z \phi[1/y])$. Therefore, the abstraction is calculated by additionally prenexing the expanded formula. We write $\text{prenex}(\Phi)$ for the prenexed form of a QBF Φ . Prenexing may require fresh variables. For instance, $\text{prenex}(\exists x (\exists z \phi[0/y] \wedge \exists z \phi[1/y]))$ gives $\exists x z^0 z^1 (\phi[0/y, z^0/z] \wedge \phi[1/y, z^1/z])$. We will see later that these fresh variables correspond to the annotations in $\forall\text{Exp}+\text{Res}$.

Definition 8 (ω -abstraction). Let X, Y be finite sets of variables and ω be a set of assignments to Y .

The ω -abstraction of a closed QBF $\forall X \exists Y \Phi$ is the formula $\text{prenex}(\forall X \bigvee_{\mu \in \omega} \Phi[\mu])$.

The ω -abstraction of a closed QBF $\exists X \forall Y \Phi$ is the formula $\text{prenex}(\exists X \bigwedge_{\mu \in \omega} \Phi[\mu])$.

The algorithm is presented as a recursive function `solve`. Its implementation for the existential quantifier is presented in Algorithm 2. The implementation for the universal quantifier is analogous. The function accepts a closed QBF $QX\Phi$ where $Q \in \{\forall, \exists\}$; it returns a winning move for QX , if such exists and it returns \perp otherwise.

The base case of the recursion is when Φ does not contain any quantifiers, in which case a SAT solver is used to find a winning move. In the general case, an ω -abstraction is gradually strengthened by countermoves in a similar vein as in AReQS. The prenexing step causes a small technical difficulty. A winning move for the abstraction potentially contains values for variables that correspond to copies of variables originally appearing in inner quantifiers. These need to be filtered out as they do not exist in the original formula (line 10).

Algorithm 2: Basic recursive CEGAR for QBF (existential player)

```

1 Function solve( $\exists X\Phi$ )
  input   :  $\exists X\Phi$  is a closed QBF in prenex form with no adjacent blocks with the
             same quantifier
  output  : a winning move for  $\exists X\Phi$  if there is one,  $\perp$  otherwise
2 begin
3   if  $\Phi$  has no quantifiers then
4     return SAT( $\Phi$ )
5    $\omega \leftarrow \emptyset$ 
6   while true do
7      $\alpha \leftarrow \bigwedge_{\mu \in \omega} \Phi[\mu]$ 
8      $\tau' \leftarrow \text{solve}(\text{prenex}(\exists X\alpha))$  // find a candidate solution
9     if  $\tau' = \perp$  then return  $\perp$  // no winning move, formula true
10     $\tau \leftarrow \{c/v \mid \tau'(x) = c \text{ and } v \in X\}$  // filter a move for  $X$ 
11     $\mu \leftarrow \text{solve}(\Phi[\tau])$  // find a countermove
12    if  $\mu = \perp$  then return  $\tau$  // found winning move, formula false
13     $\omega \leftarrow \omega \cup \{\mu\}$  // refine

```

Observe that in each iteration there are two recursive calls. First call obtains a winning move for the abstraction—a candidate (line 8). The second call checks whether the candidate is a winning move or not (line 11). In the first call the number of quantifier levels drops by two because the second quantifier is eliminated by expansion and the third quantifier is merged with the first one during prenexing. In the second call, the number of quantifier levels drops by one.

Example 13. Consider the QBF $\exists v w \Phi$, where

$$\Phi = \forall u \exists x y ((v \vee w \vee x) \wedge (\bar{v} \vee y) \wedge (\bar{w} \vee y) \wedge (u \vee \bar{x}) \wedge (\bar{u} \vee \bar{y})),$$

The candidates $\{1/v, 1/w\}$ and $\{0/v, 0/w\}$ give the counterexamples $\{1/u\}$ and $\{0/u\}$, respectively. Refinement yields the expansion $\exists v w (\Phi[0/u] \wedge \Phi[1/u])$, with the prenex form

$$\begin{aligned} \exists v w x^0 y^0 x^1 y^1 ((v \vee w \vee x^0) \wedge (\bar{v} \vee y^0) \wedge (\bar{w} \vee y^0) \wedge (\bar{x}^0) \\ \wedge (v \vee w \vee x^1) \wedge (\bar{v} \vee y^1) \wedge (\bar{w} \vee y^1) \wedge (\bar{y}^1)) \end{aligned}$$

At this point, the abstraction is purely propositional and it is unsatisfiable. Hence, it has no winning move and the function terminates with the return value \perp , which means that the formula is false.

The arguments for correctness and termination are analogous to AReQS. Candidate moves or counterexamples cannot repeat. If in any of the iterations of the loop, a candidate τ was countered by some μ , the move τ will never be drawn from the abstraction because the refinement guarantees that τ is losing in the strengthened abstraction.

RAREQS, compared to the presentation here implements a modification that mitigates the growth of the abstraction for larger number of qualification levels (starting at 4). Rather than prenexing the whole prefix, only the outermost quantifier is prenexed and the rest is maintained in non-prenex form. For instance,

$\forall X \exists Y \forall Z \exists W \phi$ may be expanded as $\forall X Z^1 Z^2 ((\exists W \phi^1) \vee (\exists W \phi^2))$. Since \forall distributes over disjunction, any winning move for \forall must be a winning move for each of the individual disjuncts. Like so, candidate tests and refinements are carried out for each disjunct separately. From the game-theoretical point of view, each disjunct can be seen as a separate game that the quantifier must win. Therefore the approach is referred to as *multi-games* [JKMC16, Sec 4.1]. The existential case is again analogous.

31.4.5. Connecting RAReQS to $\forall\text{Exp}+\text{Res}$

We show how to produce $\forall\text{Exp}+\text{Res}$ refutations (Figure 31.9) from Algorithm 2. Consider the following naming scheme for fresh variables used in prenexing. As a part of the name of each existential variable is a annotation corresponding to a substitution to some universal variables. In the input formula these annotations are empty. The annotation is extended whenever a fresh copy of the variable is added to an abstraction. Like so, as the recursion proceeds, the annotations are getting longer and at the same time the universal variables disappear from the formula.

Consider the prefix $\exists E_1 \forall U_2 \exists E_3 \dots \exists E_n \phi$. If we are given a formula that starts by the universal quantifier, add a dummy $\exists E_1$. The expansion by some assignments μ_1 and μ_2 to the variables U_2 corresponds to the following transformations.

$$\exists E_1 ((\exists E_3 \dots \exists E_n \phi[\mu_1]) \wedge (\exists E_3 \dots \exists E_n \phi[\mu_2])) \quad (31.1)$$

$$\exists E_1 E_3^{\mu_1} E_3^{\mu_2} \dots \exists E_n^{\mu_1} \exists E_n^{\mu_2} (\phi[\mu_1, E_3^{\mu_1}/E, \dots, E_n^{\mu_1}/E_n] \wedge \phi[\mu_2, E_3^{\mu_2}/E, \dots, E_n^{\mu_2}/E_n]) \quad (31.2)$$

The original formula is expanded in (31.1) and prenexed in (31.2). In (31.2), X^μ denotes a set of variables obtained by appending μ to the annotation of each variable in X . Since ϕ is in CNF, the matrix of (31.2) is also in CNF. At the same time the clauses observe the invariant that each clause that comes from the expansion by μ_i has μ_i in its annotations.

The base case of the recursion of Algorithm 2 takes place when there are no universal variables left in the matrix. This means that in such case the matrix contains annotated clauses containing only existential variables, as required by the expansion rule in the calculus. These are handed to a SAT solver. If the expansion is false, the SAT solver deems the expansion unsatisfiable, which is then certified by propositional resolution refutation. This refutation is readily translated to a $\forall\text{Exp}+\text{Res}$ refutation as each propositional resolution step corresponds to a $\forall\text{Exp}+\text{Res}$ resolution step.

31.5. Preprocessing

Preprocessing [BLS11, BK07, GMN10, LE18, SDB06, VGWL12, WRMB17] a QBF before it is passed to a complete solver is beneficial in many cases [LSVG16], Preprocessing is particularly helpful when the solver does not try do reconstruct information that was lost by the transformation to prenex conjunctive normal

form (cf. [JKMC16, GB13] for such solvers). Preprocessors like sQueezBF [GMN10], Bloqqer [BLS11], HQSpre [WRMB17], or QRATPre+ [LE18] apply rewriting techniques that preserve (satisfiability) equivalence and that modify formulas in such a way such that information relevant for the solver becomes easier to access and such that irrelevant information is eliminated.

31.5.1. Background

There are three types of preprocessing rules: (1) clause elimination rules, (2) clause addition rules, and (3) clause modification rules. The application of these rules might also require a modification of the prefix, because new variables could be introduced while some variables might vanish.

Clause elimination rules [HJL⁺15] remove clauses while preserving unsatisfiability. Examples of such rules are tautology elimination, subsumption, the existential pure literal rule, and blocked clause elimination. Tautology elimination removes clauses containing a positive and negative occurrence of a variable. Subsumption [Bie04] removes clauses that are a superset of other clauses. The existential pure literal rule [CGS98a] removes all clauses with an existential literal that occurs only positively or only negatively in the formula (there is also a universal pure literal rule, but as being a clause modification rule, it is discussed below). Blocked clause elimination [BLS11] removes a clause C from a QBF $\Pi\psi$ if C contains an existential literal l such that for all $D \in \psi$ with $\bar{l} \in D$, there exists a literal k with $k \leq_{\Pi} l$ such that $k, \bar{k} \in C \cup D \setminus \{\bar{l}\}$, i.e., the clause $C \cup D \setminus \{\bar{l}\}$ is a tautology.

Example 14. Consider the QBF ϕ given by

$$\forall x_1 x_2 \exists y_1 y_2 ((x_1 \vee y_1) \wedge (y_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{y}_1) \wedge (\bar{y}_2 \vee y_1) \wedge (x_1 \vee y_1 \vee x_2) \wedge (\bar{x}_1 \vee x_1 \vee y_2)).$$

The last clause is a tautology, hence it can be safely removed. After the removal of the last clause, the existential variable y_2 occurs only in one polarity, therefore the existential pure literal elimination rule is applicable and clause $(\bar{y}_2 \vee y_1)$ can be removed. Also x_2 occurs only in one polarity, but since it is universally quantified, we are not allowed to remove clause $(x_1 \vee y_1 \vee x_2)$ with the existential pure literal rule. Nevertheless, we can remove this clause, because it is subsumed by $(x_1 \vee y_1)$. Next, we eliminate clause $(x_1 \vee y_1)$, because it is blocked on y_1 . Finally, we obtain the simplified QBF $\forall x_1 x_2 \exists y_1 ((y_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{y}_1))$ which is equivalent to ϕ .

Clause addition rules enrich a formula with new clauses besides modifying and removing clauses. Variable elimination [Bie04] replaces the clauses in which a certain existential variable occurs by all non-tautological resolvents on that variable. Therefore, the *res*-Rule as introduced in Section 31.3.1 is applied on the existential variables of the innermost quantifier block given that a certain limit of additional clauses is not reached.

Partial universal expansion [Bie04, BK07] is a restricted form of universal expansion as discussed in Section 31.4. It eliminates a universal variable x of the innermost universal quantifier block by copying the matrix of the QBF. Then x is set to true in one copy and to false in the other copy. For combing these two CNFs, in one copy new names must be assigned to the variables of the innermost existential quantifier block.

Example 15. Consider the QBF $\forall x_1 x_2 \exists y_1 ((y_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{y}_1))$ from the previous example. Eliminating y_1 results in QBF $\forall x_1 x_2 ((x_2 \vee \bar{x}_1))$. The universal expansion of the universal variables derives a formula containing the empty clause. If we expand x_1 in $\forall x_1 x_2 \exists y_1 ((y_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{y}_1))$, we obtain $\forall x_2 \exists y_1 y_1^0 ((y_1 \vee x_2) \wedge (\bar{y}_1) \wedge (y_1^0 \vee x_2))$. Note that y_1 was renamed to y_1^0 in the case that x_1 was set to false, for the case that x_1 was set to true, we keep y_1 . Eliminating variable x_2 finally results in $\exists y_1 y_1^{00} y_1^{01} ((\bar{y}_1) \wedge (y_1^{00}) \wedge (\bar{y}_1^{00}) \wedge (y_1^{01}))$.

Clause modification rules add, remove, and rename literals. One important rule is universal reduction, the *red-Rule*, as introduced above in Section 31.3.1. Strengthening [Bie04] removes a literal l from a clause C if there is another clause $D \vee \bar{l}$ in the formula such that D subsumes C . The unit literal elimination rule [CGS98a] is applicable if a QBF $\Pi\psi$ contains a clause C with exactly one existential literal l and for all universal literals $k \in C$ $l \leq_{\Pi} k$. Then all clauses containing l are removed and so are all occurrences of \bar{l} . Universal pure literal [CGS98a] elimination removes all occurrences of a universal literal l if it occurs only in one polarity in the considered QBF. Covered literal addition adds literals to a clause C that occur in all non-tautological resolvents obtained from C . The equivalence replacement rule [Bie04] can be applied in QBF $\Pi\psi$ when two literals l, k with l is existentially quantified and $k \leq_{\Pi} l$ are found to be equivalent by detecting the clauses $(l \vee k)$ and $(\bar{l} \vee k)$ in ψ . Finally, the blocked literal [HSB15] elimination rule can remove a universal literal l from a clause C if all resolvents on l contain two opposite literals k and \bar{k} with $k \leq_{\Pi} l$. Blocked literal elimination generalizes the universal pure literal rule.

Example 16. Consider the QBF

$$\forall x_1 x_2 \exists y_1 y_2 ((y_1 \vee x_2 \vee \bar{y}_2) \wedge (x_1 \vee \bar{y}_2) \wedge (\bar{x}_1 \vee y_2) \wedge (\bar{y}_1 \vee \bar{x}_1 \vee \bar{y}_2)).$$

By strengthening, the clause $D = (\bar{y}_1 \vee \bar{x}_1 \vee \bar{y}_2)$ can substituted by $(\bar{y}_1 \vee \bar{x}_1)$, because its resolvent x_1 which obtained by resolving D on \bar{y}_2 with clause $(\bar{x}_1 \vee y_2)$ subsumes D . By equivalence replacement, we may substitute y_2 by x_1 and under omission of the two tautological clauses, we get $\forall x_1 x_2 \exists y_1 ((y_1 \vee x_2 \vee \bar{x}_1) \wedge (\bar{y}_1 \vee \bar{x}_1))$. Now x_1 and x_2 are pure literals and can therefore be omitted. The application of unit literal elimination results in a conflict.

For almost all of these preprocessing rules, Q-resolution proofs (see Section 31.3) can be generated during their application [JGM13] to witness unsatisfiability. However, this approach does not work for universal expansion which is a very crucial technique in preprocessing. In order to capture all recent preprocessing techniques including universal expansion, the QRAT proof system was developed.

31.5.2. The QRAT Proof System

The QRAT proof system [HSB17] lifts the RAT proof system (see Chapter 15) from SAT to QBF. The RAT proof system introduces rules for adding and removing clauses such that the satisfiability of a formula is preserved. Besides the QBF variants of clause addition and clause deletion rules that have to take the ordering

imposed by the prefix into account, the QRAT proof system provides additional rules for clause modification. Before we introduce the rules of QRAT, we first define the notions of *outer resolvent* and *implication via unit propagation*.

Definition 31.5.1. The *outer resolvent* of clauses $C \vee l$ and $D \vee \bar{l}$ on literal l w.r.t. prefix Π is defined as $\text{OR}(\Pi, C, D, l) = C \cup \{k \mid k \in D, k \leq_{\Pi} l, k \neq l\}$.

In contrast to the classical resolvent $C \cup D$, the outer resolvent contains only those literals of D that occur earlier in the prefix than the pivot literal l .

Example 17. Given prefix $\Pi = \forall x_1 \exists y_1 \forall x_2 \exists y_2 y_3$ and clauses $C = (y_1 \vee \bar{x}_2 \vee y_3)$ and $D = (x_1 \vee \bar{y}_1 \vee y_3)$ the outer resolvent $\text{OR}(\Pi, C, D, y_1) = (y_1 \vee \bar{x}_2 \vee y_3 \vee x_1)$. The outer resolvent $\text{OR}(\Pi, D, C, \bar{y}_1) = (x_1 \vee \bar{y}_1 \vee y_3)$.

Proof systems like resolution and Q-resolution derive clauses that—when added to the formula under consideration—preserve logical equivalence. The QRAT proof system is an interference-based proof system, i.e., the addition of newly derived clauses or the elimination of a redundant clause only preserves satisfiability equivalence meaning that the set of models/counter-models might change. As in RAT, the concept of reverse unit propagation is used to justify clause addition or deletion.

Definition 31.5.2. A propositional formula ψ *implies a clause* $(l_1 \vee \dots \vee l_n)$ *via unit propagation* (denoted by $\psi \vdash_1 C$) iff unit propagation derives the empty clause \perp on $\psi \wedge \bar{l}_1 \wedge \dots \wedge \bar{l}_n$ where unit propagation refers to the application of the unit literal elimination rule until fixpoint.

A clause that is implied by unit propagation is sometimes also called an *asymmetric tautology* [HJL⁺15] or a clause that has the redundancy property of reverse unit propagation (RUP) [VG12b].

Example 18. Consider the propositional formula $(x \vee y) \wedge (\bar{x} \vee y)$. The clause $(x \vee y)$ is an asymmetric tautology, because for $((x \vee y) \wedge (\bar{x} \vee y) \wedge \bar{x} \wedge \bar{y})$ unit propagation derives a conflict.

Based on outer resolvents, we introduce the *quantified asymmetric tautology* property (QRAT) next.

Definition 31.5.3. A clause C has QRAT on a literal $l \in C$ w.r.t. QBF $\Pi\psi$ iff $\psi \vdash_1 \text{OR}(\Pi, C, D, l)$ for all $D \in \psi$ with $\bar{l} \in D$.

If a clause C has QRAT on literal l w.r.t. $\Pi\psi$, we call l a QRAT-literal of C for $\Pi\psi$. Note that a clause C that is implied via unit propagation by a propositional formula ψ has QRAT because all outer resolvents built from C contain C and are therefore implied via unit propagation as well. The following properties of QRAT-literals proven in [HSB17] finally allow us to formulate the rules of the QRAT proof system (see Figure 31.11). If a clause contains an existential QRAT-literal for a QBF $\Pi\psi$ then clause C is redundant in $\Pi\psi$, i.e., $\Pi\psi$ and $\Pi(\psi \cup \{C\})$ are satisfiability equivalent. If a clause C contains a universal QRAT-literal for QBF $\Pi\psi$, then l is redundant in C , i.e., $\Pi(\psi \cup \{C\})$ and $\Pi(\psi \cup \{C \setminus \{l\}\})$ are satisfiability equivalent. Note that the clause and literal addition rules can introduce new variables that have to be included in the prefix.

Rule	Rule Application	Side Conditions
Clause Elimination	$\Pi(\psi \cup \{C\}) \xrightarrow{\text{QRATE}(C, l)} \Pi\psi$	<ul style="list-style-type: none"> • l is existential or $l = \perp^*$, $l \in C$ • l is a QRAT-literal of C for $\Pi\psi$
Clause Addition	$\Pi\psi \xrightarrow{\text{QRATA}(C, l)} \Pi'(\psi \cup \{C\})$	<ul style="list-style-type: none"> • l is existential or $l = \perp^*$, $l \in C$ • l is a QRAT-literal of C for $\Pi'(\psi)$ • Π' is obtained from Π by adding the variables only occurring in C <p>*if $l = \perp$ then C is an asymmetric tautology</p>
Literal Elimination	$\Pi(\psi \cup \{C\}) \xrightarrow{\text{QRATE}(C, l)} \Pi(\psi \cup \{C'\})$	<ul style="list-style-type: none"> • l is universal, $l \in C$, $C' = C \setminus \{l\}$ • l is a QRAT-literal of C for $\Pi\psi$
Literal Addition	$\Pi(\psi \cup \{C\}) \xrightarrow{\text{QRATA}(C, l)} \Pi'(\psi \cup \{C'\})$	<ul style="list-style-type: none"> • l is universal, $C' = C \cup \{l\}$, $l \notin C$ • l is a QRAT-literal of C for $\Pi'\psi$ • Π' is obtained from Π plus the variable of l if it is new
Extended Universal Reduction	$\Pi(\psi \cup \{C\}) \xrightarrow{\text{EUR}(C, l)} \Pi(\psi \cup \{C'\})$	<ul style="list-style-type: none"> • l is universal, $l \in C$, $C' = C \setminus \{l\}$ • for all $k \in C$ with $k \supset_{\Pi} l$, l and k are independent w.r.t. the resolution-path dependency scheme

Figure 31.11. Rules of the QRAT Proof System

Besides the clause addition, clause elimination, literal addition, and literal elimination rules based on the QRAT property, there is a generalized version of universal reduction included that is based on resolution-path dependency schemes (see also Section 31.3.2). Given a QBF ϕ_0 , a derivation in the QRAT proof system is a sequence M_1, \dots, M_n where M_i is one of the rules shown in Figure 31.11 applied on QBF ϕ_{i-1} to obtain QBF ϕ_i . Hence, starting from a given QBF $\phi = \phi_0$, a QRAT derivation M_1, \dots, M_n produces new, equi-satisfiable formulas ϕ_1, \dots, ϕ_n . If ϕ_n contains the empty clause, then the derivation is a *proof of unsatisfiability*. If the matrix of ϕ_n is empty, then the derivation is a *proof of satisfiability*.

Example 19. Consider the following true QBF $\Pi\psi$ with $\Pi = \forall x \exists y_1 y_2$ with $\psi = ((x \vee y_1) \wedge (\bar{x} \vee y_2) \wedge (\bar{y}_1 \vee \bar{y}_2))$. It has the following QRAT proof of satisfiability:

$\Pi\psi$	$\frac{\text{QRATA}((\bar{y}_1 \wedge \bar{x}), \bar{y}_1)}{\text{QRATE}((y_2 \wedge \bar{x}), y_2)}$	$\Pi(\psi \cup \{(\bar{y}_1 \wedge \bar{x})\})$ $\Pi(((x \vee y_1) \wedge (\bar{y}_1 \vee \bar{y}_2) \wedge (\bar{y}_1 \wedge \bar{x}))$	$(\bar{y}_1 \wedge \bar{x})$ is blocked on \bar{y}_1 OR ($\Pi, (y_2 \wedge \bar{x}), (\bar{y}_1 \vee \bar{y}_2), y_2$) has RUP
	$\frac{\text{QRATE}((\bar{y}_2 \wedge \bar{y}_1), \bar{y}_2)}{\text{QRATE}((\bar{y}_1 \wedge \bar{x}), \bar{y}_1)}$	$\Pi(((x \vee y_1) \wedge (\bar{y}_1 \wedge \bar{x}))$ $\Pi((x \vee y_1))$	$(\bar{y}_2 \wedge \bar{y}_1)$ is blocked on \bar{y}_2 $(\bar{y}_1 \wedge \bar{x})$ is blocked on \bar{y}_1
	$\frac{\text{QRATE}((y_1 \wedge x), y_1)}{\text{QRATE}((y_1 \wedge x), y_1)}$	$\Pi(\top)$	$(y_1 \wedge x)$ is blocked on y_1

Example 20. Consider the following false QBF $\Pi\psi$ with $\Pi = \forall x \exists y_1 y_2$ with $\psi = ((x \vee y_1) \wedge (x \vee y_2) \wedge (\bar{y}_1 \vee \bar{y}_2))$. It has the following QRAT proof:

$\Pi\psi$	$\frac{\text{QRATA}((\bar{y}_1), \bar{y}_1)}{\text{QRATE}((\bar{y}_1 \vee \bar{y}_2), \perp)}$	$\Pi(\psi \cup \{(\bar{y}_1)\})$ $\Pi((x \vee y_1) \wedge (x \vee y_2) \vee (\bar{y}_1))$	OR ($\Pi, \bar{y}_1, (x \vee y_1), \bar{y}_1$) = $(x \vee \bar{y}_1)$ has RUP $(\bar{y}_1 \vee \bar{y}_2)$ has RUP
	$\frac{\text{QRATE}((x), \perp)}{\text{EUR}((x), x)}$	$\Pi((x \vee y_1) \wedge (x \vee y_2) \vee (\bar{y}_1) \wedge (x))$ $\Pi((x \vee y_1) \wedge (x \vee y_2) \vee (\bar{y}_1) \wedge (\perp))$	(x) has RUP universal reduction de- rives \perp

31.5.3. QRAT and Its Extension QRAT⁺ for Preprocessing

Heule et al. [HSB17] showed how to express preprocessing techniques in terms of QRAT rules, implemented QRAT proof generation in the preprocessor **Bloqper** and provided a proof checking tool. In many cases, the proof generation is straight forward. For example, a clause C that contains a pure literal l , obviously has QRAT on l . Hence, if l is existential, QRAT witnesses that C may be safely removed. If l is universal then QRAT witnesses that l may be safely removed from C . The argument generalizes to blocked clauses and blocked literals. Also tautologies and subsumed clauses have the QRAT property. For other rules the translation is more involved, because multiple different QRAT rule applications are necessary. In the following, we show an example of a QRAT proof for the restricted form universal expansion as used in preprocessing, i.e., the expanded universal variable occurs in the innermost universal quantifier block. For the details we refer to [HSB17].

Example 21. In Example 15 we have seen that for QBF $\Pi.\psi$ with $\Pi = \forall x_1 x_2 \exists y_1$ and $\psi = ((y_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{y}_1))$ universally expanding x_1 results in the formula $\forall x_2 \exists y_1 y_1^0 ((y_1 \vee x_2) \wedge (\bar{y}_1) \wedge (y_1^0 \vee x_2))$. In the following, we certify this rewriting of $\Pi.\psi$ with the following QRAT proof.

$$\begin{array}{ll}
\Pi\psi \xrightarrow{\text{QRATA}((y_1 \vee x_2 \vee \bar{x}_1), \perp)} & \Pi((y_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{y}_1) \wedge (y_1 \vee x_2 \vee \bar{x}_1)) \quad (1) \\
\xrightarrow{\text{QRATA}((\bar{y}_1^0 \vee x_1 \vee y_1), \bar{y}_1^0)} & \Pi'((y_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{y}_1) \wedge (y_1 \vee x_2 \vee \bar{x}_1) \wedge (\bar{y}_1^0 \vee x_1 \vee y_1)) \quad (2) \\
\xrightarrow{\text{QRATA}((y_1^0 \vee x_1 \vee \bar{y}_1), y_1^0)} & \Pi'((y_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{y}_1) \wedge (y_1 \vee x_2 \vee \bar{x}_1) \wedge (\bar{y}_1^0 \vee x_1 \vee y_1) \wedge (y_1^0 \vee x_1 \vee \bar{y}_1)) \quad (3) \\
\xrightarrow{\text{QRATA}((y_1^0 \vee x_2 \vee x_1), y_1^0)} & \Pi'((y_1 \vee x_2) \wedge (\bar{x}_1 \vee \bar{y}_1) \wedge (y_1 \vee x_2 \vee \bar{x}_1) \wedge (\bar{y}_1^0 \vee x_1 \vee y_1) \wedge (y_1^0 \vee x_1 \vee \bar{y}_1) \wedge (y_1^0 \vee x_2 \vee x_1)) \quad (4) \\
\xrightarrow{\text{QRATE}((y_1 \vee x_2), \perp)} & \Pi'((\bar{x}_1 \vee \bar{y}_1) \wedge (y_1 \vee x_2 \vee \bar{x}_1) \wedge (\bar{y}_1^0 \vee x_1 \vee y_1) \wedge (y_1^0 \vee x_1 \vee \bar{y}_1) \wedge (y_1^0 \vee x_2 \vee x_1)) \quad (5) \\
\xrightarrow{\text{QRATE}((\bar{y}_1^0 \vee x_1 \vee y_1), y_1)} & \Pi'((\bar{x}_1 \vee \bar{y}_1) \wedge (y_1 \vee x_2 \vee \bar{x}_1) \wedge (y_1^0 \vee x_1 \vee \bar{y}_1) \wedge (y_1^0 \vee x_2 \vee x_1)) \quad (6) \\
\xrightarrow{\text{QRATE}((y_1^0 \vee x_1 \vee \bar{y}_1), \bar{y}_1)} & \Pi'((\bar{x}_1 \vee \bar{y}_1) \wedge (y_1 \vee x_2 \vee \bar{x}_1) \wedge (y_1^0 \vee x_2 \vee x_1)) \quad (7) \\
\xrightarrow{\text{EUR}^*} & \forall x_2 \exists y_1 y_1^0 ((\bar{y}_1) \wedge (y_1 \vee x_2) \wedge (y_1^0 \vee x_2)) \quad (8)
\end{array}$$

In Step (1), the subsumed clause $(y_1 \vee x_2 \vee \bar{x}_1)$ is introduced. This is possible, because it has RUP. In Step (2) the clause $(\bar{y}_1^0 \vee x_1 \vee y_1)$ with the fresh variable y_1^0 variable is introduced. Obviously, \bar{y}_1^0 is a QRAT literal for prefix $\Pi' = \Pi \exists y_1^0$. The clause introduced in Step (3) is needed for renaming occurrences of y_1 to y_1^0 as done in Step (5). In fact, the clauses introduced in Step (3) and Step (4) form a conditional equivalence between y_1 and y_1^0 . In Step (5) and Step (6) the clauses of the conditional equivalence are removed again, because no further renaming is necessary. The removal is possible, because y_1 and \bar{y}_1 are RAT literals. Finally, all occurrences of x_1 be removed by the application of EUR and we obtain indeed the formula $\forall x_2 \exists y_1 y_1^0 ((y_1 \vee x_2) \wedge (\bar{y}_1) \wedge (y_1^0 \vee x_2))$.

Originally, QRAT was developed to provide a uniform way to certify the result of a preprocessor. As the QRAT proof system provides sound rules to add, remove and modify clauses, the QRAT rules themselves can be used within a preprocessor to modify a formula. For this purpose, even a generalization of QRAT called QRAT⁺ was developed in [LE18]. The version of QRAT as introduced above uses propositional unit propagation for testing the QRAT property (see Def 31.5.3). Here the quantification of the variables is not taken into account. QRAT⁺ uses a QBF-specific variant of unit propagation which also includes universal reduction. So certain clauses can be shortened during unit propagation resulting in a more powerful redundancy property.

31.6. Extraction of Winning Strategies from Proofs

Only few solvers explicitly generate winning strategies while evaluating a formula. For example the incremental determinization approach [RTRS18] generalizes the ideas behind CDCL (see Chapter 4 from searching for satisfying assignments to searching for Skolem functions. The solver QESTO [Jan18b] uses strategies instead of assignments for generating expanded formulas (see also Section 31.4). Most solvers, however, generate winning strategies only implicitly. For the solving approaches discussed before, proofs serve not only as witnesses for satisfiability/unsatisfiability, but they provide the necessary information for extracting a winning strategy, i.e., a model for a true QBF or countermodel for a false QBF. We distinguish between static function-extraction approaches (offline approaches)

and dynamic round-based approaches (online approaches). Both are shortly discussed in the following.

31.6.1. Function-Extraction Approaches

Balabanov and Jiang [BJ11, BJ12] presented an approach that allows for the extraction of Herbrand functions from clause Q-resolution proofs, and dually for the extraction of Skolem functions from cube Q-resolution proofs. Given a proof, the computation of such a function is linear in the size of the proof, allowing to use the simple representation format of decision lists.

Definition 9. A decision list $D = (t_1, v_1), \dots, (t_n, v_n), (\top, 0)$ is a finite sequence of pairs where t_i is a conjunction of literals and $v_i \in \{0, 1\}$. Let σ be an assignment over the variables occurring in a decision list D . Then D evaluates to v_i under σ if i is the least index such that t_i is true under σ .

Now let ϕ be a false QBF refuted by a Q-resolution proof π as described above. As ϕ is false, there is a winning strategy for the universal player. By traversing the proof in topological order, for each universal variable u , a decision list D_u is constructed that encodes such a winning strategy. Let C_i be a clause occurring in π that has been derived by removing the universal literal l from the previously derived clause C_k by the application of the universal reduction rule. If $l = u$, then the pair $(\bar{C}_i, 0)$ is appended to D_u . If $l = \bar{u}$, then the pair $(\bar{C}_i, 1)$ is appended to D_u . After the full proof has been traversed, all decision lists are closed with a pair $(\top, 0)$.

Example 22. Consider the false QBF $\exists x \forall a \exists z ((x \vee a \vee y) \wedge (\bar{x} \vee \bar{a} \vee y) \wedge \bar{y})$. A possible resolution proof first derives $(x \vee a)$ by resolving the first and the last clause. Applying universal reduction results in the clause x . Further, $(\bar{x} \wedge \bar{a})$ is then derived by resolving the second and the third clause. Applying universal reduction results in the clause \bar{x} . Another application of the resolution rule on x and \bar{x} derives the empty clause.

The proof contains two applications of the universal reduction rule from which the decision list $(\bar{x}, 0), (x, 1), (\top, 0)$ can be extracted. This decision list represents the Herbrand function $f_y(x) = x$ which is indeed a counter-model of the given formula.

This form of function extraction is also possible for long-distance Q-resolution proofs [BJJW15]. Also from QRAT proofs of satisfiability Skolem functions can be extracted by traversing the proof for constructing conditional expressions [HSB14, HSB17]. In contrast to decision lists, the conditions are not only conjunctions of literals, but more complicated formulas involving all outer resolvents of the QRAT literal of each clause that is deleted. This approach allows also the extraction of incomplete Skolem functions in case the preprocessor cannot solve a given formula. If a complete solver can solve the preprocessed formula, the Skolem functions of the preprocessed formula can be combined with the incomplete Skolem functions for obtaining the Skolem functions of the original formula [FHSB17]. For QRAT proofs of unsatisfiability, it is not known how to extract Herbrand functions so far.

31.6.2. Round-Based Approaches

An alternative approach directly implements the game semantics of QBFs. The quantifier prefix is processed from left to right. First, an arbitrary assignment is chosen by the existential player for the outermost existential variables. Based on this assignment, the proof is rewritten to a smaller refutation proof which also provides the information how the universal player has to assign the variables of the next universal quantifier block in order to win the game. Then it is again the existential player's turn to assign the variables of the next existential quantifier block. This assignment is again used to rewrite the proof, yielding the values of the next universal variables and so on. This approach works very similar for Q-resolution proofs and $\forall\text{Exp}+\text{Res}$ proofs. The main difference is in finding the values for the universal variables.

Q-Resolution. Given an assignment of the outermost existential variables, Goultiaeva et al. [GVGB11] presented a set of rules that reduces a Q-resolution proof under this assignment such that the result is again a Q-resolution proof. The values of the outermost universal variables in a winning strategy follow from the clause C in the reduced proof consisting only of universal literals—from such a clause the empty clause is derived by universal reduction. The polarity of the literal occurrences in C determines the value in the winning strategy. If a variable does not occur in C , or the conflict is derived by the application of the resolution rule, the value may be chosen freely. The approach works also for long-distance Q-resolution proofs [ELW13] and also for proofs [PSS16, PSS18] for reflexive resolution path.

Example 23. Consider the QBF $\exists x \forall a \exists z ((x \vee a \vee y) \wedge (\bar{x} \vee \bar{a} \vee y) \wedge \bar{y})$. If x is set to true, the approach presented in [GVGB11] simplifies the Q-resolution proof of the original formula to a Q-resolution proof for the formula $\forall a \exists z ((\bar{a} \vee y) \wedge \bar{y})$ that first resolves the two clauses and obtains the clause \bar{a} from which the empty clause is derived with universal reduction. Clause \bar{a} contains only universal literals, therefore, it is used to determine the value of a . Setting a to true results in the empty clause. This is the only choice for a winning move for the universal player under the assignment that sets x to true. If x had been set to false, the approach would force a to be set to false as well.

$\forall\text{Exp}+\text{Res}$. After the outermost existential variables have been assigned a truth value, the proof reduced under this assignment contains only annotations of the variables occurring in the outermost universal quantifier block in one polarity, i.e., those annotations are unopposed [BCJ14]. The polarities indicate how the respective universal variables have to be set in a winning strategy. Then the annotations of the outermost universal variables are removed, and the variables in the next existential block are assigned a value.

Example 24. Consider the QBF $\exists x \forall a \exists z ((x \vee a \vee y) \wedge (\bar{x} \vee \bar{a} \vee y) \wedge \bar{y})$. Instantiation results in the propositional formula $(x \vee y^0) \wedge (\bar{x} \vee y^1) \wedge \bar{y}^0 \wedge \bar{y}^1$ that is refuted in three steps, e.g., by resolving the first and the second clause resulting in the clause $(y^0 \vee y^1)$. Two further applications of the resolution rule result in the derivation

of the empty clause. If x is set to true, the instantiated formula simplifies to $(y^1) \wedge \bar{y}^0 \wedge \bar{y}^1$. The resolution proof simplifies respectively, and contains only unopposed annotations with a . Hence, a has to be set to true. The approach works similar for the case that x is set to false.

31.7. Connections Between Proof Systems

In this section we turn towards a proof-complexity analysis of the QBF proof systems defined earlier. Proof complexity offers two main threads towards this goal: a relative comparison of proof calculi via simulations and absolute (mostly exponential) lower bounds for the proof size of specific families of formulas in the systems. We survey and sketch some results for both these threads. Both approaches provide relevant information for solving as solver running time corresponds to proof size in the underlying calculi.

31.7.1. Enhanced Expansion Calculi

Before we start the comparison between the different calculi, we introduce two more proof systems that combine the CDCL and expansion calculi from Sections 31.3 and 31.4. Both these systems use the idea of expanding universal variables as in $\forall\text{Exp}+\text{Res}$ and keep track of the expansions in annotations, but incorporate additional features of CDCL-systems as in Section 31.3.

In $\forall\text{Exp}+\text{Res}$ each axiom clause is immediately annotated with a *fixed, complete* assignment to the universal variables. The proof then proceeds exactly as a propositional resolution proof, with clauses in fully annotated variables. In short, $\forall\text{Exp}+\text{Res}$ is propositional resolution on the conjuncts of a PCNF's complete expansion.

IR-calc, defined in [BCJ14], improves on this approach by working instead with *partial* assignments. In addition to resolution, the calculus is equipped with an *instantiation* rule by which partial annotations are grown throughout the course of the proof. To facilitate instantiation, the \circ operator describes how two partial assignments τ and σ are combined: $\tau \circ \sigma := \tau \cup \{l \in \sigma \mid \bar{l} \notin \tau\}$.

The rules of IR-calc are given in Figure 31.12. We provide a description of each of the IR-calc rules and illustrate them with some simple examples.

Axiom clauses are introduced into the proof, or *downloaded*, by selecting a clause C from the matrix and applying the *download assignment* to the existential literals. By design, the download assignment σ for C is the smallest partial assignment that falsifies every universal literal in C . Represented as a set of literals, then, $\sigma = \{\bar{l} \mid l \text{ is universal in } C\}$. When applying the download assignment, existentials are annotated only with universals *to their left* (i.e., those on which they depend). Consider the PCNF with prefix $\forall u \exists x \forall v \exists y$ and matrix clauses $\{u, \bar{x}, \bar{v}, y\}$ and $\{\bar{u}, x, \bar{y}\}$. Downloading the two matrix clauses gives rise to axioms $\{\bar{x}^{\bar{u}}, y^{\bar{u}v}\}$ and $\{x^u, \bar{y}^u\}$.

Instantiation applies a single partial assignment τ to all the annotations in a clause. As in the axiom rule, universals to the right of a variable are omitted from its annotation. Formally, for a partial assignment τ and an annotated clause

$$\frac{}{\{l^{[\tau]} \mid l \in C, l \text{ is an existential literal}\}} \text{ (Axiom)}$$

C is a non-tautological clause from the original matrix. τ is a partial 0/1 assignment to universal variables, which has all universal variables from C as its domain and falsifies all universal literals in C , i.e., $\tau = \{0/u \mid u \text{ is universal in } C\}$, where the notation $0/u$ for literals u is shorthand for $0/x$ if $u = x$ and $1/x$ if $u = \bar{x}$.

$$\frac{\{x^\tau\} \cup C_1 \quad \{\bar{x}^\tau\} \cup C_2}{C_1 \cup C_2} \text{ (Resolution)} \qquad \frac{C}{\text{inst}(\tau, C)} \text{ (Instantiation)}$$

C_1 , C_2 , and C are clauses of annotated variables.

τ is a partial 0/1 assignment to universal variables with $\text{rng}(\tau) \subseteq \{0, 1\}$.

Figure 31.12. The rules of IR-calc [BCJ14].

Axiom and instantiation rules as in IR-calc in Figure 31.12.

$$\frac{\{x^{\tau \cup \xi}\} \cup C_1 \quad \{\bar{x}^{\tau \cup \sigma}\} \cup C_2}{\text{inst}(\sigma, C_1) \cup \text{inst}(\xi, C_2)} \text{ (Resolution)}$$

C_1 and C_2 are clauses of annotated variables. τ is a partial assignment to universal variables (i.e., $\text{rng}(\tau) = \{0, 1\}$) and ξ, σ are extended partial assignments that assign universal variables to $\{0, 1, *\}$. $\text{dom}(\xi) \cap \text{dom}(\sigma) = \emptyset$.

$$\frac{C \cup \{l^\mu\} \cup \{l^\sigma\}}{C \cup \{l^\xi\}} \text{ (Merging)}$$

C is a clause of annotated variables. l is a literal and μ and σ are extended assignments with $\text{dom}(\mu) = \text{dom}(\sigma)$. $\xi = \{c/u \mid c/u \in \mu, c/u \in \sigma\} \cup \{*/u \mid c/u \in \mu, d/u \in \sigma, c \neq d\}$

Figure 31.13. The rules of IRM-calc [BCJ14]

C , the function $\text{inst}(\tau, C)$ returns the annotated clause $\{l^{[\sigma \circ \tau]} \mid l^\sigma \in C\}$. For example, given the prefix $\forall u_1 u_2 \exists x \forall u_3 u_4 \exists y$ and a clause $\{x^{u_1}, y^{\bar{u}_4}\}$, instantiation by $\tau = \bar{u}_2 u_3 u_4$ derives $\{x^{u_1 \bar{u}_2}, y^{u_3 \bar{u}_4}\}$. Note that u_3 and u_4 , which are right of x , do not appear in that variable's annotation after the instantiation. Also note that u_4 does not appear in the annotation to y , which is already annotated with the negated literal \bar{u}_4 before the instantiation takes place (see the earlier definition of \circ).

Resolution in IR-calc is identical to propositional resolution. We emphasize that annotations are labelling distinct variables (e.g., x^u and x^v are different variables), so that a resolution step is only valid if the annotations of the pivot literals match.

The calculus IRM-calc additionally incorporates long-distance steps in the spirit of LD-Q-Res. The rules of the calculus are depicted in Figure 31.13.

Figure 31.14. The simulation order of QBF resolution systems

31.7.2. The Simulation Order of QBF Resolution Calculi

We now provide an overview of the simulation order of the resolution systems defined earlier. A pictorial representation of the simulation order is given in Figure 31.14.

In Figure 31.14, solid lines denote simulations where the simulating system is placed at the higher position, e.g. $\forall\text{Exp}+\text{Res}$ simulates tree-like Q-Res by the simulation labeled with 1. Furthermore, all simulations are strict, e.g. tree-like Q-Res does not simulate $\forall\text{Exp}+\text{Res}$ as witnessed by a formula family with short proofs in $\forall\text{Exp}+\text{Res}$, but requiring exponential-size proofs in tree-like Q-Res. Dashed lines indicate incomparability results, e.g. $\forall\text{Exp}+\text{Res}$ and Q-Res are incomparable as per line 11. This means that there are formulas with polynomial-size proofs in $\forall\text{Exp}+\text{Res}$, but requiring exponential-size proofs in Q-Res, and vice versa.

We highlight that our information with respect to the simulation order of the eight depicted systems is complete, i.e., we either have a simulation result or an incomparability result. Missing lines follow by transitivity. We also point out that all the separations (either by strict simulations or incomparability) are exponential separations. References to the original results as well as pointers to the separating formulas are placed in Table 31.1 accompanying Figure 31.14.

Most of the simulation results follow straightforwardly from the definitions. This applies to the two simulations 3 and 7 between the expansion calculi on the left as well as to all simulations between the CDCL-type calculi on the right. Nontrivial simulations arise between conceptually different proof systems, which applies to simulations 1, 4 and 8, details of which can be found in [BCJ14].

Table 31.1. Formulas and references establishing simulations and separations. Numbers in the first column refer to the labels in Figure 31.14.

	Simulation	Separation

31.7.3. Lower Bounds and Separations

We now turn to the separations of the proof systems in Figure 31.14. This involves constructing specific formula families that provide the separations, e.g. for the separation of LD-Q-Res from Q-Res we need formulas ϕ_n that have polynomial-size proofs in LD-Q-Res, but require exponential-size proofs in Q-Res. For this separation we have multiple canonical choices for ϕ_n as either the equality formulas EQ_n from [BBH18a], the formulas $KBKF_n$ of Kleine Büning et al. [KBKF95], or the parity formulas [BCJ15].

In most instances, giving the upper bounds, i.e., constructing short proofs in the stronger system, turns out to be fairly easy, whereas establishing the lower bounds, i.e., showing the absence of short proofs in the weaker system, presents the main technical challenge. This is in line with the general picture in computational complexity, where the task of showing lower bounds turns out to be the most intricate.

Arguably, what is even more important than the actual lower bounds, is to devise generally applicable *lower-bound techniques*. For propositional resolution we have a number of such techniques (cf. [Seg07, Bus12]) and it is illuminating to review their applicability in the QBF context.

The (in)effectiveness of propositional techniques in QBF. The most widely used classical technique is the seminal *size-width technique* of [BSW01], which shows lower bounds for size via lower bounds for the width in resolution. However, this technique drastically fails even in the base system Q-Res [BCMS18a] and also does not seem applicable more widely [CB18].

Feasible interpolation is another widely-used propositional technique that connects circuit complexity to proof complexity. Feasible interpolation applies to a number of classical proof systems [Kra97, Pud97], and in [BCMS17] it was

demonstrated that this technique lifts to all QBF resolution systems depicted in Figure 31.14. However, the applicability of feasible interpolation is restricted by the fact that it imports lower bounds for monotone Boolean circuits (of which we only have relatively few [Juk12]).

A further general approach is through *Prover-Delayer games*. While this is effective in both propositional resolution [PI00, BGL13] as well as in QBF resolution [BCS17] (and can even yield optimal bounds [BGL13, BGL10, BCS17]), it only applies to the weak tree-like versions of these systems, where proofs are always in form of a tree, i.e., if derived formulas are needed multiple times in the proof they need to be rederived.

There is another short-coming of using propositional ideas in QBF. On existentially quantified formulas, all the QBF resolution systems coincide with classical proposition resolution. As such, all formulas hard for propositional resolution will be hard for any of the QBF resolution systems shown in Figure 31.14, e.g. the existentially quantified pigeonhole formulas are hard for all the QBF resolution calculi. Neither is this the phenomenon one wants to study in QBF proof complexity (cf. [Che17a, BHP17] for discussions), nor can such formulas provide any of the separations in Figure 31.14 (except for Q-Res from tree-like Q-Res). The same applies to the lifted interpolation technique: while it applies to new classes of QBFs (not just Σ_1^b formulas) it also does not provide any separations, as lower bounds via this technique will hold for all QBF resolution calculi simultaneously.

Summarising the current impact of propositional techniques in QBF it is fair to say that, at present, *ideas from the propositional world have limited impact to the QBF framework*, and *genuinely new ideas are needed* to cope with the more complex setting of quantifiers.

31.7.4. Genuine QBF Lower Bound Techniques

We will now turn to ideas for lower bounds specific to QBF and along the way explain some of the separations in Figure 31.14.

The principal approach to lower bounds in QBF is via *strategy extraction*, which originates from the game semantics of QBF. We recall the *two-player game* between an existential and a universal player, who in turn choose 0/1 values for the variables in the QBF in the order of the quantifier prefix, starting from the leftmost quantifier. The universal player wins as soon as one of the clauses in the QBF matrix gets falsified, otherwise the existential player wins. A fully quantified QBF is false if and only if the universal player has a winning strategy; likewise it is true if and only if the existential player has a winning strategy.

Strategy extraction computes a strategy from a proof of the formula. In particular, from a refutation of a false QBF in a QBF resolution system, a winning strategy for the universal player can be efficiently extracted [BCJ14, BJJW15]. This is practically important, as strategies witness the answers of QBF solvers [BJ12], but it can also be exploited for lower-bound techniques [BCJ15, BBC16, BBH18a].

The basic idea of this method is both conceptually simple and elegant: If we know that a family φ_n of false QBFs requires ‘complex’ winning strategies, then proofs of φ_n must be large in all proof systems with ‘feasible’ strategy extraction.

Lower bounds from circuit complexity. The qualification ‘complex’ can be given different specific definitions. The first is to consider the computational complexity required to compute the witnessing functions. For Q-Res and QU-Res we know that winning strategies can be computed by decision lists (cf. Section 31.6). It is easy to verify that decision lists can be turned into AC^0 circuits (cf. [BCJ15]). Hence winning strategies can be computed from Q-Res refutations in AC^0 .

To turn this into a lower bound, we need to construct false QBFs where all winning strategies are hard for bounded-depth circuits. As an example, consider the parity formulas $QParity_n$ from [BCJ15]

$$\exists x_1, \dots, x_n \forall z \exists t_2, \dots, t_n \text{ xor}(x_1, x_2, t_2) \cup \bigcup_{i=3}^n \text{ xor}(t_{i-1}, x_i, t_i) \cup \{z \vee t_n, \bar{z} \vee \bar{t}_n\}$$

where $\text{xor}(o_1, o_2, o)$ defines o to be $o_1 \oplus o_2$ through the following set of clauses

$$\{\bar{o}_1 \vee \bar{o}_2 \vee \bar{o}, o_1 \vee o_2 \vee \bar{o}, \bar{o}_1 \vee o_2 \vee o, o_1 \vee \bar{o}_2 \vee o\}.$$

Informally, $QParity_n$ reasons about $x_1 \oplus \dots \oplus x_n$, where the variables t_i encode the prefix sums $x_1 \oplus \dots \oplus x_i$. Hence t_n encodes $x_1 \oplus \dots \oplus x_n$. Through the only universal variable z the formula expresses the obvious contradiction that $x_1 \oplus \dots \oplus x_n$ is neither 0 nor 1. Crucially, the only strategy of the universal player to win on this false QBF is to play $z = x_1 \oplus \dots \oplus x_n$.

A seminal result of [FSS84, Hås87] states that every non-uniform family of bounded-depth circuits computing the parity function is of exponential size. Combined with the fact that strategy extraction for Q-Res and also QU-Res is possible in AC^0 , this results in an exponential lower bound for $QParity_n$ in Q-Res and QU-Res, first shown in [BCJ15].

In contrast, it turns out that the $QParity_n$ formulas admit short proofs both in $\forall\text{Exp}+\text{Res}$ [BCJ15] and in LD-Q-Res [Che17b]. We sketch the construction of the linear-size refutations of $QParity_n$ in $\forall\text{Exp}+\text{Res}$. We first instantiate all clauses in both polarities of z , generating the clauses

$$\text{xor}(x_1, x_2, t_2^{0/z}) \cup \bigcup_{i=3}^n \text{ xor}(t_{i-1}^{0/z}, x_i, t_i^{0/z}) \cup \{t_n^{0/z}\}$$

and $\text{xor}(x_1, x_2, t_2^{1/z}) \cup \bigcup_{i=3}^n \text{ xor}(t_{i-1}^{1/z}, x_i, t_i^{1/z}) \cup \{\bar{t}_n^{1/z}\}$.

Inductively, for $i = 2, \dots, n$ we now derive clauses representing $t_i^{0/z} \leftrightarrow t_i^{1/z}$. This yields a contradiction using the clauses $t_n^{0/z}$ and $\bar{t}_n^{1/z}$.

Therefore the $QParity$ formulas give one part of the separation between $\forall\text{Exp}+\text{Res}$ and Q-Res: formulas easy for $\forall\text{Exp}+\text{Res}$, but hard for Q-Res. Formulas easy in Q-Res, but hard in $\forall\text{Exp}+\text{Res}$ are contained in [JM15]. These formulas use n universal variables, which all need to be expanded in both polarities 0/1 in order to obtain an unsatisfiable set of clauses. Hence the expansion phase in all $\forall\text{Exp}+\text{Res}$ refutations of the formula is of size 2^n . It is not difficult to construct such formulas that are also easy for Q-Res.

Lower bounds through cost. We now explore a second way of how to interpret the qualification of ‘complex’ in winning strategies. Following the semantic approach of [BBH18a], we consider false QBFs where all winning strategies require

many moves of the universal player. We will see that such formulas are hard for QU-Res and further QBF systems.

We measure the size of winning strategies (for a single block) by the cost of a formula.

Definition 31.7.1 ([BBH18a]). The *cost* of a false QBF is the minimum, over all winning strategies, of the largest number of responses for a single universal block.

Strategies that require many responses of the universal player (in one block) are costly. This measure provides an absolute lower bound on the number of clauses in QU-Res refutations.

Theorem 31.7.1 ([BBH18a]). *Let π be a QU-Res refutation of a QBF Φ . Then $|\pi| \geq \text{cost}(\Phi)$.*

We consider the *equality formulas* from [BBH18a] as an example. The QBF EQ_n is defined as

$$\exists x_1 \cdots x_n \forall u_1 \cdots u_n \exists t_1 \cdots t_n \left(\bigwedge_{i=1}^n (x_i \vee u_i \vee \bar{t}_i) \wedge (\bar{x}_i \vee \bar{u}_i \vee \bar{t}_i) \right) \wedge \left(\bigvee_{i=1}^n t_i \right).$$

The only winning strategy for these formulas is to play $u_i = x_i$ for $i = 1, \dots, n$. There is only one universal block. Hence the cost of EQ_n is 2^n and all QU-Res (and Q-Res) proofs of EQ_n are of exponential size.

In contrast, EQ_n are easily verified to have linear-size proofs in LD-Q-Res [BBM19], hence the formulas provide the separation between Q-Res and LD-Q-Res (line 5 in Figure 31.14).

Another such separation is provided by the $KBKF_n$ formulas of Kleine Büning et al. [KBKF95], which appear widely in the QBF literature (for examples, see [Egl16, BCJ15, BWJ14, LES16]). Again these formulas can be shown to be hard for Q-Res via a cost argument [BBH18a], while they are easy for QU-Res [VG12a] and LD-Q-Res [ELW13], thus in particular providing the separation between QU-Res and Q-Res. Modified versions of the $KBKF_n$ formulas also provide the separations of LQU⁺-Res from LD-Q-Res and QU-Res [BWJ14].

A related notion of cost is also effective as a lower bound measure for expansion calculi, whereby the $KBKF_n$ formulas can be shown to be hard for IR-calc [BB18].

31.7.5. Relations to Further Calculi

We briefly mention some facts on the proof complexity of further approaches defined in earlier subsections: dependency schemes, symmetries, and QRAT. However, in comparison to the systems in Figure 31.14 for which we know their precise relations, we only have partial results on their relative complexity.

For *dependency schemes* (cf. Section 31.3.2), the EQ_n and $KBKF_n$ formulas give theoretical justification for their use: both formulas are hard for Q-Res, but become easy when using the resolution path dependency scheme [BB17]. In fact, even the standard dependency scheme cannot identify any useful dependencies

for the EQ_n and $KBKF_n$ formulas, i.e., the formulas exponentially separate Q-Res with the resolution path dependency scheme from Q-Res with the standard dependency scheme.

In addition, the formulas $KBKF_n$ and $QParity_n$ have short proofs if Q-Res is extended by the *symmetry rule* (see Section 31.3.2). It is, however, easy to destroy the symmetries by introducing universal pure literals into those formulas such that no symmetries can be exploited. Hence LQU^+ -Res and Q-Res with the symmetry rule are incomparable.

For the QRAT proof system (see Section 31.5) it is known that it is strictly stronger than LD-Q-Res and QU-Res [KHS17]. Currently nothing is known about the relationships to LQU^+ -Res or the expansion calculi.

31.7.6. Stronger QBF Proof Systems

We now turn briefly to the wider landscape of stronger QBF calculi beyond resolution. We have seen previously that propositional resolution can be turned into the QBF system QU-Res by simply adding the universal reduction rule. This procedure can be generalised [BBC16]: every line-based propositional proof system P (fulfilling some natural conditions [BBH18a]) can be lifted to a system $P+\forall\text{red}$, which is sound and complete for QBF.

In this way, we obtain natural QBF versions of the geometric system *cutting planes* [BCMS18b], working with linear inequalities instead of clauses, of the algebraic system *polynomial calculus*, working with polynomials, and of the logical *Frege systems*, working with arbitrary finite sets of axioms and a set of propositional rules [BBC16].

We note that the two lower bound techniques via strategy extraction from Section 31.7.4 remain applicable to these much stronger QBF systems. However, when using circuit complexity as in the first approach, we need to import stronger (conditional) circuit lower bounds, i.e., for NC^1 in case of Frege and for P/poly in case of extended Frege [BBC16].

For the QBF Frege systems, we can even *characterise* their reasons for hardness: lower bounds either arise through a lower bound for propositional Frege or through a circuit lower bound (the precise condition is $NC^1 \not\subseteq PSPACE$ in case of Frege) [BP16]. Hence, QBF Frege systems naturally unite the hardest problem in propositional proof complexity (lower bounds for Frege) with the hardest task in circuit complexity (unconditional circuit lower bounds).

The second approach via cost is also effective for strong systems. However, here we need to include another measure: the *capacity* of proof lines. Informally, the capacity of a line in a proof counts how many responses can be at most extracted from it; and the capacity of a proof is defined as the maximum of the capacities of its lines. As an example, clauses have capacity one as the universal player has a unique strategy to falsify the clause. Hence resolution proofs always have capacity one.

We recall that cost measures how many responses need to be extracted from the proof and that strategy extraction is efficient by the round-based algorithm in Section 31.6. This leads to the *size-cost-capacity theorem* [BBH18a], a general result for QBF proof systems of the form $P+\forall\text{red}$, stating that for each QBF Φ

and each $P+\forall$ red proof π of Φ

$$|\pi| \geq \frac{\text{cost}(\Phi)}{\text{capacity}(\pi)} .$$

By this theorem, the equality formulas are hard not only for QU-Res, but also in QBF cutting planes and polynomial calculus [BBH18a]. Via this approach, we can also show the hardness of a large class of random QBFs in these calculi.

In contrast, QBF Frege admits short proofs for equality and these random formulas, as the capacity of Frege lines can become exponentially large.

Finally, we also mention *sequent calculi* for QBF [KP90, CM05]. In contrast to all the systems considered before they can also manipulate the quantifier prefix and thus are very strong systems, even stronger than QBF Frege [BP16]. However, there are also various restricted versions of intermediate strength [Egl12].

QBF sequent calculi and Frege systems enjoy a close connection to first-order theories of bounded arithmetic [KP90, CM05, BP16]. Via different translations many of the QBF resolution systems considered here are also closely related to first-order logic [Egl16, SLB12].

Chapter 32

SAT Techniques for Modal and Description Logics

Roberto Sebastiani and Armando Tacchella

32.1. Introduction

In a nutshell, modal logics are propositional logics enriched with *modal operators*, —like \Box , \Diamond , \Box_i — which are able to represent complex facts like necessity, possibility, knowledge and belief. For instance, “ $\Box\varphi$ ” and “ $\Diamond\varphi$ ” may represent “necessarily φ ” and “possibly φ ” respectively, whilst “ $\Box_1\Box_2\varphi$ ” may represent the fact that agent 1 knows that agent 2 knows the fact φ . Description logics are extensions of propositional logic which build on top of entities, concepts (unary relations) and roles (binary relations), which allow for representing complex concepts. For instance, the concept “ $\text{MALE} \wedge \exists \text{CHILDREN} (\neg \text{MALE} \wedge \text{TEEN})$ ”, represents the set of fathers which have at least one teenager daughter.

The research in modal and description logics had followed two parallel routes until the seminal work by Schild [Sch91], who showed that the core modal logic K_m and the core description logic \mathcal{ALC} are notational variants one of the other, and that analogous frameworks, results and algorithms had been conceived in parallel in the two communities. Since then, analogous results have been produced for a bunch of other logics, so that nowadays the two communities have substantially merged into one research flow.

In the last two decades, modal and description logics have provided a theoretical framework for important applications in many areas of computer science, including artificial intelligence, formal verification, database theory, distributed computing and, more recently, semantic web. For this reason, the problem of automated reasoning in modal and description logics has been thoroughly investigated (see, e.g., [Fit83, Lad77, HM92, BH91, Mas00]), and many approaches have been proposed for (efficiently) handling the satisfiability of modal and description logics, with a particular interest for the core logics K_m and \mathcal{ALC} (see, e.g., [Fit83, BH91, GS00, HPS99, HS99, BGdR03, PSV02, SV06]). Moreover, a significant amount of benchmarks formulas have been produced for testing the effectiveness of the different techniques [HM92, GRS96, HS96, HPSS00, Mas99, PSS01, PSS03].

We briefly overview the main approaches for the satisfiability of modal and description logics which have been proposed in the literature. The “classic” *tableau-based* approach [Fit83, Lad77, HM92, Mas00] is based on the construction of propositional-tableau branches, which are recursively expanded on demand by generating successor nodes in a candidate Kripke model. In the *DPLL-based* approach [GS96a, SV98, GS00] a DPLL procedure, which treats the modal subformulas as propositions, is used as Boolean engine at each nesting level of the modal operators: when a satisfying assignment is found, the corresponding set of modal subformulas is recursively checked for modal consistency. Among the tools employing (and extending) this approach, we recall KSAT [GS96a, GGST00], *SAT [Tac99], FACT [Hor98b], DLP [PS98], and RACER [HM01].¹ This approach has lately been exported into the context of Satisfiability Modulo Theories - SMT [ACG00, ABC⁺02], giving rise the so-called *on-line lazy approach* to SMT described in §26.4 (see also [Seb07]). The *CSP-based* approach [BGdR03] differs from the tableaux-based and DPLL-based ones mostly in the fact that a CSP engine is used instead of a tableaux/DPLL engine. KCSP is the representative tool of this approach. In the *translational* approach [HS99, AGHd00] the modal formula is encoded into first-order logic (FOL), and the encoded formula is then fed to a FOL theorem prover [AGHd00]. MSPASS [HSW99] is the most representative tool of this approach. In the *Inverse-method* approach, a search procedure is based on the inverted version of a sequent calculus [Vor99, Vor01] (which can be seen as a modalized version of propositional resolution [PSV02]). K \mathcal{X} is the representative tool of this approach. In the *Automata-theoretic* approach, or *OBDD-based* approach, (a OBDD-based symbolic representation of) a tree automaton accepting all the tree models of the input formula is implicitly built and checked for emptiness [PSV02, PV03]. KBDD [PV03] is the representative tool of this approach. [PV03] presents also an encoding of K-satisfiability into QBF-satisfiability – another PSPACE-complete problem – combined with the use of a state-of-the-art QBF solver. Finally, in the *eager approach* [SV06, SV08] K_m /*ACC*-formulas are encoded into SAT and then fed to a state-of-the-art SAT solver. K_m2SAT is the representative tool of this approach.

Most such approaches combine propositional reasoning with various techniques/encodings for handling the modalities, and thus are based on, or have largely benefited from, efficient propositional reasoning techniques. In particular, the usage of DPLL as a core Boolean reasoning technique produced a boost in the performance of the tools when it was adopted [GS96a, GS96b, Hor98b, PS98, HPS99, GGST00, HPSS00].

In this chapter we show how efficient Boolean reasoning techniques have been imported, used and integrated into reasoning tools for modal and description logics. To this extent, we focus on modal logics, and in particular mainly on K_m . Importantly, this chapter *does not* address the much more general issue of satisfiability in modal and description logics, because the reasoning techniques

¹ Notice that there is not an universal agreement on the terminology “tableau-based” and “DPLL-based”. E.g., tools like FACT, DLP, and RACER are often called “tableau-based”, although they use a DPLL-like algorithm instead of propositional tableaux for handling the propositional component of reasoning [Hor98b, PS98, HPS99, HM01], because many scientists in these communities consider DPLL as an optimized version of propositional tableaux. The same issue holds for the Boolean system KE [DM94] and its derived systems.

which are specific for the different modal and description logics are orthogonal to the issue of Boolean reasoning. We refer the reader to the bibliography presented above and to [BCM⁺03] for a detailed description of those topics.

The chapter is organized as follows. In §32.2 we provide some background in modal logics. In §32.3 we describe a basic theoretical framework and we present and analyze the basic tableau-based and DPLL-based techniques. In §32.4 we present optimizations and extensions of the DPLL-based procedures. In §32.5 we present the automata-theoretic/OBDD-based approach. Finally, in §32.6 we present the eager approach.

32.2. Background

In this section we provide some background in modal logics. We refer the reader to, e.g., [Che80, Fit83, HM92] for a more detailed introduction.

32.2.1. The Modal Logic K_m

We start with some basic notions and notation (see, e.g., [Che80, Fit83, HM92] for more details). Given a non-empty set of primitive propositions $\mathcal{A} = \{A_1, A_2, \dots\}$ and a set of m modal operators $\mathcal{B} = \{\Box_1, \dots, \Box_m\}$, let the language Λ_m be the least set of formulas containing \mathcal{A} , closed under the set of propositional connectives $\{\neg, \wedge\}$ and the set of modal operators in \mathcal{B} . Notationally, we use capital letters A_i, B_i, \dots to denote primitive propositions and Greek letters $\alpha_i, \beta_i, \varphi_i, \psi_i$ to denote formulas in Λ_m . We use the standard abbreviations, that is: “ $\diamond_r \varphi_1$ ” for “ $\neg \Box_r \neg \varphi_1$ ”, “ $\varphi_1 \vee \varphi_2$ ” for “ $\neg(\neg \varphi_1 \wedge \neg \varphi_2)$ ”, “ $\varphi_1 \rightarrow \varphi_2$ ” for “ $\neg(\varphi_1 \wedge \neg \varphi_2)$ ”, “ $\varphi_1 \leftrightarrow \varphi_2$ ” for “ $\neg(\varphi_1 \wedge \neg \varphi_2) \wedge \neg(\varphi_2 \wedge \neg \varphi_1)$ ”, “ \top ” and \perp for the true and false constants respectively. Formulas like $\neg\neg\psi$ are implicitly assumed to be simplified into ψ ; thus, if ψ is $\neg\phi$, then by “ $\neg\psi$ ” we mean “ ϕ ”. We often write “ $(\bigwedge_i l_i) \rightarrow \bigvee_j l_j$ ” for the clause “ $\bigvee_j \neg l_i \vee \bigvee_j l_j$ ”, and “ $(\bigwedge_i l_i) \rightarrow (\bigwedge_j l_j)$ ” for the conjunction of clauses “ $\bigwedge_j (\bigvee_i \neg l_i \vee l_j)$ ”. We call *depth* of φ , written $depth(\varphi)$, the maximum degree of nesting of modal operators in φ .

A K_m -formula is said to be in *Negative Normal Form (NNF)* if it is written in terms of the symbols $\Box_r, \diamond_r, \wedge, \vee$ and propositional literals $A_i, \neg A_i$ (i.e., if all negations occur only before propositional atoms in \mathcal{A}). Every K_m -formula φ can be converted into an equivalent one $NNF(\varphi)$ by recursively applying the rewriting rules: $\neg \Box_r \varphi \implies \diamond_r \neg \varphi$, $\neg \diamond_r \varphi \implies \Box_r \neg \varphi$, $\neg(\varphi_1 \wedge \varphi_2) \implies (\neg \varphi_1 \vee \neg \varphi_2)$, $\neg(\varphi_1 \vee \varphi_2) \implies (\neg \varphi_1 \wedge \neg \varphi_2)$, $\neg\neg\varphi \implies \varphi$.

A K_m -formula is said to be in *Box Normal Form (BNF)* [PSV02, PV03] if it is written in terms of the symbols $\Box_r, \neg \Box_r, \wedge, \vee$, and propositional literals $A_i, \neg A_i$ (i.e., if there are no diamonds, and if all negations occurs only before boxes or before propositional atoms in \mathcal{A}). Every K_m -formula φ can be converted into an equivalent one $BNF(\varphi)$ by recursively applying the rewriting rules: $\diamond_r \varphi \implies \neg \Box_r \neg \varphi$, $\neg(\varphi_1 \wedge \varphi_2) \implies (\neg \varphi_1 \vee \neg \varphi_2)$, $\neg(\varphi_1 \vee \varphi_2) \implies (\neg \varphi_1 \wedge \neg \varphi_2)$, $\neg\neg\varphi \implies \varphi$.

The basic normal modal logic K_m can be defined axiomatically as follows. A formula in Λ_m is a theorem in K_m if it can be inferred from the following axiom

schema:

$$K. (\Box_r \varphi_1 \wedge \Box_r(\varphi_1 \rightarrow \varphi_2)) \rightarrow \Box_r \varphi_2. \quad (32.1)$$

by means of tautological inference and of the application of the following inference rule:

$$\frac{\varphi}{\Box_r \varphi} \text{ (Necessitation)}, \quad (32.2)$$

for every formula $\varphi, \varphi_1, \varphi_2$ in Λ_m and for every $\Box_r \in \mathcal{B}$. The rule *Necessitation* characterizes most modal logics; the axiom *K* characterizes the normal modal logics.

The semantics of modal logics is given by means of Kripke structures. A *Kripke structure* for K_m is a tuple $M = \langle \mathcal{U}, \pi, \mathcal{R}_1, \dots, \mathcal{R}_m \rangle$, where \mathcal{U} is a set of states, π is a function $\pi : \mathcal{A} \times \mathcal{U} \mapsto \{\text{True}, \text{False}\}$, and each \mathcal{R}_r is a binary relation on the states of \mathcal{U} . With a little abuse of notation we write “ $u \in M$ ” instead of “ $u \in \mathcal{U}$ ”. We call a pair M, u , a *situation*. The binary relation \models between a modal formula φ and a pair M, u s.t. $u \in M$ is defined as follows:

$$\begin{aligned} M, u \models A_i, A_i \in \mathcal{A} &\iff \pi(A_i, u) = \text{True}; \\ M, u \models \neg \varphi_1 &\iff M, u \not\models \varphi_1; \\ M, u \models \varphi_1 \wedge \varphi_2 &\iff M, u \models \varphi_1 \text{ and } M, u \models \varphi_2; \\ M, u \models \Box_r \varphi_1, \Box_r \in \mathcal{B} &\iff M, v \models \varphi_1 \text{ for every } v \in M \text{ s.t. } \mathcal{R}_r(u, v) \text{ holds in } M. \end{aligned}$$

We extend the definition of \models to formula sets $\mu = \{\varphi_1, \dots, \varphi_n\}$ as follows:

$$M, u \models \mu \iff M, u \models \varphi_i, \text{ for every } \varphi_i \in \mu.$$

“ $M, u \models \varphi$ ” should be read as “ M, u satisfy φ in K_m ” (alternatively, “ M, u K_m -satisfy φ ”). We say that a formula $\varphi \in \Lambda_m$ is satisfiable in K_m (K_m -satisfiable from now on) if and only if there exist M and $u \in M$ s.t. $M, u \models \varphi$. φ is *valid* for M , written $M \models \varphi$, if $M, u \models \varphi$ for every $u \in M$. φ is valid for a class of Kripke structures \mathcal{K} if $M \models \varphi$ for every $M \in \mathcal{K}$. φ is said to be *valid in K_m* iff $M \models \varphi$ for every Kripke structure M . It can be proved that a Λ_m -formula φ is a theorem in K_m if and only if it is valid in K_m [Che80, Fit83, HM92].

When this causes no ambiguity we sometimes write “satisfiability” meaning “ K_m -satisfiability”. If $m = 1$, we simply write “ K ” for “ K_1 ”.

The problem of determining the K_m -satisfiability of a K_m -formula φ is decidable and PSPACE-complete [Lad77, HM92], even restricting the language to a single Boolean atom (i.e., $\mathcal{A} = \{A_1\}$) [Hal95]; if we impose a bound on the modal depth of the K_m -formulas, the problem reduces to NP-complete [Hal95]. Intuitively, every satisfiable formula φ in K_m can be satisfied by a Kripke structure M which is a finite tree and whose depth is given by $\text{depth}(\varphi) + 1$ (i.e., s.t. $|M| \leq |\varphi|^{\text{depth}(\varphi)}$). Such a structure can be spanned by an alternating-and/or search procedure, similarly to what is done with QBF. An encoding of K_m -satisfiability into QBF is presented in [Lad77, HM92]. For a detailed description on K_m , including complexity results, we refer the reader to [Lad77, HM92, Hal95].

Table 32.1. Axiom schemata and corresponding properties of \mathcal{R}_r for the normal modal logics.

Axiom Schema	Property of \mathcal{R}_r
B. $\neg\varphi \rightarrow \Box_r\neg\Box_r\varphi$	symmetric $\forall u v. [\mathcal{R}_r(u, v) \implies \mathcal{R}_r(v, u)]$
D. $\neg\Box_r\perp$	seriality $\forall u. \exists v. [\mathcal{R}_r(u, v)]$
T. $\Box_r\varphi \rightarrow \varphi$	reflexive $\forall u. [\mathcal{R}_r(u, u)]$
4. $\Box_r\varphi \rightarrow \Box_r\Box_r\varphi$	transitive $\forall u v w. [\mathcal{R}_r(u, v) \wedge \mathcal{R}_r(v, w) \implies \mathcal{R}_r(u, w)]$
5. $\neg\Box_r\varphi \rightarrow \Box_r\neg\Box_r\varphi$	euclidean $\forall u v w. [\mathcal{R}_r(u, v) \wedge \mathcal{R}_r(u, w) \implies \mathcal{R}_r(v, w)]$

Table 32.2. Properties of \mathcal{R}_r for the various normal modal logics. The names between parentheses denote the names each logic is commonly referred with. (For better readability, we omit the pedex “ m ” from the name of the logics.)

Logic $\mathcal{L} \in \mathcal{N}$ (Axiomatic Characterization)	Corresponding Properties of \mathcal{R}_r (Semantic Characterization)

32.2.2. Normal Modal Logics

We consider the class \mathcal{N} of the normal modal logics. We briefly recall some of the standard definitions and results for these logics (see, e.g., [Che80, Fit83, HM92, Hal95]).

Given the language Λ_m , the class of normal modal logics on Λ_m , \mathcal{N} , can be described axiomatically as follows. The set of theorems in a logic \mathcal{L} in \mathcal{N} is the set of Λ_m -formulas which can be inferred by means of tautological inference and of the application of the Necessitation rule from the axiom schema K , plus a given subset of the axiom schemata $\{B, D, T, 4, 5\}$ described in the left column of Table 32.1. A list of normal modal logics built by combining such axiom schemata is presented in the left column of Table 32.2. Notice that each logic \mathcal{L} is named after the list of its (modal) axiom schemata, and that many logics are equivalent, so that we have only 15 distinct logics out of the 32 possible combinations.

From the semantic point of view, the logics $\mathcal{L} \in \mathcal{N}$ differ from one another by imposing some restrictions on the relations \mathcal{R}_r of the Kripke structures. As described in Table 32.1, each axiom schema in $\{B, D, T, 4, 5\}$ corresponds to a property on \mathcal{R}_r . In each logic \mathcal{L} , a formula φ can be satisfied only by Kripke structures whose relations \mathcal{R}_r 's verify the properties corresponding to \mathcal{L} , as described in Table 32.2. (E.g., φ is satisfiable in $KD4$ only by Kripke structures whose relations are both serial and transitive.) Consequently, φ is said to be *valid in \mathcal{L}* if it is valid in the corresponding class of Kripke structures. For every \mathcal{L} in \mathcal{N} , it can be proved that a Λ_m -formula is a theorem in \mathcal{L} if and only if it is valid in \mathcal{L} [Che80, Fit83].

The problem of determining the satisfiability in \mathcal{L} in \mathcal{N} (“ \mathcal{L} -satisfiability” hereafter) of a Λ_m -formula φ is decidable for every \mathcal{L} . The computational complexity of the problem depends on the logic \mathcal{L} and on many other factors, including the maximum number m of distinct box operators, the maximum number $|\mathcal{A}|$ of distinct primitive propositions, and the maximum modal depth of the formulas (denoted by *depth*). In the general case, for most logics $\mathcal{L} \in \mathcal{N}$ \mathcal{L} -satisfiability is PSPACE-complete; in some cases it may reduce to NP-complete, if $m = 1$ (e.g., with $K45$, $KD45$, $S5$), if *depth* is bounded (e.g., with K_m , T_m , $K45_m$, $KD45_m$, $S5_m$); in some cases it may reduce even to PTIME-complete is some of the features above combine with the fact that $|\mathcal{A}|$ is finite [Lad77, Hal95]. We refer the reader to [Lad77, HM92, Hal95, Ngu05] for a detailed description of these issues.

A *labeled formula* is a pair $\sigma : \varphi$, where φ is a formula in Λ and σ is a *label* (typically a sequence of integers) labeling a world in a Kripke structure for \mathcal{L} . If $\Gamma = \{\varphi_1, \dots, \varphi_n\}$, we write $\sigma : \Gamma$ for $\{\sigma : \varphi_1, \dots, \sigma : \varphi_n\}$. Intuitively, $\sigma : \varphi$ means “the formula φ in the world σ ”. For every $\mathcal{L} \in \mathcal{N}$, [Fit83, Mas94, Mas00] give a notion of *accessibility relation* between labels and gives the properties for these relations for the various logics \mathcal{L} . Essentially, they mirror the accessibility relation between the worlds they label.

32.2.3. Non-normal Modal Logics

We now consider the class of classical – also known as non-normal – modal logics. We briefly recall some of the standard definitions and results for these logics (see, e.g., [Che80, FHMV95]).

Given the language Λ_m , the basic classical modal logic on Λ_m , E_m , can be defined axiomatically as follows. The theorems in E_m are the set of formulas in Λ_m which can be inferred by tautological inference and by the application of the inference rule:

$$\frac{\varphi \leftrightarrow \psi}{\Box_r \varphi \leftrightarrow \Box_r \psi} \quad (E). \quad (32.3)$$

As a consequence, the schemata

$$\begin{aligned} N. & \Box_r \top \\ M. & \Box_r(\varphi \wedge \psi) \rightarrow \Box_r \varphi \\ C. & (\Box_r \varphi \wedge \Box_r \psi) \rightarrow \Box_r(\varphi \wedge \psi) \end{aligned} \quad (32.4)$$

which are theorems in K_m do not hold in E_m . The three principles N , M , and C enforce closure conditions on the set of provable formulas which are not always desirable, especially if the \Box_r operator has an epistemic (such as knowledge or belief)

reading. If we interpret $\Box_r\varphi$ as “a certain agent r believes φ ”, then N enforces that r believes all the logical truths, M that r 's beliefs are closed under logical consequence, and C that r 's beliefs are closed under conjunction. These three closure properties are different forms of omniscience, and —as such— they might not be appropriate for modeling the beliefs of a real agent (see, e.g., [FHMV95]). By combining the schemata in (32.4) and using them as axiom schemata, we can get eight different combinations corresponding to eight distinct logics, where each logic is named after the list of its modal axiom schemata. The logic $EMCN_m$ corresponds to the basic normal modal logic K_m .

The semantics of classical modal logics is given by means of Montague-Scott structures. A *Montague-Scott structure* for E_m is a tuple $S = \langle \mathcal{U}, \pi, \mathcal{N}_1, \dots, \mathcal{N}_m \rangle$, where \mathcal{U} is a set of states, π is a function $\pi : \mathcal{A} \times \mathcal{U} \mapsto \{True, False\}$, and each \mathcal{N}_r is a relation $\mathcal{N}_r : \mathcal{U} \mapsto \mathcal{P}(\mathcal{P}(\mathcal{U}))$, i.e., for each $u \in \mathcal{U}$, $\mathcal{N}_r(u) \subseteq \mathcal{P}(\mathcal{U})$. Notice that Montague-Scott structures are a generalization of Kripke structures, so the class of possible models for K_m is indeed a subclass of the possible models for E_m . In analogy with Section 32.2.1, we write “ $u \in S$ ” instead of “ $u \in \mathcal{U}$ ”, and we call S, u a situation. The binary relation \models between a modal formula φ and a pair S, u s.t. $u \in S$ is defined as follows:

$$\begin{aligned}
 S, u \models A_i, A_i \in \mathcal{A} &\iff \pi(A_i, u) = True; \\
 S, u \models \neg\varphi_1 &\iff S, u \not\models \varphi_1; \\
 S, u \models \varphi_1 \wedge \varphi_2 &\iff S, u \models \varphi_1 \text{ and } S, u \models \varphi_2; \\
 S, u \models \Box_r\varphi_1, \Box_r \in \mathcal{B} &\iff \{v \mid M, v \models \varphi_1\} \in \mathcal{N}_r(u)
 \end{aligned}
 \tag{32.5}$$

We extend the definition of \models to formula sets $\mu = \{\varphi_1, \dots, \varphi_n\}$ as follows:

$$S, u \models \mu \iff S, u \models \varphi_i, \text{ for every } \varphi_i \in \mu.$$

“ $S, u \models \varphi$ ” should be read as “ S, u satisfy φ in E_m ” (alternatively, “ S, u E_m -satisfy φ ”). We say that a formula $\varphi \in \Lambda_m$ is satisfiable in E_m (E_m -satisfiable from now on) if and only if there exist S and $u \in S$ s.t. $S, u \models \varphi$. φ is *valid* for S , written $S \models \varphi$, if $S, u \models \varphi$ for every $u \in S$. φ is valid for a class of Montague-Scott structures \mathcal{C} if $S \models \varphi$ for every $S \in \mathcal{C}$. φ is said to be *valid in E_m* iff $S \models \varphi$ for every Montague-Scott structure S . The semantics of the logic E is given by the relation defined in 32.5 only. The logics where one of M , C and N is an axiom require the following closure conditions on \mathcal{N}_r to be satisfied for each r :

- (M) if $U \subseteq V$ and $U \in \mathcal{N}_r(w)$ then $V \in \mathcal{N}_r(w)$ (closure by superset inclusion),
- (C) if $U \in \mathcal{N}_r(w)$ and $V \in \mathcal{N}_r(w)$ then $U \cap V \in \mathcal{N}_r(w)$ (closure by intersection),
- (N) $\mathcal{U} \in \mathcal{N}_r(w)$ (unit containment).

Notice that if an E_m structure S is such that $\mathcal{N}_r(u)$ satisfies all the above conditions for each world $u \in S$, then S is also a K_m structure.

In analogy with Section 32.2.1, if $m = 1$, we simply write, e.g., “ E ” for “ E_1 ”, “ EM ” for “ EM_1 ”, and so on. For every non-normal logic \mathcal{L} , it can be proved that a Λ_m -formula is a theorem in \mathcal{L} if and only if it is valid in \mathcal{L} [Che80, Fit83].

The problem of determining the E_m -satisfiability of a E_m -formula φ is decidable, and the E_m -satisfiability problem is NP-complete [Var89]. Satisfiability

is also NP-complete in all the classical modal logics that do not contain C as an axiom (EM, EN, EMN), while it is PSPACE-complete in the remaining ones (EC, EMC, ECN, EMCN). The satisfiability problems maintain the same complexity classes when considering multi-agent extensions.

32.2.4. Modal Logics and Description Logics

The connection between modal logics and terminological logics – also known as description logics – is due to a seminal paper by Klaus Schild [Sch91] where the description logic \mathcal{ALC} [SSS91] is shown to be a notational variant of the modal logic K_m . Here we survey some of the results of [Sch91], and we refer the reader to [BCM⁺03] for further reading about the current state of the art in modal and description logics.

Following [Sch91], we start by defining the language of \mathcal{ALC} . Formally, the language \mathcal{ALC} is defined by grammar rules of the form:

$$\begin{aligned} C &\rightarrow c \mid \top \mid C_1 \sqcap C_2 \mid \neg C \mid \forall R.C \\ R &\rightarrow r \end{aligned} \tag{32.6}$$

where C , and C_i denote generical concepts, c denotes an atomic concept symbol and r a role symbol. The formal semantics of \mathcal{ALC} is specified by an *extension function*. Let \mathcal{D} be any set called the *domain*. An extension function ε over \mathcal{D} is a function mapping concepts to subsets of \mathcal{D} and roles to subsets of $\mathcal{D} \times \mathcal{D}$ such that

$$\begin{aligned} \varepsilon[\top] &= \mathcal{D} \\ \varepsilon[C \sqcap D] &= \varepsilon[C] \cap \varepsilon[D] \\ \varepsilon[\neg C] &= \mathcal{D} \setminus \varepsilon[C] \\ \varepsilon[\forall R.C] &= \{d \in \mathcal{D} \mid \forall \langle d, e \rangle \in \varepsilon[R] \quad e \in \varepsilon[C]\} \end{aligned} \tag{32.7}$$

Using extension functions, we can define the semantic notion of *subsumption*, *equivalence* and *coherence*: D *subsumes* C , written $\models C \sqsubseteq D$, iff for each extension function ε , $\varepsilon[C] \subseteq \varepsilon[D]$, whereas C and D are *equivalent*, written $\models C = D$ iff for each extension function ε , $\varepsilon[C] = \varepsilon[D]$. Finally, C is *coherent* iff there is an extension function ε with $\varepsilon[C] \neq \emptyset$. The following result allows us to concentrate on any of the above notions without loss of generality:

Lemma 1. [Sch91] *Subsumption, equivalence, and incoherence are log-space reducible to each other in any terminological logic comprising Boolean operations on concepts.*

Viewing \mathcal{ALC} from the modal logic perspective (see 32.2.1), atomic concepts simply can be expounded as atomic propositions, and can be interpreted as the set of states in which such propositions hold. In this case “ \forall .” becomes a modal operator since it is applied to formulas. Thus, e.g., $\neg c_1 \sqcup \forall r.(c_2 \sqcap c_3)$ can be expressed by the K_m -formula $\neg A_1 \vee \square_r(A_2 \wedge A_3)$. The subformula $\square_r(A_2 \wedge A_3)$ is to be read as “agent r knows $A_2 \wedge A_3$ ”, and means that in every state accessible for r , both A_2 and A_3 hold.² Actually

²Notice that we replaced primitive concepts c_i with $i \in \{1, 2, 3\}$ with propositions A_i , assuming the obvious bijection between the two sets.

- the domain of an extension function can be read as a set of states \mathcal{U} ,
- atomic concepts can be interpreted as the set of worlds in which they hold, if expounded as atomic formulas, and
- atomic roles can be interpreted as accessibility relations.

Hence $\forall R.C$ can be expounded as “all states in which agent R knows proposition C ” instead of “all objects for which all R 's are in C ”.

To establish the correspondence between \mathcal{ALC} and K_m consider the function f mapping \mathcal{ALC} concepts to K_m -formulas with $f(c_i) = A_i$ for $i \in 1, 2, \dots$, i.e., f maps concept symbols to primitive propositions, $f(\top) = \top$, $f(C \sqcap D) = f(C) \wedge f(D)$, $f(\neg C) = \neg f(C)$ and $f(\forall R.C) = \Box_R f(C)$. It could easily be shown by induction on the complexity of \mathcal{ALC} -concepts that f is a linearly length-bounded isomorphism such that an \mathcal{ALC} -concept C is coherent iff the K_m -formula $f(C)$ is satisfiable. Formally:

Theorem 1. [Sch91] *\mathcal{ALC} is a notational variant of the propositional modal logic K_m , and satisfiability in K_m has the same computational complexity as coherence in \mathcal{ALC} .*

By this correspondence, several theoretical results for K_m can easily be carried over to \mathcal{ALC} . We immediately know, for example, that without loss of generality, any decision procedure for K_m -satisfiability is also a decision procedure for \mathcal{ALC} -coherence.

There are other result (see, e.g., [BCM⁺03]) that link normal modal logics, as described in 32.2.2, to various description logics that extend \mathcal{ALC} in several ways. According to these results, decision procedures for expressive description logics may be regarded as decision procedures for various normal modal logics, e.g., KD, T, B, and the other way round.

32.3. Basic Modal DPLL

In this section we introduce the basic concepts of modal tableau-based and DPLL-based procedures, and we discuss their relation.

32.3.1. A Formal Framework

Assume w.l.o.g. that the \diamond_r 's are not part of the language (each $\diamond_r \varphi$ can be rewritten into $\neg \Box_r \neg \varphi$). We call *atom* every formula that cannot be decomposed propositionally, that is, every formula whose main connective is not propositional. Examples of atoms are, A_1, A_i (*propositional atoms*), $\Box_1(A_1 \vee \neg A_2)$ and $\Box_2(\Box_1 A_1 \vee \neg A_2)$ (*modal atoms*). A *literal* is either an atom or its negation. Given a formula φ , an atom [literal] is a *top-level atom [literal]* for φ if and only if it occurs in φ and under the scope of no boxes. $Atoms^0(\varphi)$ is the set of the top-level atoms of φ .

We call a *truth assignment* μ for a formula φ a truth value assignment to all the atoms of φ . A truth assignment is *total* if it assigns a value to all atoms in φ , *partial* otherwise. Syntactically identical instances of the same atom are always assigned identical truth values; syntactically different atoms, e.g., $\Box_1(\varphi_1 \vee \varphi_2)$

and $\Box_1(\varphi_2 \vee \varphi_1)$, are treated differently and may thus be assigned different truth values.

To this extent, we introduce a bijective function $\mathcal{L2P}$ (“ \mathcal{L} -to-Propositional”) and its inverse $\mathcal{P2L} := \mathcal{L2P}^{-1}$ (“Propositional-to- \mathcal{L} ”), s.t. $\mathcal{L2P}$ maps top-level Boolean atoms into themselves and top-level non-Boolean atoms into fresh Boolean atoms — so that two atom instances in φ are mapped into the same Boolean atom iff they are syntactically identical— and distributes with sets and Boolean connectives. (E.g., $\mathcal{L2P}(\{\Box_r\varphi_1, \neg(\Box_r\varphi_1 \vee \neg A_1)\})$ is $\{B_1, \neg(B_1 \vee \neg A_1)\}$.) $\mathcal{L2P}$ and $\mathcal{P2L}$ are also called *Boolean abstraction* and *Boolean refinement* respectively.

We represent a truth assignment μ for φ as a set of literals

$$\begin{aligned} \mu = \{ & \Box_1\alpha_{11}, \dots, \Box_1\alpha_{1N_1}, \neg\Box_1\beta_{11}, \dots, \neg\Box_1\beta_{1M_1}, \\ & \vdots \\ & \Box_m\alpha_{m1}, \dots, \Box_m\alpha_{mN_m}, \neg\Box_m\beta_{m1}, \dots, \neg\Box_m\beta_{mM_m}, \\ & A_1, \dots, \neg A_R, \neg A_{R+1}, \dots, \neg A_S\}, \end{aligned} \quad (32.8)$$

$\Box_r\alpha_i$'s, $\Box_r\beta_j$'s being modal atoms and A_i 's being propositional atoms. Positive literals $\Box_r\alpha_i$ and A_k in μ mean that the corresponding atom is assigned to true, negative literals $\neg\Box_r\beta_i$ and $\neg A_k$ mean that the corresponding atom is assigned to false. If $\mu_2 \subseteq \mu_1$, then we say that μ_1 *extends* μ_2 and that μ_2 *subsumes* μ_1 . A *restricted truth assignment*

$$\mu^r = \{\Box_r\alpha_{r1}, \dots, \Box_r\alpha_{rN_r}, \neg\Box_r\beta_{r1}, \dots, \neg\Box_r\beta_{rM_r}\} \quad (32.9)$$

is given by restricting μ to the set of atoms in the form $\Box_r\psi$, where $1 \leq r \leq m$. Trivially μ^r subsumes μ .

Notationally, we use the Greek letters μ, η to represent truth assignments. Sometimes we represent the truth assignments in (32.8) and (32.9) also as the formulas given by the conjunction of their literals:

$$\mu = \begin{cases} \bigwedge_{i=1}^{N_1} \Box_1\alpha_{1i} \wedge \bigwedge_{j=1}^{M_1} \neg\Box_1\beta_{1j} \wedge \\ \dots \\ \bigwedge_{i=1}^{N_m} \Box_m\alpha_{mi} \wedge \bigwedge_{j=1}^{M_m} \neg\Box_m\beta_{mj} \wedge \\ \bigwedge_{k=1}^R A_k \wedge \bigwedge_{h=R+1}^S \neg A_h, \end{cases} \quad (32.10)$$

$$\mu^r = \bigwedge_i \Box_r\alpha_{ri} \wedge \bigwedge_j \neg\Box_r\beta_{rj}. \quad (32.11)$$

For every logic \mathcal{L} , we say that an assignment μ [restricted assignment μ^r] is \mathcal{L} -satisfiable meaning that its corresponding formula (32.10) [(32.11)] is \mathcal{L} -satisfiable.

We say that a total truth assignment μ for φ *propositionally satisfies* φ , written $\mu \models_p \varphi$, if and only if $\mathcal{L2P}(\mu) \models \mathcal{L2P}(\varphi)$, that is, for all sub-formulas

φ_1, φ_2 of φ :

$$\begin{aligned} \mu \models_p \varphi_1, \varphi_1 \in \text{Atoms}^0(\varphi) &\iff \varphi_1 \in \mu, \\ \mu \models_p \neg\varphi_1 &\iff \mu \not\models_p \varphi_1, \\ \mu \models_p \varphi_1 \wedge \varphi_2 &\iff \mu \models_p \varphi_1 \text{ and } \mu \models_p \varphi_2. \end{aligned}$$

We say that a partial truth assignment μ *propositionally satisfies* φ if and only if all the total truth assignments for φ which extend μ propositionally satisfy φ . For instance, if $\varphi = \Box_1\varphi_1 \vee \neg\Box_2\varphi_2$, then the partial assignment $\mu = \{\Box_1\varphi_1\}$ is such that $\mu \models_p \varphi$. In fact, both $\{\Box_1\varphi_1 \Box_2\varphi_2\}$ and $\{\Box_1\varphi_1, \neg\Box_2\varphi_2\}$ propositionally satisfy φ . Henceforth, if not otherwise specified, when dealing with propositional satisfiability we do not distinguish between assignments and partial assignments. Intuitively, if we consider a formula φ as a propositional formula in its top-level atoms, then \models_p is the standard satisfiability in propositional logic. Thus, for every φ_1 and φ_2 , we say that $\varphi_1 \models_p \varphi_2$ if and only if $\mu \models_p \varphi_2$ for every μ s.t. $\mu \models_p \varphi_1$. We say that φ is *propositionally satisfiable* if and only if there exist an assignment μ s.t. $\mu \models_p \varphi$. We also say that $\models_p \varphi$ (φ is *propositionally valid*) if and only if $\mu \models_p \varphi$ for every assignment μ for φ . Thus $\varphi_1 \models_p \varphi_2$ if and only if $\models_p \varphi_1 \rightarrow \varphi_2$, and $\models_p \varphi$ iff $\neg\varphi$ is propositionally unsatisfiable. Notice that \models_p is stronger than \models , that is, if $\varphi_1 \models_p \varphi_2$, then $\varphi_1 \models \varphi_2$, but not vice versa. E.g., $\Box_r\varphi_1 \wedge \Box_r(\varphi_1 \rightarrow \varphi_2) \models \Box_r\varphi_2$, but $\Box_r\varphi_1 \wedge \Box_r(\varphi_1 \rightarrow \varphi_2) \not\models_p \Box_r\varphi_2$.

Example 1. Consider the following K_2 formula φ and its Boolean abstraction $\mathcal{L}2\mathcal{P}(\varphi)$:

$$\begin{aligned} \varphi = & \{ \neg\Box_1(\neg A_3 \vee \neg A_1 \vee A_2) \vee A_1 \vee A_5 \} \\ & \wedge \{ \neg A_2 \vee \neg A_5 \vee \Box_1(\neg A_2 \vee A_4 \vee A_5) \} \\ & \wedge \{ A_1 \vee \Box_2(\neg A_4 \vee A_5 \vee A_2) \vee A_2 \} \\ & \wedge \{ \neg\Box_2(A_4 \vee \neg A_3 \vee A_1) \vee \neg\Box_1(A_4 \vee \neg A_2 \vee A_3) \vee \neg A_5 \} \\ & \wedge \{ \neg A_3 \vee A_1 \vee \Box_2(\neg A_4 \vee A_5 \vee A_2) \} \\ & \wedge \{ \Box_1(\neg A_5 \vee A_4 \vee A_3) \vee \Box_1(\neg A_1 \vee A_4 \vee A_3) \vee \neg A_1 \} \\ & \wedge \{ A_1 \vee \Box_1(\neg A_2 \vee A_1 \vee A_4) \vee A_2 \} \end{aligned}$$

$$\begin{aligned} \mathcal{L}2\mathcal{P}(\varphi) = & \{ \neg B_1 \vee A_1 \vee A_5 \} \\ & \wedge \{ \neg A_2 \vee \neg A_5 \vee B_2 \} \\ & \wedge \{ A_1 \vee B_3 \vee A_2 \} \\ & \wedge \{ \neg B_4 \vee \neg B_5 \vee \neg A_5 \} \\ & \wedge \{ \neg A_3 \vee A_1 \vee B_3 \} \\ & \wedge \{ B_6 \vee B_7 \vee \neg A_1 \} \\ & \wedge \{ A_1 \vee B_8 \vee A_2 \} \end{aligned}$$

The partial assignment $\mu^p = \{B_6, B_8, \neg B_1, \neg B_5, B_3, \neg A_2\}$ satisfies $\mathcal{L}2\mathcal{P}(\varphi)$, so that the following assignment $\mu := \mathcal{P}2\mathcal{L}(\mu^p)$ propositionally satisfies φ :

$$\begin{aligned} \mu = & \Box_1(\neg A_5 \vee A_4 \vee A_3) \wedge \Box_1(\neg A_2 \vee A_1 \vee A_4) \wedge \left[\bigwedge_i \Box_1 \alpha_{1i} \right] \\ & \neg\Box_1(\neg A_3 \vee \neg A_1 \vee A_2) \wedge \neg\Box_1(A_4 \vee \neg A_2 \vee A_3) \wedge \left[\bigwedge_j \neg\Box_1 \beta_{1j} \right] \\ & \Box_2(\neg A_4 \vee A_5 \vee A_2) \wedge \left[\bigwedge_i \Box_2 \alpha_{2i} \right] \\ & \neg A_2. \left[\bigwedge_k A_k \wedge \bigwedge_h \neg A_h \right] \end{aligned}$$

μ gives rise to two restricted assignments μ^1 and μ^2 :

$$\begin{aligned} \mu^1 &= \Box_1(\neg A_5 \vee A_4 \vee A_3) \wedge \Box_1(\neg A_2 \vee A_1 \vee A_4) \wedge [\bigwedge_i \Box_1 \alpha_{1i}] \\ &\quad \neg \Box_1(\neg A_3 \vee \neg A_1 \vee A_2) \wedge \neg \Box_1(A_4 \vee \neg A_2 \vee A_3) \quad [\bigwedge_j \neg \Box_1 \beta_{1j}] \\ \mu^2 &= \Box_2(\neg A_4 \vee A_5 \vee A_2) \quad [\bigwedge_i \Box_2 \alpha_{2i}]. \end{aligned}$$

We say that a collection $\mathcal{M} := \{\mu_1, \dots, \mu_n\}$ of (possibly partial) assignments propositionally satisfying φ is *complete* if and only if, for every total assignment η s.t. $\eta \models_p \varphi$, there exists $\mu_j \in \mathcal{M}$ s.t. $\mu_j \subseteq \eta$. Intuitively, \mathcal{M} can be seen as a compact representation of the whole set of total assignments propositionally satisfying φ .

Proposition 1. [SV98] *Let φ be a formula and let $\mathcal{M} := \{\mu_1, \dots, \mu_n\}$ be a complete collection of truth assignments propositionally satisfying φ . Then, for every \mathcal{L} , φ is \mathcal{L} -satisfiable if and only if μ_j is \mathcal{L} -satisfiable for some $\mu_j \in \mathcal{M}$.*

We also notice the following fact.

Proposition 2. [Seb01] *Let α be a non-Boolean atom occurring only positively [resp. negatively] in φ . Let \mathcal{M} be a complete set of assignments satisfying φ , and let*

$$\mathcal{M}' := \{\mu_j \setminus \{\neg\alpha\} \mid \mu_j \in \mathcal{M}\} \quad [\text{resp. } \{\mu_j \setminus \{\alpha\} \mid \mu_j \in \mathcal{M}\}].$$

Then (i) for every $\mu'_j \in \mathcal{M}'$, $\mu'_j \models_p \varphi$, and (ii) φ is \mathcal{L} -satisfiable if and only if there exist a \mathcal{L} -satisfiable $\mu'_j \in \mathcal{M}'$.

proposition 1 shows that the \mathcal{L} -satisfiability of a formula can be reduced to that of a complete collection of sets of literals (assignment), for every call. Proposition 2 says that, if we have non-Boolean atoms occurring only positively [resp. negatively] in the input formula, we can safely drop every negative [resp. positive] occurrence of them from all assignments in a complete set \mathcal{M} preserving the completeness of \mathcal{M} . In general, \mathcal{L} -satisfiability of a conjunction of literals depends on \mathcal{L} [Fit83, Che80]. The following propositions give a recursive definition for K_m .

Proposition 3. [GS00] *The truth assignment μ of Equation (32.10) is K_m -satisfiable if and only if the restricted truth assignment μ^r of Equation (32.11) is K_m -satisfiable, for all \Box_r 's.³*

Proposition 4. [GS00] *The restricted assignment μ^r of Equation (32.11) is K_m -satisfiable if and only if the formula*

$$\varphi^{rj} = \bigwedge_i \alpha_{ri} \wedge \neg \beta_{rj} \tag{32.12}$$

is K_m -satisfiable, for every $\neg \Box_r \beta_{rj}$ occurring in μ^r .

Notice that propositions 3 and 4 can be merged into one single theorem stating that μ is K_m -satisfiable if and only if φ^{rj} is K_m -satisfiable, for all r and j . Notice furthermore that the depth of every φ^{rj} is strictly smaller than the depth of φ .

³Notice that the component $\bigwedge_{k=1}^R A_k \wedge \bigwedge_{h=R+1}^S \neg A_h$ in (32.10) is consistent because μ is a truth assignment.

Example 2. Consider the formula φ and the assignments μ , μ^1 and μ^2 in Example 1. μ propositionally satisfies φ . Thus, for proposition 1, φ is K_m -satisfiable if μ is K_m -satisfiable. By proposition 3, μ is K_m -satisfiable if and only if both μ^1 and μ^2 are K_m -satisfiable; by proposition 4, μ^2 is trivially K_m -satisfiable, as it contains no negated boxes, and μ^1 is K_m -satisfiable if and only if each of the formulas

$$\begin{aligned}\varphi^{11} &= \bigwedge_i \alpha_{1i} \wedge \neg\beta_{11} = (\neg A_5 \vee A_4 \vee A_3) \wedge (\neg A_2 \vee A_1 \vee A_4) \wedge A_3 \wedge A_1 \wedge \neg A_2, \\ \varphi^{12} &= \bigwedge_i \alpha_{1i} \wedge \neg\beta_{12} = (\neg A_5 \vee A_4 \vee A_3) \wedge (\neg A_2 \vee A_1 \vee A_4) \wedge \neg A_4 \wedge A_2 \wedge \neg A_3\end{aligned}$$

is K_m -satisfiable. As they both are satisfiable propositional formulas, then φ is K_m -satisfiable.

Proposition 1 reduces the \mathcal{L} -satisfiability of a formula φ to the \mathcal{L} -satisfiability of a complete collection of its truth assignments, for every \mathcal{L} . If \mathcal{L} is K_m , propositions 3 and 4 show how to reduce the latter to the K_m -satisfiability of formulas of smaller depth. This process can be applied recursively, decreasing the depth of the formula considered at each iteration. Following these observations, it is possible to test the K_m -satisfiability of a formula φ by implementing a recursive alternation of two basic steps [GS96a, GS96b]:

1. Propositional reasoning: using some procedure for propositional satisfiability, find a truth assignment μ for φ s.t. $\mu \models_p \varphi$;
2. Modal reasoning: check the K_m -satisfiability of μ by generating the corresponding restricted assignments μ_r 's and formulas φ^{rj} 's.

The two steps recurse down until we get to a truth assignment with no modal atoms. At each level, the process is repeated until either a K_m -satisfiable assignment is found (in which case φ is K_m -satisfiable) or no more assignments are found (in which case φ is not K_m -satisfiable).

32.3.2. Modal Tableaux

We call “tableau-based” a system that implements and extends to other logics the Smullyan’s propositional tableau calculus, as defined in [Smu68]. Tableau-based procedures basically consist of a control strategy applied on top of a tableau framework. By tableau framework for modal logics we denote a refutation formal system extending Smullyan’s propositional tableau with rules handling the modal operators (modal rules). Thus, for instance, in our terminology KRIS [BH91, BFH⁺94], CRACK [BFT95] and LWB [HJSS96] are tableau-based systems.

For instance, in the labeled tableau framework for normal modal logics in \mathcal{N} described in [Fit83, Mas94, Mas00], branches are represented as sets of labeled formulas $u : \psi$, where u labels the state in which the formula ψ has to be satisfiable. At the first step the root $1 : \varphi$ is created, φ being the modal formula to be proved (un)satisfiable. At the i -th step, a branch is expanded by applying to a chosen labeled formula the rule corresponding to its main connective, and adding the resulting labeled formula to the branch. The rules are the following: ⁴

⁴Analogous rules handling negated \wedge 's and \vee 's, double negations $\neg\neg$, single and double implications \rightarrow and \leftrightarrow , diamonds \diamond_r , n-ary \wedge 's and \vee 's, and the negation of all them, can

$$\frac{u : (\varphi_1 \wedge \varphi_2)}{u : \varphi_1, u : \varphi_2} (\wedge) \quad \frac{u : (\varphi_1 \vee \varphi_2)}{u : \varphi_1 \quad u : \varphi_2} (\vee), \quad (32.13)$$

$$\frac{u : \neg \Box_r \varphi}{u' : \neg \varphi} (\neg \Box_r) \quad \frac{u : \Box_r \varphi}{u'' : \varphi} (\Box_r). \quad (32.14)$$

The modal rules are constrained by the following applicability conditions:

- $\neg \Box_r$ -rule: u' is a new state (u' is said to be *directly accessible* from u);
- \Box_r -rule: u'' is an existing state which is accessible from u via \mathcal{R}_r .

Distinct logics \mathcal{L} differ for different notions of accessibility in the \Box_r -rule [Fit83, Mas94, Mas00].

Every application of the \vee -rule splits the branch into two sub-branches. A branch is *closed* when a formula ψ and its negation $\neg \psi$ occur in it. The procedure stops when all branches are closed (φ is \mathcal{L} -unsatisfiable) or no more rule is applicable (φ is \mathcal{L} -satisfiable).

For some modal logics it is possible to drop labels by using alternative sets of non-labeled modal rules [Fit83]. For instance in K_m it is possible to use unlabeled formulas and update branches according to the rules

$$\frac{\Gamma, \varphi_1 \wedge \varphi_2}{\Gamma, \varphi_1, \varphi_2} (\wedge) \quad \frac{\Gamma, \varphi_1 \vee \varphi_2}{\Gamma, \varphi_1 \quad \Gamma, \varphi_2} (\vee) \quad (32.15)$$

$$\frac{\mu}{\alpha_1 \wedge \dots \wedge \alpha_m \wedge \neg \beta_j} (\Box_r / \neg \Box_r) \quad (32.16)$$

for each box-index $r \in \{1, \dots, m\}$. Γ is an arbitrary set of formulas, and μ is a set of literals which includes $\neg \Box_r \beta_j$ and whose only positive \Box_r -atoms are $\Box_r \alpha_1, \dots, \Box_r \alpha_m$.

This describes the tableau-based decision procedure of Figure 32.1, which is the restriction to K_m of the basic version of the KRIS procedure described in [BH91]. Tableau-based formalisms for many modal logics are described, e.g., in [Fit83, Mas94]. Tableau-based procedures for many modal logics are described, e.g., in [BH91, BFH⁺94, BFT95, HJSS96].

32.3.3. From Modal Tableaux to Modal DPLL

We call “DPLL-based” any system that implements and extends to other logics the Davis-Putnam-Logemann-Loveland procedure (DPLL) [DP60, DLL62]. DPLL-based procedures basically consist on the combination of a procedure handling purely-propositional component of reasoning, typically a variant of the DPLL algorithm, and some procedure handling the purely-modal component, typically consisting of a control strategy applied on top of a modal tableau rules.

be derived straightforwardly, and are thus omitted here. Following [Fit83], the \wedge -, \vee -, $\neg \Box_r$ - and \Box_r -rules (and those for their equivalent operators) are often called α -, β -, π -, and ν -rules respectively.

```

function  $K_m$ -Tableau( $\Gamma$ )
  if  $\psi_i \in \Gamma$  and  $\neg\psi_i \in \Gamma$  /* branch closed */
    then return False;
  if  $(\varphi_1 \wedge \varphi_2) \in \Gamma$  /*  $\wedge$ -elimination */
    then return  $K_m$ -Tableau( $\Gamma \cup \{\varphi_1, \varphi_2\} \setminus \{(\varphi_1 \wedge \varphi_2)\}$ );
  if  $(\varphi_1 \vee \varphi_2) \in \Gamma$  /*  $\vee$ -elimination */
    then return
       $K_m$ -Tableau( $\Gamma \cup \{\varphi_1\} \setminus \{(\varphi_1 \vee \varphi_2)\}$ ) or
       $K_m$ -Tableau( $\Gamma \cup \{\varphi_2\} \setminus \{(\varphi_1 \vee \varphi_2)\}$ );
  for every  $r \in \{1, \dots, m\}$  do
    for every  $\neg\Box_r\beta_j \in \Gamma$  do /* branch expanded */
      if not  $K_m$ -Tableau( $\{\neg\beta_j\} \cup \bigcup_{\Box_r\alpha_i \in \Gamma} \{\alpha_i\}$ )
        then return False;
  return True;

```

Figure 32.1. An example of a tableau-based procedure for K_m . We omit the steps for the other operators.

Thus, for instance, in our terminology K_{SAT} [GS96a, GS00], FACT [Hor98b, Hor98a], DLP [PS98], RACER [HM01] are DPLL-based systems.⁵

From a purely-logical viewpoint, it is possible to conceive a DPLL-based framework by substituting the propositional tableaux rules with some rules implementing the DPLL algorithms in a tableau-based framework [SV98]. For instance, one can conceive a DPLL-based framework for a normal logic \mathcal{L} from Fitting or Massacci's frameworks (see §32.3.2) by substituting the \vee -rule (32.13) with the following rules:

$$\frac{u : (l \vee C)}{u : l \quad u : \neg l} \text{ (Branch)} \quad \frac{u : l \quad u : (\neg l \vee C)}{u : C} \text{ (Unit)}, \quad (32.17)$$

where l is a and C is a disjunction of literals.⁶ More recent and richer formal frameworks for representing DPLL and DPLL-based procedures are described in [Tin02, NOT06].

As stated in §32.3.2, for some modal logics it is possible to drop labels by using alternative sets of non-labeled modal rules [Fit83]. If so, DPLL-based procedures can be implemented more straightforwardly. For instance, in K_m it is possible to use unlabeled formulas and update branches according to the following rules [SV98]:

$$\frac{\varphi}{\mu_1 \quad \mu_2 \quad \dots \quad \mu_n} \text{ (DPLL)} \quad \frac{\mu}{\alpha_1 \wedge \dots \wedge \alpha_m \wedge \neg\beta_j} \text{ } (\Box_r / \neg\Box_r) \quad (32.18)$$

where the $\Box_r / \neg\Box_r$ -rule is that of (32.16), and $\{\mu_1, \dots, \mu_n\}$ is a *complete* set of assignments for φ , which can be produced by the DPLL algorithm.

⁵See footnote 1 in §32.1.

⁶Here we assume for simplicity that the input formula is in conjunctive normal form (CNF). Equivalent formalisms are available for non-CNF formulas [DM94, Mas98].

```

function KSAT( $\varphi$ )
  return KSATF( $\varphi$ ,  $\top$ );

function KSATF( $\varphi$ ,  $\mu$ )
  if  $\varphi = \top$                                      /* base */
    then return KSATA( $\mu$ );
  if  $\varphi = \perp$                                      /* backtrack */
    then return False;
  if {a unit clause ( $l$ ) occurs in  $\varphi$ }             /* unit */
    then return KSATF(assign( $l$ ,  $\varphi$ ),  $\mu \wedge l$ );
   $l :=$  choose-literal( $\varphi$ );                         /* split */
  return KSATF(assign( $l$ ,  $\varphi$ ),  $\mu \wedge l$ ) or
        KSATF(assign( $\neg l$ ,  $\varphi$ ),  $\mu \wedge \neg l$ );

/*  $\mu$  is  $\bigwedge_i \Box_i \alpha_i \wedge \bigwedge_j \neg \Box_j \beta_j \wedge \dots \wedge \bigwedge_i \Box_m \alpha_{mi} \wedge \bigwedge_j \neg \Box_m \beta_{mj} \wedge \bigwedge_k A_k \wedge \bigwedge_h \neg A_h$  */
function KSATA( $\mu$ )
  for each box index  $r \in \{1\dots m\}$  do
    if not KSATAR( $\bigwedge_i \Box_r \alpha_{ri} \wedge \bigwedge_j \neg \Box_r \beta_{rj}$ )
      then return False;
  return True;

/*  $\mu^r$  is  $\bigwedge_i \Box_r \alpha_{ri} \wedge \bigwedge_j \neg \Box_r \beta_{rj}$  */
function KSATAR( $\mu^r$ )
  for each literal  $\neg \Box_r \beta_{rj} \in \mu$  do
    if not KSAT( $\bigwedge_i \alpha_{ri} \wedge \neg \beta_{rj}$ )
      then return False;
  return True;

```

Figure 32.2. The basic version of KSAT algorithm.

32.3.4. Basic Modal DPLL for K_m

The ideas described in §32.3.3 were implemented in the KSAT procedure [GS96a, GS00], whose basic version is reported in Figure 32.2. This schema evolved from that of the PTAUT procedure in [AG93], and is based on the “classic” DPLL procedure [DP60, DLL62]. KSAT takes in input a modal formula φ and returns a truth value asserting whether φ is K_m -satisfiable or not. KSAT invokes KSAT_F (where “F” stands for “Formula”), passing as arguments φ and (by reference) the empty assignment \top . KSAT_F tries to build a K_m -satisfiable assignment μ propositionally satisfying φ . This is done recursively, according to the following steps:

- (base) If $\varphi = \top$, then μ satisfies φ . Thus, if μ is K_m -satisfiable, then φ is K_m -satisfiable. Therefore KSAT_F invokes KSAT_A(μ) (where “A” stands for Assignment), which returns a truth value asserting whether μ is K_m -satisfiable or not.
- (backtrack) If $\varphi = \perp$, then μ does not satisfy φ , so that KSAT_F returns *False*.
- (unit) If a literal l occurs in φ as a unit clause, then l must be assigned \top .⁷ To obtain this, KSAT_F is invoked recursively with arguments the formula returned by *assign*(l , φ) and the assignment obtained by adding l to μ .

⁷A notion of unit clause for non-CNF propositional formulas is given in [AG93].

$assign(l, \varphi)$ substitutes every occurrence of l in φ with \top and evaluates the result.

- (split) If none of the above situations occurs, then *choose-literal*(φ) returns an unassigned literal l according to some heuristic criterion. Then $KSAT_F$ is first invoked recursively with arguments $assign(l, \varphi)$ and $\mu \wedge l$. If the result is negative, then $KSAT_F$ is invoked with arguments $assign(\neg l, \varphi)$ and $\mu \wedge \neg l$.

$KSAT_F$ is a variant of the “classic” DPLL algorithm [DP60, DLL62]. The $KSAT_F$ schema differs from that of classic DPLL by only two steps.

The first difference is the “base” case: when finding an assignment μ which propositionally satisfies the input formula, it simply returns “True”. $KSAT_F$ instead is supposed also to check the K_m -satisfiability of the corresponding set of literals, by invoking $KSAT_A$ on μ . If the latter returns *true*, then the whole formula is satisfiable and $KSAT_F$ returns *True* as well; otherwise, $KSAT_F$ backtracks and looks for the next assignment.

The second difference is in the fact that in $KSAT_F$ the pure-literal step [DLL62] is removed.⁸ In fact the sets of assignments generated by DPLL with pure-literal might be incomplete and might cause incorrect results, as shown by the following example.

Example 3. Let φ be the following formula:

$$(\Box_1 A_1 \vee A_1) \wedge (\Box_1(A_1 \rightarrow A_2) \vee A_2) \wedge (\neg \Box_1 A_2 \vee A_2) \wedge (\neg A_2 \vee A_3) \wedge (\neg A_2 \vee \neg A_3).$$

φ is K_m -satisfiable, because $\mu = \{A_1, \neg A_2, \Box_1(A_1 \rightarrow A_2), \neg \Box_1 A_2\}$ is an assignment which propositionally satisfies φ and which is also modally consistent. It is easy to see that no satisfiable assignment propositionally satisfying φ assigns $\Box_1 A_1$ to true. As $\Box_1 A_1$ occurs only positively in φ , DPLL with the pure literal rule would assign $\Box_1 A_1$ to true as first step, which would lead the procedure to return *False*.

With these simple modifications, the embedded DPLL procedure works as an enumerator of a complete set of assignments, whose K_m -satisfiability is recursively checked by $KSAT_A$.

$KSAT_A(\mu)$ invokes $KSAT_{AR}(\mu_r)$ (where “ AR ” stands for *Restricted Assignment*) for every box index r . This is repeated until either $KSAT_{AR}$ returns a negative value (in which case $KSAT_A(\mu)$ returns *False*) or no more \Box_r ’s are available (in which case $KSAT_A(\mu)$ returns *True*). $KSAT_{AR}(\mu_r)$ invokes $KSAT(\varphi^{rj})$ for any conjunct $\neg \Box_r \beta_{rj}$ occurring in μ_r . Again, this is repeated until either $KSAT$ returns a negative value (in which case $KSAT_{AR}(\mu_r)$ returns *False*) or no more $\neg \Box_r \beta_{rj}$ ’s are available (in which case $KSAT_{AR}(\mu_r)$ returns *True*). Notice that $KSAT_F$, $KSAT_A$ and $KSAT_{AR}$ are a direct implementation of propositions 1, 3 and 4, respectively. This guarantees their correctness and completeness.

32.3.5. Modal DPLL vs. Modal Tableaux

[GS96a, GS96b, GS00, GGST98, GGST00, HPS99, HPSS00] presented extensive

⁸Alternatively, the application of the pure-literal rule can be restricted to atomic propositions only.

empirical comparisons, in which DPLL-based procedures outperformed tableau-based ones, with performance gaps that can reach orders of magnitude. (Similar performance gaps between tableau-based vs. DPLL-based procedures were obtained lately also in a completely-different context [ACG00].) Remarkably, most such results were obtained with tools implementing the “classic” DPLL procedure of §32.3.4, very far from the efficiency of current DPLL implementations.

We concentrate on the basic tableau-based and DPLL-based algorithms for K_m -satisfiability described in §32.3.2 and §32.3.4. Both procedures work (i) by enumerating truth assignments which propositionally satisfy the input formula φ and (ii) by recursively checking the K_m -satisfiability of the assignments found. Both algorithms perform the latter step in the same way. The key difference is thus in the way they handle propositional inference. [GS96b, GS00] remarked that, regardless the quality of implementation and the optimizations performed, tableau-based procedures have, with respect to DPLL-based procedures, two weaknesses which make them intrinsically less efficient, and whose effects get up to exponentially amplified when using them in modal inference. We consider them in turn.

Syntactic vs. semantic branching. In a propositional tableau truth assignments are generated as branches induced by the application of the \vee -rule to *disjunctive subformulas* of the input formula φ . Thus, they perform what we call *syntactic branching* [GS96b], that is, the branching in the search tree is induced by the syntactic structure of φ . As discussed in [D’A92, DM94], an application of the \vee -rule generates two subtrees which can be *mutually consistent*, i.e., which may share propositional models.⁹ Therefore, the set of truth assignments enumerated by propositional tableau procedures grows exponentially with the number of disjunctions occurring positively in φ , regardless the fact that it may contain up to exponentially-many duplicated and/or subsumed assignments.

Things get even worse in the modal case. When testing K_m -satisfiability, unlike the propositional case where tableaux look for *one* assignment satisfying the input formula, the propositional tableaux are used to enumerate *all* the truth assignments, which must be recursively checked for K_m -consistency. This requires checking recursively possibly-many sub-formulas of the form $\bigwedge_i \alpha_{ri} \wedge \neg\beta_j$ of depth $d - 1$, for which a propositional tableau will enumerate all truth assignments, and so on. At all levels of nesting, a redundant truth assignment introduces a redundant modal search tree. Thus, with modal formulas the redundancy of the propositional case propagates with the modal depth, and, in the worst case, the number of redundant truth assignments can become exponential.

DPLL instead, performs a search which is based on what we call *semantic branching* [GS96b], that is, a branching on the *truth value* of sub-formulas ψ of φ

⁹As pointed out in [D’A92, DM94], the propositional tableaux rules are unable to represent *bivalence*: “every proposition is either true or false, *tertium non datur*”. This is a consequence of the elimination of the cut rule in cut-free sequent calculi, from which propositional tableaux are derived.

Figure 32.3. Search trees for the formula $\Gamma = (\alpha \vee \neg\beta) \wedge (\alpha \vee \beta) \wedge (\neg\alpha \vee \neg\beta)$. Left: a tableau-based procedure. Right: a DPLL-based procedure.

(typically atoms): ¹⁰

$$\frac{\varphi}{\varphi[\psi/\top] \quad \varphi[\psi/\perp]},$$

where $\varphi[\psi/\top]$ is the result of substituting with \top all occurrences of ψ in φ and then simplify the result. Thus, every branching step generates two *mutually-inconsistent* subtrees. ¹¹ Because of this, DPLL always generates non-redundant sets of assignments. This avoids any search duplication and, in the case of modal search, any recursive exponential propagation of such a redundancy.

Example 4. Consider the simple formula $\Gamma = (\alpha \vee \neg\beta) \wedge (\alpha \vee \beta) \wedge (\neg\alpha \vee \neg\beta)$, where α and β are modal atoms s.t. $\alpha \wedge \neg\beta$ is not modally consistent. and let d be the depth of Γ . The only possible assignment propositionally satisfying Γ is $\mu = \alpha \wedge \neg\beta$. Look at Figure 32.3 left. Assume that in a tableau-based procedure, the \vee -rule is applied to the three clauses occurring in Γ in the order they are listed. Then two distinct but identical open branches are generated, both representing the assignment μ . Then the tableau expands the two open branches in the same way, until it generates two identical (and possibly big) closed modal sub-trees T of modal depth d , each proving the K_m -unsatisfiability of μ .

This phenomenon may repeat itself at the lower level in each sub-tree T , and so on. For instance, if $\alpha = \Box_1((\alpha' \vee \neg\beta') \wedge (\alpha' \vee \beta'))$ and $\beta = \Box_1(\alpha' \wedge \beta')$, then at the lower level we have a formula Γ' of depth $d - 1$ analogous to Γ . This propagates exponentially the redundancy with the depth d .

Finally, notice that if we considered the formula $\Gamma^K = \bigwedge_{i=1}^K (\alpha_i \vee \neg\beta_i) \wedge (\alpha_i \vee \beta_i) \wedge (\neg\alpha_i \vee \neg\beta_i)$, the tableau would generate 2^K identical truth assignments $\mu^K = \bigwedge_i \alpha_i \wedge \neg\beta_i$, and things would get exponentially worse.

Look at Figure 32.3, right. A DPLL-based procedure branches asserting $\alpha = \top$ or $\alpha = \perp$. The first branch generates $\alpha \wedge \neg\beta$, while the second gives $\neg\alpha \wedge \neg\beta \wedge \beta$, which immediately closes. Therefore, only one instance of $\mu = \alpha \wedge \neg\beta$ is generated. The same applies to μ^K .

¹⁰Notice that the notion of “semantic branching” introduced in [GS96b] is stronger than that lately used in [Hor98b, HPS99], the former corresponding to the latter plus the usage of unit-propagation.

¹¹This fact holds for both “classic” [DP60, DLL62] and “modern” DPLL (see, e.g., [ZM02]), because in both cases two branches differ for the truth value of at least one atom, although for the latter case the explanation is slightly more complicate.

Figure 32.4. Search trees for the formula $\Gamma = (\alpha \vee \phi_1) \wedge (\beta \vee \phi_2) \wedge \phi_3 \wedge (\neg\alpha \vee \neg\beta)$. Left: a tableau-based procedure. Right: a DPLL-based procedure.

Detecting constraint violations. A propositional formula φ can be seen as a set of constraints for the truth assignments which possibly satisfy it. For instance, a clause $A_1 \vee A_2$ constrains every assignment not to set both A_1 and A_2 to \perp . Unlike tableaux, DPLL prunes a branch as soon as it violates some constraint of the input formula. (For instance, in KSAT this is done by the function *assign*.)

Example 5. Consider the formula $\Gamma = (\alpha \vee \phi_1) \wedge (\beta \vee \phi_2) \wedge \phi_3 \wedge (\neg\alpha \vee \neg\beta)$, α and β being atoms, ϕ_1 , ϕ_2 and ϕ_3 being sub-formulas, such that $\alpha \wedge \beta \wedge \phi_3$ is propositionally satisfiable and $\alpha \wedge \phi_2$ is K_m -unsatisfiable. Look at Figure 32.4, left. Again, assume that, in a tableau-based procedure, the \vee -rule is applied in order, left to right. After two steps, the branch α, β is generated, which violates the constraint imposed by the last clause $(\neg\alpha \vee \neg\beta)$. A tableau-based procedure is not able to detect such a violation until it explicitly branches on that clause, that is, only after having generated the whole sub-tableau T_3 for $\alpha \wedge \beta \wedge \phi_3$, which may be rather big. DPLL instead (Figure 32.4, right) avoids generating the violating assignment detects the violation and immediately prunes the branch.

32.4. Advanced Modal DPLL

In this section we present the most important optimizations of the DPLL-based procedures described in §32.3, and one extension to non-normal modal logics.

32.4.1. Optimizations

As described in §32.3.4, the first DPLL-based tools of [GS96a, GS96b, SV98, GS00] were based on the “classic” recursive DPLL schema [DP60, DLL62]. Drastic improvements in performances were lately obtained by importing ideas and techniques from the SAT literature and/or by directly implementing tools on top of modern DPLL solvers, which are applied to the Boolean abstraction of the input formula [GGST98, GGST00, HPS99, Tac99, GGT01, HM01].

In particular, modern DPLL implementation are non-recursive, and are based on very efficient, destructive data structures to handle Boolean formulas and assignments. They benefit of sophisticated search techniques (e.g., backjumping, learning, restarts [MSS96, BS97, GSK98]), smart splitting heuristics (e.g.,

[MMZ⁺01, GN02, ES04]), highly-engineered data structures and implementation tricks (e.g., the two-watched literal scheme [MMZ⁺01]), and advanced preprocessing techniques [Bra01, BW03, EB05]. In particular, modern DPLL implementations perform *conflict analysis* on failed assignments μ 's, which detect the *reason* of each failure, that is, a (typically much smaller) subset μ' of μ which alone causes the failure. When this happens, the procedure

- adds the negation of μ' as a new clause to the formula, so that no assignment containing μ' will be ever investigated again. This technique is called *learning*;
- backtracks to the highest point in the stack where one literal l in the learned clause $\neg\mu'$ is not assigned, it unit propagates l , and it proceeds with the search. This technique is called *backjumping*.

Backjumping and learning are of great interest in our discussion, as it will be made clear in §32.4.1.4. The other DPLL optimizations come for free by using state-of-the-art SAT solvers and they are substantially orthogonal to our discussion, so that they will not be discussed here.

We describe some further optimizations which have been proposed to the basic schema of §32.3.4. For better readability, the description will refer to the case of K_m , but they can be extended to other logics. Most of these techniques and optimizations have lately been adopted by the so-called lazy tools for Satisfiability Modulo Theories, SMT (see §26.4.3).

32.4.1.1. Normalizing atoms

One potential source of inefficiency for DPLL-based procedures is the occurrence in the input formula of equivalent though syntactically-different atoms (e.g., $\Box_r(A_1 \vee A_2)$ and $\Box_r(A_2 \vee A_1)$), or pairs atoms in which one is equivalent to the negation of the other (e.g. $\Box_r(A_1 \vee A_2)$ and $\Diamond_r(\neg A_1 \wedge \neg A_2)$). If two atoms ψ_1, ψ_2 are s.t. $\psi_1 \neq \psi_2$ and $\models \psi_1 \leftrightarrow \psi_2$ [resp. $\psi_1 \neq \neg\psi_2$ and $\models \psi_1 \leftrightarrow \neg\psi_2$], then they are recognized as distinct Boolean atoms $B_1 =_{def} \mathcal{L}2\mathcal{P}(\psi_1)$ and $B_2 =_{def} \mathcal{L}2\mathcal{P}(\psi_2)$, which may be assigned different [resp. identical] truth values by DPLL. This may cause the useless generation of many unsatisfiable assignments and the corresponding useless calls to KSAT_A (e.g., up to $2^{|Atoms^0(\varphi)|-2}$ calls on assignments like $\{\Box_r(A_1 \vee A_2), \neg\Box_r(A_2 \vee A_1)\dots\}$).

In order to avoid these problems, it is wise to preprocess atoms so that to map as many as possible equivalent literals into syntactically identical ones [GS96a, GS00, HPS99]. This can be achieved by applying some rewriting rules, like, e.g.:

- *Drop dual operators:* $\Box_r(\varphi_1 \vee \varphi_2), \Diamond_r(\neg\varphi_1 \wedge \neg\varphi_2) \implies \Box_r(\varphi_1 \vee \varphi_2), \neg\Box_r(\varphi_1 \vee \varphi_2)$, or even $(\varphi_1 \wedge \varphi_2), (\neg\varphi_1 \vee \neg\varphi_2) \implies (\varphi_1 \wedge \varphi_2), \neg(\varphi_1 \wedge \varphi_2)$
- *Exploit associativity:* $\Box_r(\varphi_1 \vee (\varphi_2 \vee \varphi_3)), \Box_r((\varphi_1 \vee \varphi_2) \vee \varphi_3) \implies \Box_r(\varphi_1 \vee \varphi_2 \vee \varphi_3)$,
- *Sort:* $\Box_r(\varphi_2 \vee \varphi_1 \vee \varphi_3), \Box_r(\varphi_3 \vee \varphi_1 \vee \varphi_2) \implies \Box_r(\varphi_1 \vee \varphi_2 \vee \varphi_3)$.
- *Exploit properties of normal modal logics:* $\Box_r(\varphi_1 \wedge \varphi_2) \implies \Box_r\varphi_1 \wedge \Box_r\varphi_2$ if $\mathcal{L} \in \mathcal{N}$.
- *Exploit specific properties of some logic \mathcal{L} :* $\Box_r\Box_r\varphi_1 \implies \Box_r\varphi_1$ if \mathcal{L} is S5.

Notice that pre-conversion to BNF (§32.2.1) goes in this direction.

Example 6. Consider the modal atoms occurring in the formula φ in Example 1. For every modal atom in φ there are $3! = 6$ equivalent permutations, which are all mapped into one atom if the modal atoms are sorted. E.g., if we consider an equivalent formula φ' in which the second occurrence of the atom $\Box_2(\neg A_4 \vee A_5 \vee A_2)$, occurring in rows 3 and 5, is rewritten as $\Box_2(A_5 \vee \neg A_4 \vee A_2)$, then the latter will be encoded by $\mathcal{L2P}$ into a different Boolean variable, namely B_9 , which could be assigned by DPLL a different truth value wrt. B_3 , generating an modally inconsistent assignment μ' . If all atoms in φ' are pre-sorted, then the problem does not occur.

32.4.1.2. Early Pruning

Another optimization [GS96a, GS00, Tac99] was conceived after the empirical observation that most assignments found by DPLL are “trivially” K_m -unsatisfiable, that is, they will remain K_m -unsatisfiable even after removing some of their conjuncts. If an incomplete ¹² assignment μ' is K_m -unsatisfiable, then all its extensions are K_m -unsatisfiable. If the unsatisfiability of μ' is detected on time, then this prevents checking the K_m -satisfiability of all the up to $2^{|Atoms^0(\varphi)| - |\mu'|}$ truth assignments which extend μ' .

This suggests the introduction of an intermediate K_m -satisfiability test on incomplete assignments just before the split. (Notice there is no need to introduce similar tests before unit propagation.) In the basic algorithm of Figure 32.2, this is done by introducing the three lines below in the function KSAT_F of Figure 32.2, just before the “split”:

```

if (Likely-Unsatisfiable( $\mu$ )           /* early-pruning */
    if not  $\text{KSAT}_A(\mu)$ 
    then return False;
```

(We temporarily ignore the test performed by *Likely-Unsatisfiable*.) KSAT_A is invoked on the current incomplete assignment μ . If $\text{KSAT}_A(\mu)$ returns *False*, then all possible extensions of μ are unsatisfiable, and therefore KSAT_F returns *False*. The introduction of this intermediate check, which is called *early pruning*, caused a drastic improvement in the overall performances [GS96a, GS00].

Example 7. Consider the formula φ of Example 1. Suppose that, after three recursive calls, KSAT_F builds the incomplete assignment:

$$\mu' = \Box_1(\neg A_1 \vee A_4 \vee A_3) \wedge \Box_1(\neg A_2 \vee A_1 \vee A_4) \wedge \neg \Box_1(A_4 \vee \neg A_2 \vee A_3)$$

(rows 6, 7 and 4 of φ). If it is invoked on μ' , KSAT_A will check the K_2 -satisfiability of the formula

$$(\neg A_1 \vee A_4 \vee A_3) \wedge (\neg A_2 \vee A_1 \vee A_4) \wedge \neg A_4 \wedge A_2 \wedge \neg A_3,$$

which is unsatisfiable. Therefore there will be no more need to select further literals, and KSAT_F will backtrack.

¹²By *incomplete* assignment μ for φ we mean that μ has not assigned enough atoms to determine whether $\mu \models \varphi$ or not.

The intermediate consistency checks, however, may introduce some useless calls to KSAT_A .

One way of addressing this problem is to condition the calls to KSAT_A in early-pruning steps to some heuristic criteria (here represented by the heuristic function *Likely-Unsatisfiable*). The main idea is to avoid invoking KSAT_A when it is very unlikely that, since the last call, the new literals added to μ can cause inconsistency: e.g., when they are added only literals which are purely-propositional or contain new Boolean atoms [GS96a, GS00].

Another way is to make KSAT_A work in an *incremental* way: if for some box index $r \in \{1 \dots m\}$ no literal of the form $\Box_r \psi$ or $\neg \Box_r \psi$ has been added to μ since the last call to KSAT_A , then KSAT_A can avoid performing the corresponding call to KSAT_{AR} ; moreover, if for some box index $r \in \{1 \dots m\}$ no positive $\Box_r \psi$'s have been added to μ since the last call to KSAT_A , then KSAT_{AR} can avoid calling recursively KSAT on the subformulas $(\bigwedge_i \alpha_{ri} \wedge \neg \beta_{rj})$ s.t. $\neg \Box_r \beta_{rj}$ was already passed to KSAT_A in the last call [Tac99].

32.4.1.3. Caching

This section is an overview of [GT01] to which we refer for further reading. Consider the basic version of KSAT algorithm in Figure 32.2. Without loss of generality, in the remainder of this section we assume that $|\mathcal{B}| = 1$, so that the call to KSAT_A is the same as KSAT_{AR} . The extension to the case where $|\mathcal{B}| > 1$ is straightforward since it simply requires checking the different modalities in separate calls to KSAT_{AR} . Given two assignments μ and μ' , it may be the case that $\text{KSAT}_A(\mu)$ and $\text{KSAT}_A(\mu')$ perform some equal substests, i.e., recursive calls to KSAT . This is the case, e.g., when μ and μ' differ only for the propositional conjuncts and there is at least one conjunct of the form $\neg \Box \beta$. To prevent recomputation, the obvious solution is to cache both the formula whose satisfiability is being checked and the result of the check. Then, the cache is consulted before performing each subtest to determine whether the result of the subtest can be assessed on the basis of the cache contents.

In the following, we assume to have two different caching mechanisms, each using a separate caching structure:

- S-cache to store and query about satisfiable formulas, and
- U-cache to store and query about unsatisfiable formulas.

In this way, storing a subtest amounts to storing the formula in the appropriate caching structure. Of course, the issue is how to implement effective caching mechanisms allowing to reduce the number of substests as much as possible. To this extent, the following considerations are in order:

1. if a formula $\bigwedge_{\alpha \in \Delta} \alpha \wedge \neg \beta$ has already been determined to be satisfiable then, if $\Delta \subseteq \Delta'$, we can conclude that also $\bigwedge_{\alpha \in \Delta} \alpha \wedge \neg \beta$ is satisfiable, and
2. if a formula $\bigwedge_{\alpha \in \Delta} \alpha \wedge \neg \beta$ has already been determined to be unsatisfiable then, if $\Delta \supseteq \Delta'$, we can conclude that also $\bigwedge_{\alpha \in \Delta} \alpha \wedge \neg \beta$ is unsatisfiable.

The above observations suggest the usage of caching mechanisms that allow for storing sets of formulas and for efficiently querying about subsets or supersets.

```

function KSATA(μ)
  Δ := {α | □α is a conjunct of μ};
  Γ := {β | ¬□β is a conjunct of μ};
  if U-cache.get(Δ, Γ) return False;
  Γr := S-cache.get(Δ, Γ);
  Γs := ∅;
  foreach β ∈ Γr do
    if not KSAT(∧α∈Δ α ∧ ¬β) then
      if Γs ≠ ∅ then S-cache.store(Δ, Γs);
      U-cache.store(Δ, β);
      return False
    else Γs := Γs ∪ {β};
  S-cache.store(Δ, Γs);
  return True.

```

Figure 32.5. KSAT_A: satisfiability checking for K with caching

In other words, given a subtest

$$\text{KSAT}\left(\bigwedge_{\alpha \in \Delta} \alpha \wedge \neg\beta\right), \quad (32.19)$$

we want to be able to query our S-cache about the presence of a formula

$$\bigwedge_{\alpha \in \Delta'} \alpha \wedge \neg\beta \quad (32.20)$$

with $\Delta \subseteq \Delta'$ (query for subsets or *subset-matching*). Analogously, given the subtest (32.19), we want to be able to query our U-cache about the presence of a formula (32.20) with $\Delta \supseteq \Delta'$ (query for supersets or *superset-matching*). In this way, caching a subtest avoids the recomputation of the very same subtest, *and* of the possibly many “subsumed” subtests.

Observations 1 and 2 are independent of the particular modal logic being considered. They are to be taken into account when designing caching structures for satisfiability in any modal logic. Of course, depending on the particular modal logic considered, some other considerations might be in order. For example, in K, we observe that in KSAT_A there is a natural unbalance between satisfiable subtests and unsatisfiable ones. In fact, with reference to Figure 32.2, when testing an assignment μ

3. many subtests can be determined to be satisfiable, all sharing the same set Δ , and
4. at most one subtest may turn out to be unsatisfiable.

Observation 3 suggests that S-cache should be able to store satisfiable subtests sharing a common set Δ in a compact way. Therefore, S-cache associates the set Δ to the set $\Gamma' \subseteq \Gamma$, representing the “computed” satisfiable subtests $\bigwedge_{\alpha \in \Delta} \alpha \wedge \neg\beta$ for each $\beta \in \Gamma'$. Observation 4 suggests that U-cache should not care about subtests sharing a common Δ . Therefore, U-cache associates Δ to the single β for which the subtest $\bigwedge_{\alpha \in \Delta} \alpha \wedge \neg\beta$ failed.

Given the design issues outlined above, we can modify KSAT to yield the procedure KSAT_A shown in Figure 32.5. In the Figure:

- $\text{U-cache.get}(\Delta, \Gamma)$ returns *True* if U-cache contains a set Δ' such that $\Delta \supseteq \Delta'$, Δ' is associated with β and $\beta \in \Gamma$;
- $\text{S-cache.get}(\Delta, \Gamma)$ returns the set $\Gamma \setminus \Gamma'$ where Γ' is the union over all the sets Γ'' such that for some set $\Delta' \supseteq \Delta$, Γ'' is associated to Δ' in S-cache.
- $\text{U-cache.store}(\Delta, \beta)$ stores in U-cache the set Δ and associates β to it;
- $\text{S-cache.store}(\Delta, \Gamma)$ stores in S-cache the set Δ and associates to it the set Γ .

The new issue is now to implement effective data structures for S-cache and U-cache supporting the above functions. Clearly, we expect that the computational costs associated to the above functions will be superior to the computational costs associated to other caching structures designed for “equality-matching”, i.e., effectively supporting the functions obtained from the above by substituting “ \supseteq ” with “ $=$ ”. There is indeed a trade-off between “smart but expensive” and “simple but efficient” data-structures for caching. Of course, depending on

- the particular logic being considered, and
- the characteristics of the particular formula being tested,

we expect that one caching mechanism will lead to a faster decision process than the others.

Independently from the data-structure being used, the following (last) observation needs to be taken into account when dealing with modal logics whose decision problem is not in NP (e.g., K, S4):

5. testing the consistency of a formula may require an exponential number of substests.

This is the case for the Halpern and Moses formulas presented in [HM85] for various modal logics. Observation 5 suggests that it may be necessary to bound the size of the cache, and introduce mechanisms for deciding which formulas to discard when the bound is reached. Further discussion about the implementation of caching and low-level optimizations can be found in [GT01].

32.4.1.4. Modal Backjumping

Another very important optimization, called *modal backjumping* [Hor98a, PS98], generalizes the idea of backjumping in DPLL. KSAT_A can be easily modified so that, when invoked on a K_m -unsatisfiable set of modal literals μ , it returns also the subset μ' of μ which caused the inconsistency of μ . We call μ' , a *modal conflict set* of μ .

An easy way of computing μ' is that of returning the set $\mathcal{L2P}(\{\Box_r \alpha_{ri}\}_i \cup \{\neg \Box_r \beta_{rj}\})$ corresponding to the first formula $\varphi^{rj} = \bigwedge_i \alpha_{ri} \wedge \neg \beta_{rj}$ which is found unsatisfiable by KSAT.

Example 8. Consider the formula φ of Example 1. The assignment $\mu^P = \{B_6, B_8, B_2, \neg B_1, \neg B_5, B_3\}$ is found by KSAT_F , which satisfies $\mathcal{L2P}(\varphi)$. Thus

KSAT_A is given as input

$$\begin{aligned} \mu = & \quad \Box_1(\neg A_5 \vee A_4 \vee A_3) \wedge & & [\bigwedge_i \Box_1 \alpha_{1i}] \\ & \Box_1(\neg A_2 \vee A_1 \vee A_4) \wedge \Box_1(\neg A_2 \vee A_4 \vee A_5) \wedge & & [\bigwedge_j \neg \Box_1 \beta_{1j}] \\ & \neg \Box_1(\neg A_3 \vee \neg A_1 \vee A_2) \wedge \neg \Box_1(A_4 \vee \neg A_2 \vee A_3) \wedge & & \\ & \Box_2(\neg A_4 \vee A_5 \vee A_2) & & [\bigwedge_i \Box_2 \alpha_{2i}] \end{aligned}$$

and hence invokes KSAT_{AR} on the two restricted assignments:

$$\begin{aligned} \mu^1 = & \quad \Box_1(\neg A_5 \vee A_4 \vee A_3) \wedge & & [\bigwedge_i \Box_1 \alpha_{1i}] \\ & \Box_1(\neg A_2 \vee A_1 \vee A_4) \wedge \Box_1(\neg A_2 \vee A_4 \vee A_5) \wedge & & [\bigwedge_j \neg \Box_1 \beta_{1j}] \\ & \neg \Box_1(\neg A_3 \vee \neg A_1 \vee A_2) \wedge \neg \Box_1(A_4 \vee \neg A_2 \vee A_3) & & \\ \mu^2 = & \quad \Box_2(\neg A_4 \vee A_5 \vee A_2) & & [\bigwedge_i \Box_2 \alpha_{2i}]. \end{aligned}$$

μ^2 is trivially K_m -satisfiable. μ^1 requires invoking KSAT on the two formulas

$$\begin{aligned} \varphi^{11} = & (\neg A_5 \vee A_4 \vee A_3) \wedge (\neg A_2 \vee A_1 \vee A_4) \wedge \\ & (\neg A_2 \vee A_4 \vee A_5) \wedge A_3 \wedge A_1 \wedge \neg A_2, \\ \varphi^{12} = & (\neg A_5 \vee A_4 \vee A_3) \wedge (\neg A_2 \vee A_1 \vee A_4) \wedge \\ & (\neg A_2 \vee A_4 \vee A_5) \wedge \neg A_4 \wedge A_2 \wedge \neg A_3. \end{aligned}$$

The latter is unsatisfiable, from which we can conclude that

$$\Box_1(\neg A_5 \vee A_4 \vee A_3) \wedge \Box_1(\neg A_2 \vee A_1 \vee A_4) \wedge \Box_1(\neg A_2 \vee A_4 \vee A_5) \wedge \neg \Box_1(A_4 \vee \neg A_2 \vee A_3)$$

is K_m -unsatisfiable, so that $\{B_6, B_8, B_2, \neg B_5\}$ is a conflict set of μ^p .

The conflict set μ' found is then used to drive the backjumping mechanism of DPLL. Different strategies are possible. The DPLL-based modal tools [Hor98a, PS98] and earlier SMT tools [WW99] used to jump up to the most recent branching point s.t. at least one literal $l^p \in \mu'$ is not assigned. Intuitively, all open subbranches departing from the current branch at a lower decision point contain μ' , so that there is no need to explore them; this allows for pruning all these subbranches from the search tree. (Notice that these strategies do not explicitly require adding the clause $\neg \mu'$ to φ .) More sophisticated versions of this technique, which mirror the most-modern backjumping techniques introduced in DPLL, were lately introduced in the context of SMT (see §26.4.3.5).

In substance, modal backjumping differs from standard Boolean backjumping only for the notion of conflict set used: whilst a Boolean conflict set μ is an assignment which causes a propositional inconsistency if conjoined to φ (i.e. s.t. $\mu \wedge \varphi \models_p \perp$), a modal conflict set is a set of literals which in K_m -inconsistent (i.e. s.t. $\mu \models \perp$).

32.4.1.5. Pure-literal filtering

This technique, which we call *pure-literal filtering*,¹³ was implicitly proposed by [WW99] and then generalized and adopted in the *SAT tool [Tac99] (and lately imported into SMT [ABC⁺02], see §26.4.3.7). The idea is that, if we have non-Boolean atoms occurring only positively [resp. negatively] in the input formula,

¹³Also called *triggering* in [WW99, ABC⁺02].

we can safely drop every negative [resp. positive] occurrence of them from the assignment μ to be checked by KSAT_A . (The correctness and completeness of this process is a consequence of proposition 2 in §32.3.1.)

There are some benefits for this behavior. Let μ' be the reduced version of μ .

First, μ' might be K_m -satisfiable despite μ is K_m -unsatisfiable. If so, and if μ (and hence μ') propositionally satisfies φ , then KSAT_F can stop, potentially saving a lot of search.

Second, if both μ' and μ are K_m -unsatisfiable, the call to KSAT_A on μ' rather than that on μ can cause smaller conflict sets, in order to improve the effectiveness of backjumping and learning.

Third, checking the K_m -satisfiability of μ' rather than that of μ can be significantly faster. In fact, suppose $\Box_r\beta_{rj}$ occurs only positively in φ and it is assigned a negative value by KSAT_F , so that $\neg\Box_r\beta_{rj} \in \mu$ but $\neg\Box_r\beta_{rj} \notin \mu'$. Thus $\neg\Box_r\beta_{rj}$ will not occur in the restricted assignment μ' fed to KSAT_{AR} , avoiding the call to KSAT on $(\bigwedge_i \alpha_{ri} \wedge \neg\beta_{rj})$. This allows for extending the notion of “incrementality” of §32.4.1.2, by considering only the literals in μ' rather than those in μ .

32.4.2. Extensions to Non-Normal Modal Logics

This section briefly surveys some of the contents of [GGT01] to which we refer for further reading. Following the notation of [GGT01], we say that an assignment μ satisfies a formula φ if μ entails φ by propositional reasoning, and that a formula φ is *consistent* in a logic L (or *L-consistent*) if $\neg\varphi$ is not a theorem of L, i.e., if $\neg\varphi \notin L$. Whether an assignment is consistent, depends on the particular classical modal logic L being considered. Furthermore, depending on the logic L considered, the consistency problem for L (i.e., determining whether a formula is consistent in L) belongs to different complexity classes. In particular, the consistency problem for E, EM, EN, EMN is NP-complete, while for EC, ECN, EMC it is PSPACE-complete (see [Var89, FHMV95]). Here, to save space, we divide these eight logics in two groups. We present the algorithms for checking the L-consistency of an assignment first in the case in which L is one of E, EM, EN, EMN, and then in the case in which L is one of the others.

32.4.2.1. Logics E, EM, EN, EMN

The following proposition is an easy consequence of the results presented in [Var89].

Proposition 5. *Let $\mu = \bigwedge_i \Box\alpha_i \wedge \bigwedge_j \neg\Box\beta_j \wedge \gamma$ be an assignment in which γ is a propositional formula. Let L be one of the logics E, EM, EN, EMN. μ is consistent in L if for each conjunct $\neg\Box\beta_j$ in μ one of the following conditions is satisfied:*

- $(\alpha_i \equiv \neg\beta_j)$ is L-consistent for each conjunct $\Box\alpha_i$ in μ , and $L=E$;
- $(\alpha_i \wedge \neg\beta_j)$ is L-consistent for each conjunct $\Box\alpha_i$ in μ , and $L=EM$;
- $\neg\beta_j$ and $(\alpha_i \equiv \neg\beta_j)$ are L-consistent for each conjunct $\Box\alpha_i$ in μ , and $L=EN$;
- $\neg\beta_j$ and $(\alpha_i \wedge \neg\beta_j)$ are L-consistent for each conjunct $\Box\alpha_i$ in μ , and $L=EMN$.

```

function LSATA(μ)
  foreach conjunct □βj do
    foreach conjunct □αi do
      if M[i, j] = Undef then M[i, j] := LSAT(αi ∧ ¬βj);
      if L ∈ {EN, EMN} and M[i, j] = True then M[j, j] := True;
      if L ∈ {E, EN} and M[i, j] = False then
        if M[j, i] = Undef then M[j, i] := LSAT(¬αi ∧ βj);
        if L = EN and M[j, i] = True then M[i, i] := True;
        if M[j, i] = False then return False
      end
    if L ∈ {EN, EMN} then
      if M[j, j] = Undef then M[j, j] := LSAT(¬βj);
      if M[j, j] = False then return False
    end;
  return True.

```

Figure 32.6. LSAT_A for E, EM, EN, EMN

When implementing the above conditions, care must be taken in order to avoid repetitions of consistency checks. In fact, while an exponential number of assignments satisfying the input formula can be generated, at most n^2 checks are possible in L, where n is the number of “□” in the input formula. Given this upper bound, for each new consistency check, we can cache the result for a future possible re-utilization in a $n \times n$ matrix M. This ensures that at most n^2 consistency checks will be performed. In more detail, given an enumeration $\varphi_1, \varphi_2, \dots, \varphi_n$ of the boxed subformulas of the input formula, $M[i, j]$, with $i \neq j$, stores the result of the consistency check for $(\varphi_i \wedge \neg\varphi_j)$. $M[i, i]$ stores the result of the consistency check for $\neg\varphi_i$. Initially, each element of the matrix M has value *Undef* (meaning that the corresponding test has not been done yet). The result is the procedure LSAT_A in Figure 32.6, where the procedure LSAT is identical to the procedure KSAT modulo the call to KSAT_A which must be replaced by LSAT_A.

Consider Figure 32.6 and assume that L=E or L=EN. Given a pair of conjuncts □α_i and ¬□β_j, we split the consistency test for $(\alpha_i \equiv \neg\beta_j)$ in two simpler sub-tests:

- first, we test whether $(\alpha_i \wedge \neg\beta_j)$ is consistent, and
- only if this test gives *False*, we test whether $(\neg\alpha_i \wedge \beta_j)$ is consistent.

Notice also that, in case L=EN or L=EMN, if we know that, e.g., $(\alpha_i \wedge \neg\beta_j)$ is consistent, then also $\neg\beta_j$ is consistent and we store this result in $M[j, j]$. The following proposition ensures the correctness of LSAT in the case of E, EM, EN and EMN.

Proposition 6. *Let $\mu = \bigwedge_i \square\alpha_i \wedge \bigwedge_j \neg\square\beta_j \wedge \gamma$ be an assignment in which γ is a propositional formula. Let L be one of the logics E, EM, EN, EMN. Assume that, for any formula φ whose depth is less than the depth of μ , LSAT(φ)*

- *returns True if φ is L-consistent, and*
- *False otherwise.*

```

function LSATA( $\bigwedge_i \Box \alpha_i \wedge \bigwedge_j \neg \Box \beta_j \wedge \gamma$ )
 $\Delta := \{\alpha_i \mid \Box \alpha_i \text{ is a conjunct of } \mu\};$ 
foreach conjunct  $\Box \beta_j$  do
   $\Delta' := \Delta;$ 
  if  $L \in \{EC, ECN\}$  then
    foreach conjunct  $\Box \alpha_i$  do
      if  $M[j, i] = \text{Undef}$  then  $M[j, i] := \text{LSAT}(\neg \alpha_i \wedge \beta_j);$ 
      if  $M[j, i] = \text{True}$  then  $\Delta' = \Delta' \setminus \{\alpha_i\}$ 
    end;
  if  $L \in \{ECN\}$  or  $\Delta' \neq \emptyset$  then
    if not  $\text{LSAT}(\bigwedge_{\alpha_i \in \Delta'} \alpha_i \wedge \neg \beta_j)$  then return False
  end;
return True.

```

Figure 32.7. LSAT_A for EC, ECN, EMC

LSAT_A(μ) returns True if μ is L-consistent, and False otherwise.

32.4.2.2. Logics EC, ECN, EMC

The following proposition is an easy consequence of the results presented in [Var89].

Proposition 7. Let $\mu = \bigwedge_i \Box \alpha_i \wedge \bigwedge_j \neg \Box \beta_j \wedge \gamma$ be an assignment in which γ is a propositional formula. Let Δ be the set of formulas α_i such that $\Box \alpha_i$ is a conjunct of μ . Let L be one of logics EC, ECN, EMC. μ is consistent in L if for each conjunct $\neg \Box \beta_j$ in μ one of the following conditions is satisfied:

- $((\bigwedge_{\alpha_i \in \Delta'} \alpha_i) \equiv \neg \beta_j)$ is L-consistent for each non empty subset Δ' of Δ , and $L=EC$;
- $((\bigwedge_{\alpha_i \in \Delta'} \alpha_i) \equiv \neg \beta_j)$ is L-consistent for each subset Δ' of Δ , and $L=ECN$;
- Δ is empty or $((\bigwedge_{\alpha_i \in \Delta} \alpha_i) \wedge \neg \beta_j)$ is L-consistent, and $L=EMC$;

Assume that $L=EC$ or $L=ECN$. The straightforward implementation of the corresponding condition may lead to an exponential number of checks in the cardinality $|\Delta|$ of Δ . More carefully, for each conjunct $\neg \Box \beta_j$ in μ , we can perform at most $|\Delta| + 1$ checks if

1. for each formula α_i in Δ , we first check whether $(\neg \alpha_i \wedge \beta_j)$ is consistent in L . Let Δ' be the set of formulas for which the above test fails. Then,
2. in case $L=ECN$ or $\Delta' \neq \emptyset$, we perform the last test, checking whether $((\bigwedge_{\alpha_i \in \Delta'} \alpha_i) \wedge \neg \beta_j)$ is consistent in L .

Furthermore, the result of the consistency checks performed in the first step can be cached in a matrix M analogous to the one used in the previous subsection.

If $L=EC$ or $L=ECN$, the procedure LSAT_A in Figure 32.7 implements the above ideas. Otherwise, it is a straightforward implementation of the conditions in proposition 7. The following proposition ensures the correctness of LSAT in the case of E, EM, EN and EMN.

Proposition 8. Let $\mu = \bigwedge_i \Box \alpha_i \wedge \bigwedge_j \neg \Box \beta_j \wedge \gamma$ be an assignment in which γ is a propositional formula. Let L be one of logics *EC*, *ECN*, *EMC*. Assume that, for any formula φ whose depth is less than the depth of μ , $Lsat(\varphi)$

- returns *True* if φ is L -consistent, and
- *False* otherwise.

$LSAT_A(\mu)$ returns *True* if μ is L -consistent, and *False* otherwise.

32.5. The OBDD-based Approach

In this section we briefly survey the basics of the OBDD-based approach to implement decision procedures for modal K , and we refer the reader to [PSV02, PV03] for further details. The contents of this section and the next borrow from [PSV06], including basic notation and the description of the algorithms.

The OBDD-based approach is inspired by the automata-theoretic approach for logics with the tree-model -property. In that approach, one proceeds in two steps. First, an input formula is translated to a tree automaton that accepts all the tree models of the formula. Second, the automaton is tested for non-emptiness, i.e., whether it accepts some tree. The approach described in [PSV02] combines the two steps and carries out the non-emptiness test without explicitly constructing the automaton. The logic K is simple enough that the automaton's non-emptiness test consists of a single fixpoint computation, which starts with a set of states and then repeatedly applies a monotone operator until a fixpoint is reached. In the automaton that corresponds to a formula, each state is a *type*, i.e., a set of formulas satisfying some consistency conditions. The algorithms that we describe here start from some set of types and then repeatedly apply a monotone operator until a fixpoint is reached.

32.5.1. Basics

To aid the description of the OBDD-based algorithms we introduce some additional notation. The set of propositional atoms used in a formula is denoted $AP(\varphi)$, and, given a formula ψ , we call its set of subformulas $\text{sub}(\psi)$. For $\varphi \in \text{sub}(\psi)$, we can define $\text{depth}(\varphi)$ in the usual way. If not stated otherwise, we assume all formulas to be in BNF. The *closure* of a formula $\text{cl}(\psi)$ is defined as the smallest set such that, for all subformulas φ of ψ , if φ is not of the form $\neg\varphi'$, then $\{\varphi, \neg\varphi\} \subseteq \text{cl}(\psi)$. The algorithms that we present here work on *types*, i.e., maximal sets of formulas that are consistent w.r.t. the Boolean operators, and where (negated) box formulas are treated as atoms. A set of formulas $a \subseteq \text{cl}(\psi)$ is called a ψ -*type* (or simply a type if ψ is clear from the context) if it satisfies the following conditions:

- If $\varphi = \neg\varphi'$, then $\varphi \in a$ iff $\varphi' \notin a$.
- If $\varphi = \varphi' \wedge \varphi''$, then $\varphi \in a$ iff $\varphi' \in a$ and $\varphi'' \in a$.
- If $\varphi = \varphi' \vee \varphi''$, then $\varphi \in a$ iff $\varphi' \in a$ or $\varphi'' \in a$.

For a set of types T , we define the maximal accessibility relation $\Delta \subseteq T \times T$ as follows.

$$\Delta(t, t') \text{ iff for all } \Box\varphi' \in t, \text{ we have } \varphi' \in t'$$

```

X := Init( $\psi$ )
repeat
  X' := X
  X := Update(X')
until X = X'
if exists  $x \in X$  such that  $\psi \in x$  then
  return " $\psi$  is satisfiable"
else
  return " $\psi$  is not satisfiable"

```

Figure 32.8. Basic schema for the OBDD-based algorithm.

In Figure 32.8 we present the basic schema for the OBDD-based decision procedures. The schema can be made to work in two fashions, called top-down and bottom-up in [PSV06], according to the definition of the accessory functions `Init` and `Update`. In both cases, since the algorithms operate with elements in a finite lattice $2^{\text{cl}(\psi)}$ and use a monotone `Update`, they are bound to terminate. In the case of the top-down approach, the accessory functions are defined as:

- `Init(ψ)` is the set of all ψ -types.
- `Update(T) := $T \setminus \text{bad}(T)$` , where `bad(T)` are the types in T that contain unwitnessed negated box formulas. More precisely,

$$\text{bad}(T) := \{t \in T \mid \text{there exists } \neg\Box\varphi \in t \text{ and,} \\ \text{for all } u \in T \text{ with } \Delta(t, u), \text{ we have } \varphi \in u\}.$$

Intuitively, the top-down algorithm starts with the set of *all* types and remove those types with “possibilities” $\Diamond\varphi$ for which no “witness” can be found. In the bottom-up approach, the accessory functions are defined as:

- `Init(ψ)` is the set of all those types that do not require any witness, which means that they do not contain any negated box formula, or equivalently, that they contain all positive box formulas in `cl(ψ)`. More precisely,

$$\text{Init}(\psi) := \{t \subseteq \text{cl}(\psi) \mid t \text{ is a type and } \Box\varphi \in t \text{ for each } \Box\varphi \in \text{cl}(\psi)\}.$$

- `Update(T) := $T \cup \text{supp}(T)$` , where `supp(T)` is the set of those types whose negated box formulas are witnessed by types in T . More precisely,

$$\text{supp}(T) := \{t \subseteq \text{cl}(\psi) \mid t \text{ is a type and,} \\ \text{for all } \neg\Box\varphi \in t, \text{ there exists } u \in T \\ \text{with } \neg\varphi \in u \text{ and } \Delta(t, u)\}.$$

Intuitively, the bottom-up algorithm starts with the set of types having no possibilities $\Diamond\varphi$, and adds those types whose possibilities are witnessed by a type in the set. Notice that the two algorithms described above, correspond to the two ways in which non-emptiness can be tested for automata for K .

32.5.2. Optimizations

The decision procedure described in the previous section handle the formula in three steps. First, the formula is converted into BNF. Then the initial set of

types is generated – we can think of this set as having some memory efficient representation. Finally, this set is updated through a fixpoint process. The answer of the decision procedure depends on a simple syntactic check of this fixpoint. In the following we consider three orthogonal optimizations techniques. See [PSV06] for more details, and for a description of preprocessing techniques that may further improve the performances of the OBDD-based implementations.

32.5.2.1. Particles

The approaches presented so far strongly depend on the fact that the BNF is used and they can be said to be redundant: if a type contains two conjuncts of some subformula of the input, then it also contains the corresponding conjunction – although the truth value of the latter is determined by the truth values of the former. Working with a different normal form it is possible to reduce such redundancy. We consider K -formulas in NNF (negation normal form) and we assume hereafter that all the formulas are in NNF. A set $p \subseteq \text{sub}(\psi)$ is a ψ -particle if it satisfies the following conditions:

- If $\varphi = \neg\varphi'$, then $\varphi \in p$ implies $\varphi' \notin p$
- If $\varphi = \varphi' \wedge \varphi''$, then $\varphi \in p$ implies $\varphi' \in p$ and $\varphi'' \in p$.
- If $\varphi = \varphi' \vee \varphi''$, then $\varphi \in p$ implies $\varphi' \in p$ or $\varphi'' \in p$.

Thus, in contrast to a type, a particle may contain both φ' and φ'' , but neither $\varphi' \wedge \varphi''$ nor $\varphi' \vee \varphi''$. Incidentally, particles are closer than types to assignments over modal atoms as described in Section 32.3.4. For particles, $\Delta(\cdot, \cdot)$ is defined as types. From a set of particles P and the corresponding $\Delta(\cdot, \cdot)$, a Kripke structure K_p can be constructed in the same way as from a set of types (see [PSV06]).

The schema presented in Figure 32.8 can be made to work for particles as well. In the top-down algorithm:

- $\text{Init}(\psi)$ is the set of all ψ -particles.
- $\text{Update}(P) := P \setminus \text{bad}(P)$, where $\text{bad}(P)$ is the particles in P that contain unwitnessed diamond formulas and it is defined similarly to the case of types

Also in the case of particles, the bottom-up approach differs only for the definitions of Init and Update :

- $\text{Init}(\psi) := \{p \subseteq \text{sub}(\psi) \mid p \text{ is a particle and } \diamond\varphi \notin p \text{ for all } \diamond\varphi \in \text{sub}(\psi)\}$ is the set of ψ -particles p that do not contain diamond formulas.
- $\text{Update}(P) := P \cup \text{supp}(P)$ where $\text{supp}(P)$ is the set of witnessed particles defined similarly to witnessed types.

Just like a set of types can be encoded in some efficient way, e.g., a set of bit vectors using a BDD, the same can be done for particles. It is easy to see that bit vectors for particles may be longer than bit vectors for types because, for example, the input may involve subformulas $\Box A$ and $\Diamond \neg A$. The overall size of the BDD may, however, be smaller for particles since particles impose fewer constraints than types, and improvements in the run time of the algorithms may result because the particle-based Update functions require checking less formulas than the type-based ones.

32.5.2.2. Lean approaches

Even though the particle approach imposes less constraints than the type approach, it still involves redundant information: like types, particles may contain both a conjunction and the corresponding conjuncts. To further reduce the size of the corresponding BDDs, in [PSV06] it is proposed a representation where “non-redundant” subformulas are only kept track of. A set of “non-redundant” subformulas $\mathbf{atom}(\psi)$ is defined as the set of those formulas in $\mathbf{cl}(\psi)$ that are neither conjunctions nor disjunctions, i.e., each $\varphi \in \mathbf{atom}(\psi)$ is of the form $\Box\varphi'$, A , $\neg\Box\varphi'$, or $\neg A$. By definition of types, each ψ -type $t \subseteq \mathbf{cl}(\psi)$, corresponds one-to-one to a *lean type* $\mathbf{lean}(t) := t \cap \mathbf{atom}(\psi)$. To specify algorithms for lean types, a relation $\dot{\in}$ must be defined recursively as follows: $\varphi \dot{\in} t$ if

- $\varphi \in \mathbf{atom}(\psi)$ and $\varphi \in t$,
- $\varphi = \neg\varphi'$ and not $\varphi' \dot{\in} t$,
- $\varphi = \varphi' \wedge \varphi''$, $\varphi' \dot{\in} t$, and $\varphi'' \dot{\in} t$, or
- $\varphi = \varphi' \vee \varphi''$, and $\varphi' \dot{\in} t$, or $\varphi'' \dot{\in} t$.

The top-down and bottom-up approach for types can be easily modified to work for lean types. It suffices to modify the definition of the functions **bad** and **supp** as follows:

$$\mathbf{bad}(T) := \{t \in T \mid \text{there exists } \neg\Box\varphi \in t \text{ and,} \\ \text{for all } u \in T \text{ with } \Delta(t, u), \text{ we have } \varphi \dot{\in} u\}.$$

$$\mathbf{supp}(T) := \{t \subseteq \mathbf{cl}(\psi) \mid t \text{ is a type and,} \\ \text{for all } \neg\Box\varphi \in t, \text{ there exists } u \in T \\ \text{with } \neg\varphi \dot{\in} u \text{ and } \Delta(t, u)\}.$$

A lean optimization can also be defined for particles – details are given in [PSV06]. Notice that this approach bears also some resemblances with the approach used in [CGH97] to translate LTL to SMV.

32.5.2.3. Level based evaluation

Another variation of the basic algorithm presented in Figure 32.8 exploits the fact that K enjoys the finite-tree-model property, i.e., each satisfiable formula ψ of K has a finite tree model of depth bounded by the depth of nested modal operators $\mathbf{depth}(\psi)$ of ψ . We can think of such a model as being partitioned into *layers*, where all states that are at distance i from the root are said to be in layer i . Instead of representing a complete model using a set of particles or types, each layer in the model can be represented using a separate set. Since only a subset of all subformulas appears in one layer, the representation can be more compact.

We start by (re)defining $\mathbf{cl}(\cdot)$ as

$$\mathbf{cl}_i(\psi) := \{\varphi \in \mathbf{cl}(\psi) \mid \varphi \text{ occurs at modal depth } i \text{ in } \psi\}$$

and $\Delta(\cdot, \cdot)$ as

$$\Delta(t, t') \text{ iff for all } t \subseteq \mathbf{cl}_i(\psi), t' \subseteq \mathbf{cl}_{i+1}(\psi), \text{ and } \varphi' \in t' \text{ for all } \Box\varphi' \in t.$$

```

d := depth( $\psi$ )
 $X_d := \text{Init}_d(\psi)$ 
for  $i := d - 1$  downto 0 do
   $X_i := \text{Update}(X_{i+1}, i)$ 
end
if exists  $x \in X_0$  such that  $\psi \in x$  then
  return " $\psi$  is satisfiable"
else
  return " $\psi$  is not satisfiable"

```

Figure 32.9. Algorithm for the level-based optimization.

in order to adapt them to the layered approach. A sequence of sets of types $T = \langle T_0, T_1, \dots, T_d \rangle$ with $T_i \subseteq 2^{\text{cl}_i(\psi)}$ can still be converted into a tree Kripke structure (see [PSV06] for details).

A bottom-up algorithm for level-based evaluation can be defined as in Figure 32.9. The algorithm works bottom-up in the sense that it starts with the leaves of a tree model *at the deepest level* and then moves up the tree model toward the root, adding nodes that are “witnessed”. In contrast, the bottom-up approach presented earlier starts with *all* leaves of a tree model. The accessory functions can be defined as follows:

- $\text{Init}_i(\psi) := \{t \subseteq \text{cl}_i(\psi) \mid t \text{ is a type}\}$.
- $\text{Update}(T, i) := \{t \in \text{Init}_i(\psi) \mid \text{for all } \neg \Box \varphi \in t \text{ there exists } u \in T \text{ with } \neg \varphi \in u \text{ and } \Delta_i(t, u)\}$.

For a set T of types of formulas at level $i + 1$, $\text{Update}(T, i)$ represents all types of formulas at level i that are witnessed in T .

32.6. The Eager DPLL-based approach

Recently [SV06, SV08] have explored the idea of encoding K_m/\mathcal{ALC} -satisfiability into SAT and handle it by state-of-the-art SAT tools. A satisfiability-preserving encoding from K_m/\mathcal{ALC} to SAT was proposed there, with a few variations and some important optimizations. As K_m -satisfiability is PSPACE-complete, the encoding is necessarily worst-case exponential (unless PSPACE=NP). However, the only source of exponentiality is the modal depth of the input formula: if the depth is bounded, the problem is NP-complete [Hal95], so that the encoding reduces to polynomial. In practice, the experiments presented there showed that this approach can handle most or all the problems which are at the reach of the other approaches, with performances which are comparable with, or even better than, those of the current state-of-the-art tools.

As this idea was inspired by the so-called “eager approach” to SMT [BGV99, SSB02, Str02] (see §26.3), we call this approach, *eager approach to modal reasoning*. In this section we present an overview of this approach.

32.6.1. The basic encoding

In order to make our presentation more uniform, and to avoid considering the polarity of subformulas, we adopt from [Fit83, Mas00] the representation of K_m -formulas from the following table:

α	α_1	α_2	β	β_1	β_2	π^r	π_0^r	ν^r	ν_0^r
$(\varphi_1 \wedge \varphi_2)$	φ_1	φ_2	$(\varphi_1 \vee \varphi_2)$	φ_1	φ_2	$\diamond_r \varphi_1$	φ_1	$\square_r \varphi_1$	φ_1
$\neg(\varphi_1 \vee \varphi_2)$	$\neg\varphi_1$	$\neg\varphi_2$	$\neg(\varphi_1 \wedge \varphi_2)$	$\neg\varphi_1$	$\neg\varphi_2$	$\neg\square_r \varphi_1$	$\neg\varphi_1$	$\neg\diamond_r \varphi_1$	$\neg\varphi_1$
$\neg(\varphi_1 \rightarrow \varphi_2)$	φ_1	$\neg\varphi_2$	$(\varphi_1 \rightarrow \varphi_2)$	$\neg\varphi_1$	φ_2				

in which non-literal K_m -formulas are grouped into four categories: α 's (conjunctive), β 's (disjunctive), π 's (existential), ν 's (universal). All such formulas occur in the main formula with positive polarity only.¹⁴ This allows for disregarding the issue of polarity of subformulas.

We borrow some notation from the *Single Step Tableau (SST)* framework [Mas00, DM00]. We represent univocally states in \mathcal{M} as labels σ , represented as non empty sequences of integers $1.n_1^{r_1}.n_2^{r_2} \dots .n_k^{r_k}$, s.t. the label 1 represents the root state, and $\sigma.n^r$ represents the n -th successor of σ through the relation \mathcal{R}_r . With a little abuse of notation, hereafter we may say “a state σ ” meaning “a state labeled by σ ”. We call a *labeled formula* a pair $\langle \sigma : \psi \rangle$, s.t. σ is a state label and ψ is a K_m -formula.

Let $A_{[\]}$ be an *injective* function which maps a labeled formula $\langle \sigma : \psi \rangle$, s.t. is not in the form $\neg\phi$, into a Boolean variable $A_{[\sigma, \psi]}$. Let $L_{[\sigma, \psi]}$ denote $\neg A_{[\sigma, \phi]}$ if ψ is in the form $\neg\phi$, $A_{[\sigma, \psi]}$ otherwise. Given a K_m -formula φ , K_m2SAT builds a Boolean CNF formula recursively as follows:

$$K_m2SAT(\varphi) := A_{[1, \varphi]} \wedge Def(1, \varphi) \quad (32.21)$$

$$Def(\sigma, A_i) := \top \quad (32.22)$$

$$Def(\sigma, \neg A_i) := \top \quad (32.23)$$

$$Def(\sigma, \alpha) := (L_{[\sigma, \alpha]} \rightarrow (L_{[\sigma, \alpha_1]} \wedge L_{[\sigma, \alpha_2]})) \wedge Def(\sigma, \alpha_1) \wedge Def(\sigma, \alpha_2) \quad (32.24)$$

$$Def(\sigma, \beta) := (L_{[\sigma, \beta]} \rightarrow (L_{[\sigma, \beta_1]} \vee L_{[\sigma, \beta_2]})) \wedge Def(\sigma, \beta_1) \wedge Def(\sigma, \beta_2) \quad (32.25)$$

$$Def(\sigma, \pi^{r,j}) := (L_{[\sigma, \pi^{r,j}]} \rightarrow L_{[\sigma,j, \pi_0^{r,j}]}) \wedge Def(\sigma,j, \pi_0^{r,j}) \quad (32.26)$$

$$Def(\sigma, \nu^r) := \bigwedge_{\langle \sigma : \pi^{r,i} \rangle} ((L_{[\sigma, \nu^r]} \wedge L_{[\sigma, \pi^{r,i}]} \rightarrow L_{[\sigma,i, \nu_0^r]}) \wedge \bigwedge_{\langle \sigma : \pi^{r,i} \rangle} Def(\sigma,i, \nu_0^r)). \quad (32.27)$$

Here by “ $\langle \sigma : \pi^{r,i} \rangle$ ” we mean that $\pi^{r,i}$ is the j -th distinct π^r formula labeled by σ .

We assume that the K_m -formulas are represented as DAGs, so to avoid the expansion of the same $Def(\sigma, \psi)$ more than once. Moreover, following [Mas00], we assume that, for each σ , the $Def(\sigma, \psi)$'s are expanded in the order: α, β, π, ν . Thus, each $Def(\sigma, \nu^r)$ is expanded after the expansion of all $Def(\sigma, \pi^{r,i})$'s, so that $Def(\sigma, \nu^r)$ will generate one clause $((L_{[\sigma, \pi^{r,i}]} \wedge L_{[\sigma, \pi^{r,i}]} \rightarrow L_{[\sigma,i, \nu_0^r]})$ and one novel definition $Def(\sigma,i, \nu_0^r)$ for each $Def(\sigma, \pi^{r,i})$ expanded.¹⁵

Intuitively, $K_m2SAT(\varphi)$ mimics the construction of an SST tableau expansion [Mas00, DM00], s.t., if there exists an open tableau \mathcal{T} for $\langle 1 : \varphi \rangle$, then

¹⁴E.g., a \wedge -formula [resp. \vee -formula] occurring negatively is considered a positive occurrence of a β -formula [resp. an α -formula]; a \square_r -formula [resp. a \diamond_r -formula] occurring negatively is considered a positive occurrence of a π -formula [resp. a ν -formula].

¹⁵Notice that, e.g., an occurrence of $\square_r \psi$ is considered a ν -formula if positive, a π -formula if negative.

there exists a total truth assignment μ which satisfies $K_m2SAT(\varphi)$, and vice versa. Thus, from the correctness and completeness of the SST framework, we have the following fact.

Theorem 2. [SV08] *A K_m -formula φ is K_m -satisfiable if and only if the corresponding Boolean formula $K_m2SAT(\varphi)$ is satisfiable.*

Notice that, due to (32.27), the number of variables and clauses in $K_m2SAT(\varphi)$ may grow exponentially with $depth(\varphi)$. This is in accordance to what stated in [Hal95].

Example 9 (NNF). *Let φ_{nnf} be $(\diamond A_1 \vee \diamond(A_2 \vee A_3)) \wedge \square \neg A_1 \wedge \square \neg A_2 \wedge \square \neg A_3$.¹⁶ It is easy to see that φ_{nnf} is K_1 -unsatisfiable: the \diamond -atoms impose that at least one atom A_i is true in at least one successor of the root state, whilst the \square -atoms impose that all atoms A_i are false in all successor states of the root state. $K_m2SAT(\varphi_{nnf})$ is:*

1. $A_{[1, \varphi_{nnf}]}$
2. $\wedge (A_{[1, \varphi_{nnf}]} \rightarrow (A_{[1, \diamond A_1 \vee \diamond(A_2 \vee A_3)]} \wedge A_{[1, \square \neg A_1]} \wedge A_{[1, \square \neg A_2]} \wedge A_{[1, \square \neg A_3]}))$
3. $\wedge (A_{[1, \diamond A_1 \vee \diamond(A_2 \vee A_3)]} \rightarrow (A_{[1, \diamond A_1]} \vee A_{[1, \diamond(A_2 \vee A_3)]}))$
4. $\wedge (A_{[1, \diamond A_1]} \rightarrow A_{[1.1, A_1]})$
5. $\wedge (A_{[1, \diamond(A_2 \vee A_3)]} \rightarrow A_{[1.2, A_2 \vee A_3]})$
6. $\wedge ((A_{[1, \square \neg A_1]} \wedge A_{[1, \diamond A_1]}) \rightarrow \neg A_{[1.1, A_1]})$
7. $\wedge ((A_{[1, \square \neg A_2]} \wedge A_{[1, \diamond A_1]}) \rightarrow \neg A_{[1.1, A_2]})$
8. $\wedge ((A_{[1, \square \neg A_3]} \wedge A_{[1, \diamond A_1]}) \rightarrow \neg A_{[1.1, A_3]})$
9. $\wedge ((A_{[1, \square \neg A_1]} \wedge A_{[1, \diamond(A_2 \vee A_3)]}) \rightarrow \neg A_{[1.2, A_1]})$
10. $\wedge ((A_{[1, \square \neg A_2]} \wedge A_{[1, \diamond(A_2 \vee A_3)]}) \rightarrow \neg A_{[1.2, A_2]})$
11. $\wedge ((A_{[1, \square \neg A_3]} \wedge A_{[1, \diamond(A_2 \vee A_3)]}) \rightarrow \neg A_{[1.2, A_3]})$
12. $\wedge (A_{[1.2, A_2 \vee A_3]} \rightarrow (A_{[1.2, A_2]} \vee A_{[1.2, A_3]}))$

After a run of BCP, 3. reduces to the implicate disjunction $A_{[1, \diamond A_1]} \vee A_{[1, \diamond(A_2 \vee A_3)]}$. If the first element $A_{[1, \diamond A_1]}$ is assigned to true, then by BCP we have a conflict on 4. and 6. If $A_{[1, \diamond A_1]}$ is set to false, then the second element $A_{[1, \diamond(A_2 \vee A_3)]}$ is assigned to true, and by BCP we have a conflict on 12. Thus $K_m2SAT(\varphi_{nnf})$ is unsatisfiable.

32.6.2. Optimizations

The following optimizations of the encoding have been proposed in [SV06, SV08] in order to reduce the size of the output propositional formula.

32.6.2.1. Pre-conversion to BNF

Before the encoding, some potentially useful preprocessing on the input formula can be performed. First, the input K_m -formulas can be converted into BNF. One potential advantage is that, when one $\square_r \psi$ occurs both positively and negatively (like, e.g., in $(\square_r \psi \vee \dots) \wedge (\neg \square_r \psi \vee \dots) \wedge \dots$), then both occurrences of $\square_r \psi$ are labeled by the same Boolean atom $A_{[\sigma, \square_r \psi]}$, and hence they are always assigned the

¹⁶For K_1 -formulas, we omit the box and diamond indexes.

same truth value by DPLL; with NNF, instead, the negative occurrence $\neg\Box_r\psi$ is rewritten into $\Diamond_r\neg\psi$, so that two distinct Boolean atoms $A_{[\sigma, \Box_r\psi]}$ and $A_{[\sigma, \Diamond_r\neg\psi]}$ are generated; DPLL can assign them the same truth value, creating a hidden conflict which may require some extra Boolean search to reveal.

Example 10 (BNF). *We consider the BNF variant of the φ_{nnf} formula of Example 9, $\varphi_{bnf} = (\neg\Box\neg A_1 \vee \neg\Box(\neg A_2 \wedge \neg A_3)) \wedge \Box\neg A_1 \wedge \Box\neg A_2 \wedge \Box\neg A_3$. As before, it is easy to see that φ_{bnf} is K_1 -unsatisfiable. $K_m2SAT(\varphi_{bnf})$ is:*

1. $A_{[1, \varphi_{bnf}]}$
2. $\wedge (A_{[1, \varphi_{bnf}]} \rightarrow (A_{[1, (\neg\Box\neg A_1 \vee \neg\Box(\neg A_2 \wedge \neg A_3))]} \wedge A_{[1, \Box\neg A_1]} \wedge A_{[1, \Box\neg A_2]} \wedge A_{[1, \Box\neg A_3]}))$
3. $\wedge (A_{[1, (\neg\Box\neg A_1 \vee \neg\Box(\neg A_2 \wedge \neg A_3))]} \rightarrow (\neg A_{[1, \Box\neg A_1]} \vee \neg A_{[1, \Box(\neg A_2 \wedge \neg A_3)]}))$
4. $\wedge (\neg A_{[1, \Box\neg A_1]} \rightarrow A_{[1.1, A_1]})$
5. $\wedge (\neg A_{[1, \Box(\neg A_2 \wedge \neg A_3)]} \rightarrow \neg A_{[1.2, (\neg A_2 \wedge \neg A_3)]})$
6. $\wedge ((A_{[1, \Box\neg A_1]} \wedge \neg A_{[1, \Box\neg A_1]}) \rightarrow \neg A_{[1.1, A_1]})$
7. $\wedge ((A_{[1, \Box\neg A_2]} \wedge \neg A_{[1, \Box\neg A_1]}) \rightarrow \neg A_{[1.1, A_2]})$
8. $\wedge ((A_{[1, \Box\neg A_3]} \wedge \neg A_{[1, \Box\neg A_1]}) \rightarrow \neg A_{[1.1, A_3]})$
9. $\wedge ((A_{[1, \Box\neg A_1]} \wedge \neg A_{[1, \Box(\neg A_2 \wedge \neg A_3)]}) \rightarrow \neg A_{[1.2, A_1]})$
10. $\wedge ((A_{[1, \Box\neg A_2]} \wedge \neg A_{[1, \Box(\neg A_2 \wedge \neg A_3)]}) \rightarrow \neg A_{[1.2, A_2]})$
11. $\wedge ((A_{[1, \Box\neg A_3]} \wedge \neg A_{[1, \Box(\neg A_2 \wedge \neg A_3)]}) \rightarrow \neg A_{[1.2, A_3]})$
12. $\wedge (\neg A_{[1.2, (\neg A_2 \wedge \neg A_3)]} \rightarrow (A_{[1.2, A_2]} \vee A_{[1.2, A_3]}))$

Unlike with NNF, $K_m2SAT(\varphi_{bnf})$ is found unsatisfiable directly by BCP. In fact, the unit-propagation of $A_{[1, \Box\neg A_1]}$ from 2. causes $\neg A_{[1, \Box\neg A_1]}$ in 3. to be false, so that one of the two (unsatisfiable) branches induced by the disjunction is cut a priori. With NNF, the corresponding atoms $A_{[1, \Box\neg A_1]}$ and $A_{[1, \Diamond A_1]}$ are not recognized to be one the negation of the other, s.t. DPLL may need exploring one Boolean branch more.

32.6.2.2. Lifting boxes and diamonds

The second form of preprocessing is, the K_m -formula can also be rewritten by recursively applying the K_m -validity-preserving “box/diamond-lifting rules”:

$$\begin{aligned} (\Box_r\varphi_1 \wedge \Box_r\varphi_2) &\Longrightarrow \Box_r(\varphi_1 \wedge \varphi_2), & (\Diamond_r\varphi_1 \vee \Diamond_r\varphi_2) &\Longrightarrow \Diamond_r(\varphi_1 \vee \varphi_2), \\ (\neg\Box_r\varphi_1 \vee \neg\Box_r\varphi_2) &\Longrightarrow \neg\Box_r(\varphi_1 \wedge \varphi_2), & (\neg\Diamond_r\varphi_1 \wedge \neg\Diamond_r\varphi_2) &\Longrightarrow \neg\Diamond_r(\varphi_1 \vee \varphi_2). \end{aligned} \quad (32.28)$$

This has the potential benefit of reducing the number of $\pi^{r,i}$ formulas, and hence the number of labels $\sigma.i$ to take into account in the expansion of the $Def(\sigma, \nu^r)$'s (32.27).

Example 11 (BNF with LIFT). *If we apply the rules (32.28) to the formula of Example 10, then we have $\varphi_{bnflift} = \neg\Box(\neg A_1 \wedge \neg A_2 \wedge \neg A_3) \wedge \Box(\neg A_1 \wedge \neg A_2 \wedge \neg A_3)$. $K_m2SAT(\varphi_{bnflift})$ is thus:*

1. $A_{[1, \varphi_{bnflift}]}$
2. $\wedge (A_{[1, \varphi_{bnflift}]} \rightarrow (\neg A_{[1, \Box(\neg A_1 \wedge \neg A_2 \wedge \neg A_3)]} \wedge A_{[1, \Box(\neg A_1 \wedge \neg A_2 \wedge \neg A_3)]}))$
3. $\wedge (\neg A_{[1, \Box(\neg A_1 \wedge \neg A_2 \wedge \neg A_3)]} \rightarrow \neg A_{[1.1, (\neg A_1 \wedge \neg A_2 \wedge \neg A_3)]})$
4. $\wedge ((A_{[1, \Box(\neg A_1 \wedge \neg A_2 \wedge \neg A_3)]} \wedge \neg A_{[1, \Box(\neg A_1 \wedge \neg A_2 \wedge \neg A_3)]}) \rightarrow A_{[1.1, (\neg A_1 \wedge \neg A_2 \wedge \neg A_3)]})$
5. $\wedge (\neg A_{[1.1, (\neg A_1 \wedge \neg A_2 \wedge \neg A_3)]} \rightarrow (A_{[1.1, A_1]} \vee A_{[1.1, A_2]} \vee A_{[1.1, A_3]}))$
6. $\wedge (A_{[1.1, (\neg A_1 \wedge \neg A_2 \wedge \neg A_3)]} \rightarrow (\neg A_{[1.1, A_1]} \wedge \neg A_{[1.1, A_2]} \wedge \neg A_{[1.1, A_3]}))$

$K_m2SAT(\varphi_{bnflift})$ is found unsatisfiable directly by BCP on 1. and 2..

One potential drawback of applying the lifting rules (32.28) is that, by collapsing a conjunction/disjunction of modal atoms into one single atom, the possibility of sharing box/diamond subformulas in the DAG representation of φ is reduced. To cope with this problem, it is possible to adopt a *controlled* policy for applying Box/Diamond-lifting, that is, to apply (32.28) only if neither atom has multiple occurrences.

32.6.2.3. Handling incompatible π^r and ν^r

A first straightforward optimization, in the BNF variant, avoids the useless encoding of incompatible π^r and ν^r formulas. In BNF, in fact, the same subformula $\Box_r\psi$ may occur in the same state σ both positively and negatively (e.g., if $\pi^{r:j}$ is $\neg\Box_r\psi$ and ν^r is $\Box_r\psi$). If so, K_m2SAT labels both those occurrences of $\Box_r\psi$ with the same Boolean atom $A_{[\sigma, \Box_r\psi]}$, and produces recursively two distinct subsets of clauses in the encoding, by applying (32.26) to $\neg\Box_r\psi$ and (32.27) to $\Box_r\psi$ respectively. However, the latter step (32.27) generates a *valid* clause $(A_{[\sigma, \Box_r\psi]} \wedge \neg A_{[\sigma, \Box_r\psi]}) \rightarrow A_{[\sigma.j, \psi]}$, which can be dropped. Consequently $A_{[\sigma.j, \psi]}$ no more occurs in the formula, so that also $Def(\sigma.i, \psi)$ can be dropped as well, as there is no more need of defining $\langle\sigma : \psi\rangle$.

Example 12. In the formula φ_{bnf} of Example 10 the implication 6. is valid and can be dropped. In the formula $\varphi_{bnflift}$ of Example 11, not only 4., but also 6. can be dropped.

32.6.2.4. On-the-fly Boolean Constraint Propagation

One major problem of the basic encoding of §32.6.1 is that it is *purely-syntactic*, that is, it does not consider the possible truth values of the subformulas, and the effect of their propagation through the Boolean and modal connectives. In particular, K_m2SAT applies (32.26) [resp. (32.27)] to *every* π -subformula [resp. ν -subformula], regardless the fact that the truth values which can be deterministically assigned to the labeled subformulas of $\langle 1 : \varphi \rangle$ may allow for dropping some labeled π -/ ν -subformulas, and thus prevent the need of encoding them.

One solution to this problem is that of applying BCP on-the-fly during the construction of $K_m2SAT(\varphi)$. If a contradiction is found, then $K_m2SAT(\varphi)$ is \perp . When BCP allows for dropping one implication in (32.24)-(32.27) without assigning some of its implicate literals, namely $L_{[\sigma, \psi_i]}$, then $\langle\sigma : \psi_i\rangle$ needs not to be defined, so that $Def(\sigma, \psi)$ can be dropped. Importantly, dropping $Def(\sigma, \pi^{r:j})$ for some π -formula $\langle\sigma : \pi^{r:j}\rangle$ prevents generating the label $\sigma.j$ (32.26) and all its successor labels $\sigma.j.\sigma'$ (corresponding to the subtree of states rooted in $\sigma.j$), so that all the corresponding labeled subformulas are not encoded.

Example 13. Consider Example 10. After building 1. – 3. in $K_m2SAT(\varphi_{bnf})$, the atoms $A_{[1, \varphi_{bnf}]}$, $A_{[1, (\neg\Box\neg A_1 \vee \neg\Box(\neg A_2 \wedge \neg A_3))]}$, $A_{[1, \Box\neg A_1]}$, $A_{[1, \Box\neg A_2]}$ and $A_{[1, \Box\neg A_3]}$ can be deterministically assigned to true by applying BCP. This causes the removal from 3. of the first-implicated disjunct $\neg A_{[1, \Box\neg A_1]}$, so that 4. is not generated. As label 1.1. is not defined, 6., 7. and 8. are not generated. Then after the construction of 5., 9., 10., 11. and 12., by applying BCP a contradiction is found, so that $K_m2SAT(\varphi)$ is \perp .

32.6.2.5. On-the-fly Pure-Literal Reduction

Another technique, evolved from that proposed in [PSV02, PV03], applies Pure-Literal reduction on-the-fly during the construction of $K_m2SAT(\varphi)$. When for some label σ all the clauses containing atoms $A_{[\sigma, \psi]}$ have been generated, if some of them occurs only positively [resp. negatively], then it can be safely assigned to true [resp. to false], and hence the clauses containing $A_{[\sigma, \psi]}$ can be dropped. As a consequence, some other atom $A_{[\sigma, \psi']}$ can become pure, so that the process is repeated until a fixpoint is reached.

Example 14. Consider the formula φ_{bnf} of Example 10. During the construction of $K_m2SAT(\varphi_{bnf})$, after 1.-8. are generated, no more clause containing atoms in the form $A_{[1.1, \psi]}$ is to be generated. Then we notice that $A_{[1.1, A_2]}$ and $A_{[1.1, A_3]}$ occur only negatively, so that they can be safely assigned to false. Therefore, 7. and 8. can be safely dropped. Same discourse applies lately to $A_{[1.2, A_1]}$ and 9. The resulting formula is found inconsistent by BCP. (In fact, notice that in Example 10 $A_{[1.1, A_2]}$, $A_{[1.1, A_3]}$, and $A_{[1.2, A_1]}$ play no role in the unsatisfiability of $K_m2SAT(\varphi_{bnf})$.)

Chapter 33

Satisfiability Modulo Theories

Clark Barrett, Roberto Sebastiani, Sanjit A. Seshia, and Cesare Tinelli

33.1. Introduction

Applications in artificial intelligence and formal methods for hardware and software development have greatly benefited from the recent advances in Boolean satisfiability (SAT). Often, however, applications in these fields require determining the satisfiability of formulas in more expressive logics such as first-order logic. Despite the great progress made in the last twenty years, general-purpose first-order theorem provers (such as provers based on the resolution calculus) are typically not able to solve such formulas directly. The main reason for this is that many applications require not general first-order satisfiability, but rather satisfiability with respect to some *background theory*, which fixes the interpretations of certain predicate and function symbols. For instance, applications using integer arithmetic are not interested in whether there exists a nonstandard interpretation of the symbols $<$, $+$, and 0 that makes the formula

$$x < y \wedge \neg(x < y + 0)$$

satisfiable. Instead, they are interested in whether the formula is satisfiable in an interpretation in which $<$ is the usual ordering over the integers, $+$ is the integer addition function, and 0 is the additive identity. General-purpose reasoning methods can be forced to consider only interpretations consistent with a background theory \mathcal{T} , but only by explicitly incorporating the axioms for \mathcal{T} into their input formulas. Even when this is possible,¹ the performance of such provers is often unacceptable. For some background theories, a more viable alternative is to use reasoning methods tailored to the theory in question. This is particularly the case for *quantifier-free* formulas, first-order formulas with no quantifiers but possibly with variables, such as the formula above.

For many theories, specialized methods actually yield *decision procedures* for the satisfiability of quantifier-free formulas or some subclass thereof. This is the

¹Some background theories such as the theory of real numbers or the theory of finite trees, cannot be captured by a finite set of first-order formulas, or, as in the case of the theory of integer arithmetic (with multiplication), by *any* decidable set of first-order formulas.

case, thanks to classical results in mathematics, for the theory of real numbers and the theory of integer arithmetic (without multiplication). In the last two decades, however, specialized decision procedures have also been discovered for a long and still growing list of other theories with practical applications. These include certain theories of arrays and of strings, several variants of the theory of finite sets or multisets, the theories of several classes of lattices, the theories of finite, regular and infinite trees, of lists, tuples, records, queues, hash tables, and bit-vectors of a fixed or arbitrary finite size.

The research field concerned with the satisfiability of formulas with respect to some background theory is called *Satisfiability Modulo Theories*, or SMT, for short. In analogy with SAT, SMT procedures (whether they are decision procedures or not) are usually referred to as *SMT solvers*. The roots of SMT can be traced back to early work in the late 1970s and early 1980s on using decision procedures in formal methods by such pioneers as Nelson and Oppen [NO80, NO79], Shostak [Sho78, Sho79, Sho84], and Boyer and Moore [BM90, BM88].² Modern SMT research started in the late 1990s with various independent attempts [AG93, GS96, ACG99, PRSS99, BGV99] to build more scalable SMT solvers by exploiting advances in SAT technology. Indeed, the defining characteristic of SMT is that satisfiability of a formula is determined by implicitly or explicitly translating to SAT. For this reason, early SMT solvers were often called *SAT-based decision procedures*. Since 2002, there has been a great deal of interest and research on the foundational and practical aspects of SMT. SMT solvers have been developed in academia and industry with increasing scope and performance. SMT solvers or techniques have been integrated into: interactive theorem provers for high-order logic (such as HOL, Isabelle, and PVS); extended static checkers (such as Boogie and ESC/Java 2); verification systems (such as ACL2, Caduceus, SAL, UCLID, and Why); formal CASE environments (such as KeY); model checkers (such as BLAST, Eureka, MAGIC and SLAM); certifying compilers (such as Touchstone and TVOC); unit test generators (such as DART, EXE, CUTE and PEX).

This chapter provides a brief overview of SMT and its main approaches, together with references to the relevant literature for a deeper study. In particular, it focuses on the two most successful major approaches so far for implementing SMT solvers, usually referred to as the “eager” and the “lazy” approach. We note that in recent years, ideas from both approaches have been combined in successful solvers, but it is still useful from a pedagogical approach to study them separately.

The *eager* approach is based on devising efficient, specialized translations to convert an input formula into an equisatisfiable propositional formula using enough relevant consequences of the theory \mathcal{T} . The approach applies in principle to any theory with a decidable ground satisfiability problem, possibly however at the cost of a significant blow-up in the translation. Its main allure is that the translation imposes upfront all theory-specific constraints on the SAT solver’s search space, potentially solving the input formula quickly; in addition, the translated formula can be given to any off-the-shelf SAT solver. It leverages the ability of modern SAT solvers to quickly process relevant theory-specific information

²Notable early systems building on this work are the Boyer-Moore prover, PVS, Simplify, SteP, and SVC.

encoded into large SAT formulas.

The *lazy* approach consists in building ad-hoc procedures implementing, in essence, an inference system specialized on a background theory \mathcal{T} . The main advantage of theory-specific solvers is that one can use whatever specialized algorithms and data structures are best for the theory in question, which typically leads to better performance. The common practice is to write *theory solvers* just for conjunctions of literals—i.e., atomic formulas and their negations. These pared down solvers are then embedded as separate submodules into an efficient SAT solver, allowing the joint system to accept quantifier-free formulas with an arbitrary Boolean structure.

The rest of this chapter is structured as follows. Section 33.2 provides background information, with formal preliminaries and a brief description of a few theories popular in SMT applications. The next two sections respectively describe the eager and the lazy approach in some detail. Section 33.5 describes some general methods for building theory solvers for the lazy approach. Section 33.6 focuses on techniques for combining solvers for different theories into a solvers for a combination of these theories. Finally, Section 33.7, describes some important extension and enhancements on the methods and techniques described in the previous sections.

33.2. Background

33.2.1. Formal preliminaries

In this chapter we will work in the context of (classical) first-order logic with equality (see, e.g., [EFT94, End00]). To make the chapter more self-contained, however, we introduce here all the relevant basic concepts and notation.

33.2.1.1. Syntax

A *signature* Σ is set of *predicate* and *function* symbols, each with an associated *arity*, a non-negative number. For any signature Σ , we denote by Σ^F and Σ^P respectively the set of function and of predicate symbols in Σ . We call the 0-arity symbols of Σ^F *constant* symbols, and usually denote them by the letters a, b possibly with subscripts. We call the 0-arity symbols of Σ^P *propositional* symbols, and usually denote them by the letters A, B , possibly with subscripts. Also, we use f, g and p, q , possibly with subscripts, to denote respectively the non-constant symbols of Σ^F and the non-propositional symbols of Σ^P .

In this chapter, we are mostly interested in quantifier-free terms and formulas built with the symbols of a given signature Σ . As a technical convenience, we treat the (free) variables of a quantifier-formula as constants in a suitable expansion of Σ . For example, if Σ is the signature of integer arithmetic we consider the formula $x < y + 1$ as a *ground* (i.e., variable-free) formula in which x and y are additional constant symbols. Formally, a *ground* (Σ -)term t and a *ground* (Σ -)formula φ are expressions in the language defined by the abstract grammar in Figure 33.1. As usual, we call *atomic formula* (or *atom*) a formula of the form $A, p(t_1, \dots, t_n)$,

$t ::= c$	where $c \in \Sigma^F$ with arity 0
$ f(t_1, \dots, t_n)$	where $f \in \Sigma^F$ with arity $n > 0$
$ ite(\varphi, t_1, t_2)$	
$\varphi ::= A$	where $A \in \Sigma^P$ with arity 0
$ p(t_1, \dots, t_n)$	where $p \in \Sigma^P$ with arity $n > 0$
$ t_1 = t_2 \mid \perp \mid \top \mid \neg\varphi_1$	
$ \varphi_1 \rightarrow \varphi_2 \mid \varphi_1 \leftrightarrow \varphi_2$	
$ \varphi_1 \vee \varphi_2 \mid \varphi_1 \wedge \varphi_2$	

Figure 33.1. Ground terms and formulas

$t_1 = t_2$, \perp , or \top .³ A (Σ) -*literal* is an atomic Σ -formula or the negation of one. We will use the letter l possibly with subscripts, to denote literals. The *complement* of a literal l , written $\neg l$ for simplicity, is $\neg\alpha$ if l is an atomic formula α , and is α if l is $\neg\alpha$. A (Σ) -*clause* is a disjunction $l_1 \vee \dots \vee l_n$ of literals. We will sometimes write a clause in the form of an implication: $\bigwedge_i l_i \rightarrow \bigvee_j l_j$ for $\bigvee_i \neg l_i \vee \bigvee_j l_j$ and $\bigwedge_i l_i \rightarrow \perp$ for $\bigvee_i \neg l_i$ where each l_i and l_j is a positive literal. We denote clauses with the letter c , possibly with subscripts, and identify the empty clause, i.e., the empty disjunction of literals, with the formula \perp . A *unit clause* is a clause consisting of a single literal (not containing \perp or \top). When μ is a finite set of literals l_1, \dots, l_n , we may denote by $\neg\mu$ the clause $\neg l_1 \vee \dots \vee \neg l_n$. Correspondingly, if c is a clause $l_1 \vee \dots \vee l_n$, we denote by $\neg c$ the set $\{\neg l_1, \dots, \neg l_n\}$. A *CNF formula* is a conjunction $c_1 \wedge \dots \wedge c_n$ of zero or more clauses. When it leads to no ambiguities, we will sometimes also write CNF formulas in set notation $\{c_1, \dots, c_n\}$, or simply replace the \wedge connectives by commas.

33.2.1.2. Semantics

Formulas are given a meaning, that is, a truth value from the set $\{\mathbf{true}, \mathbf{false}\}$, by means of (*first-order*) *models*. A model \mathcal{A} for a signature Σ , or Σ -model, is a pair consisting of a non-empty set A , the *universe* of the model, and a mapping $(_)^\mathcal{A}$ assigning to each constant symbol $a \in \Sigma^F$ an element $a^\mathcal{A} \in A$, to each function symbol $f \in \Sigma^F$ of arity $n > 0$ a total function $f^\mathcal{A} : A^n \rightarrow A$, to each propositional symbol $B \in \Sigma^P$ an element $B^\mathcal{A} \in \{\mathbf{true}, \mathbf{false}\}$, and to each $p \in \Sigma^P$ of arity $n > 0$ a total function $p^\mathcal{A} : A^n \rightarrow \{\mathbf{true}, \mathbf{false}\}$. This mapping uniquely determines a homomorphic extension, also denoted as $(_)^\mathcal{A}$, that maps each Σ -term t to an element $t^\mathcal{A} \in A$, and each Σ -formula φ to an element $\varphi^\mathcal{A} \in \{\mathbf{true}, \mathbf{false}\}$. The extension, which we call an *interpretation* of the terms and the formulas, is defined as expected. In particular, for any \mathcal{A} : $f(t_1, \dots, t_n)^\mathcal{A} = f^\mathcal{A}(t_1^\mathcal{A}, \dots, t_n^\mathcal{A})$; $ite(\varphi, t_1, t_2)^\mathcal{A}$ equals $t_1^\mathcal{A}$ if $\varphi^\mathcal{A} = \mathbf{true}$ and $t_2^\mathcal{A}$ otherwise; $p(t_1, \dots, t_n)^\mathcal{A} = p^\mathcal{A}(t_1^\mathcal{A}, \dots, t_n^\mathcal{A})$; $\perp^\mathcal{A} = \mathbf{false}$; $\top^\mathcal{A} = \mathbf{true}$; and $(t_1 = t_2)^\mathcal{A} = \mathbf{true}$ iff $t_1^\mathcal{A} = t_2^\mathcal{A}$.⁴

We say that a Σ -model \mathcal{A} *satisfies* (resp. *falsifies*) a Σ -formula φ iff $\varphi^\mathcal{A}$ is **true**

³Note that, by allowing propositional symbols in signatures this language properly includes the language of propositional logic.

⁴Note that we are using the symbol $=$ both as a symbol of the logic and as the usual meta-symbol for equality. The difference, however, should be always clear from context.

(resp. **false**). In SMT, one is not interested in arbitrary models but in models belonging to a given *theory* \mathcal{T} constraining the interpretation of the symbols of Σ . Following the more recent SMT literature, we define Σ -theories most generally as just sets of one or more (possibly infinitely many) Σ -models. Then, we say that a ground Σ -formula is satisfiable in a Σ -theory \mathcal{T} , or \mathcal{T} -satisfiable, iff there is an element of the set \mathcal{T} that satisfies φ . Similarly, a set Γ of ground Σ -formulas \mathcal{T} -entails a ground formula φ , written $\Gamma \models_{\mathcal{T}} \varphi$, iff every model of \mathcal{T} that satisfies all formulas in Γ satisfies φ as well. We say that Γ is \mathcal{T} -consistent iff $\Gamma \not\models_{\mathcal{T}} \perp$, and that φ is \mathcal{T} -valid iff $\emptyset \models_{\mathcal{T}} \varphi$. We call a clause c a *theory lemma* if c is \mathcal{T} -valid (i.e., $\emptyset \models_{\mathcal{T}} c$). All these notions reduce exactly to the corresponding notions in standard first-order logic by choosing as \mathcal{T} the set of all Σ -models; for that case, we drop \mathcal{T} from the notation (and for instance write just $\Gamma \models \varphi$).

Typically, given a Σ -theory \mathcal{T} , one is actually interested in the \mathcal{T} -satisfiability of ground formulas containing additional, *uninterpreted* symbols, i.e., predicate or function symbols not in Σ . This is particularly the case for uninterpreted constant symbols—which, as we have seen, play the role of free variables—and uninterpreted propositional symbols—which can be used as abstractions of other formulas. Formally, uninterpreted symbols are accommodated in the definitions above by considering instead of \mathcal{T} , the theory \mathcal{T}' defined as follows. Let Σ' be any signature including Σ . An *expansion* \mathcal{A}' to Σ' of a Σ -model \mathcal{A} is a Σ' -model that has the same universe as \mathcal{A} and agrees with \mathcal{A} on the interpretation of the symbols in Σ . The theory \mathcal{T}' is the set of *all possible expansions* of the models of \mathcal{T} to Σ' . To keep the terminology and notation simple, we will still talk about \mathcal{T} -satisfiability, \mathcal{T} -entailment and so on when dealing with formulas containing uninterpreted symbols, but with the understanding that we actually mean the Σ' -theory \mathcal{T}' where Σ' is a suitable expansion of \mathcal{T} 's original signature.

Then, the *ground \mathcal{T} -satisfiability problem* is the problem of determining, given a Σ -theory \mathcal{T} , the \mathcal{T} -satisfiability of ground formulas over an arbitrary expansion of Σ with uninterpreted constant symbols. Since a formula φ is \mathcal{T} -satisfiable iff $\neg\varphi$ is not \mathcal{T} -valid, the ground \mathcal{T} -satisfiability problem has a dual *ground \mathcal{T} -validity problem*. The literature in the field (especially the older literature) sometimes adopts this dual view.⁵ Finally, a theory \mathcal{T} is *convex* if for all sets μ of ground Σ' -literals (where Σ' is an expansion of Σ with uninterpreted constant symbols) and all sets E of equalities between uninterpreted constant symbols in Σ' , $\mu \models_{\mathcal{T}} \bigvee_{e \in E} e$ iff $\mu \models_{\mathcal{T}} e$ for some $e \in E$.

33.2.1.3. Combined Theories

Several applications of SMT deal with formulas involving two or more theories at once. In that case, satisfiability is understood as being modulo some combination of the various theories. If two theories \mathcal{T}_1 and \mathcal{T}_2 are both defined axiomatically, their combination can simply be defined as the theory axiomatized by the union of the axioms of the two theories, \mathcal{T}_1 and \mathcal{T}_2 . This is adequate if the signatures of the two theories are disjoint. If, instead, \mathcal{T}_1 and \mathcal{T}_2 have symbols in common, one has to consider whether a shared function (resp. predicate) symbol is meant

⁵In \mathcal{T} -validity problems, any uninterpreted constant symbols behave like *universally* quantified variables, so it is also common to see ground \mathcal{T} -validity being described in the literature as \mathcal{T} -validity of *universal* Σ -formulas.

to stand for the same function (resp. relation) in each theory or not. In the latter case, a proper signature renaming must be applied to the theories before taking the union of their axioms.

With theories specified as sets of first order models, as done here, a suitable notion of theory combination is defined as follows. Let us say that a Σ -model \mathcal{A} is the Σ -reduct of a Σ' -model \mathcal{B} with $\Sigma' \supseteq \Sigma$ if \mathcal{A} has the same universe as \mathcal{B} and interprets the symbols of Σ exactly as \mathcal{B} does. Then, the *combination* $\mathcal{T}_1 \oplus \mathcal{T}_2$ of \mathcal{T}_1 and \mathcal{T}_2 is the set of all $(\Sigma_1 \cup \Sigma_2)$ -models \mathcal{B} whose Σ_1 -reduct is isomorphic to a model of \mathcal{T}_1 and whose Σ_2 -reduct is isomorphic to a model of \mathcal{T}_2 .⁶ The correspondence with the axiomatic case is given by the following fact (see, e.g., [TR03]): when each \mathcal{T}_i is the set of all Σ_i -models that satisfy some set Γ_i of first-order axioms, $\mathcal{T}_1 \oplus \mathcal{T}_2$ is precisely the set of all $(\Sigma_1 \cup \Sigma_2)$ -models that satisfy $\Gamma_1 \cup \Gamma_2$.

33.2.1.4. Abstraction

For abstraction purposes, we associate with every signature Σ (possibly containing uninterpreted symbols in the sense above) a signature Ω consisting of the propositional symbols of Σ plus a set of new propositional symbols having the same cardinality as the set of ground Σ -atoms. We then fix a bijection $\mathcal{T2B}$, called *propositional abstraction*, between the set of ground Σ -formulas without *ite* expressions and the propositional formulas over Ω . This bijection maps each propositional symbol of Σ to itself and each non-propositional Σ -atom to one of the additional propositional symbols of Ω , and is homomorphic with respect to the logical operators.⁷ The restriction to formulas with no *ite*'s is without loss of generality because *ite* constructs can be eliminated in advance by a satisfiability-preserving transformation that repeatedly applies the following rule to completion: let $ite(\psi, t_1, t_2)$ be a subterm appearing in a formula φ ; we replace this term in φ by some new uninterpreted constant a and return the conjunction of the result with the formula $ite(\psi, a = t_1, a = t_2)$.⁸ We denote by $\mathcal{B2T}$ the inverse of $\mathcal{T2B}$, and call it *refinement*.

To streamline the notation we will often write φ^p to denote $\mathcal{T2B}(\varphi)$. Also, if μ is a set of Σ -formulas, we will write μ^p to denote the set $\{\varphi^p \mid \varphi \in \mu\}$; if μ^p is a set of Boolean literals, then μ will denote $\mathcal{B2T}(\mu^p)$. A Σ -formula φ is *propositionally unsatisfiable* if $\varphi^p \models \perp$. We will often write $\mu \models_p \varphi$ to mean $\mu^p \models \varphi^p$. We point out that for any theory \mathcal{T} , $\mu \models_p \varphi$ implies $\mu \models_{\mathcal{T}} \varphi$, but not vice versa.

⁶We refer the reader to, e.g., [EFT94] for a definition of isomorphic models. Intuitively, two models \mathcal{A} and \mathcal{B} are isomorphic if they are identical with the possible exception that the universe of \mathcal{B} is a renaming of the universe of \mathcal{A} .

⁷That is, $\mathcal{T2B}(\perp) = \perp$, $\mathcal{T2B}(\varphi_1 \wedge \varphi_2) = \mathcal{T2B}(\varphi_1) \wedge \mathcal{T2B}(\varphi_2)$, and so on.

⁸The newly-introduced *ite* can be thought of as syntactic sugar for $\psi \rightarrow a = t_1 \wedge \neg\psi \rightarrow a = t_2$. Alternatively, to avoid potential blowup of the formula, a formula-level if-then-else operator can be introduced into the language syntax.

33.2.2. Some theories of interest

In order to provide some motivation and connection to applications, we here give several examples of theories of interest and how they are used in applications.⁹

33.2.2.1. Equality

As described above, a theory usually imposes some restrictions on how function or predicate symbols may be interpreted. However, the most general case is a theory which imposes no such restrictions, in other words, a theory that includes all possible models for a given signature.

Given any signature, we denote the theory that includes all possible models of that theory as $\mathcal{T}_{\mathcal{E}}$. It is also sometimes called the *empty* theory because its finite axiomatization is just \emptyset (the empty set). Because no constraints are imposed on the way the symbols in the signature may be interpreted, it is also sometimes called the theory of equality with uninterpreted functions (EUF). The satisfiability problem for conjunctions of ground formulas modulo $\mathcal{T}_{\mathcal{E}}$ is decidable in polynomial time using a procedure known as *congruence closure* [BTV03, DST80, NO05b].

Some of the first applications that combined Boolean reasoning with theory reasoning used this simple theory [NO80]. Uninterpreted functions are often used as an abstraction technique to remove unnecessarily complex or irrelevant details of a system being modeled. For example, suppose we want to prove that the following set of literals is unsatisfiable: $\{a * (f(b) + f(c)) = d, b * (f(a) + f(c)) \neq d, a = b\}$. At first, it may appear that this requires reasoning in the theory of arithmetic. However, if we abstract $+$ and $*$ by replacing them with uninterpreted functions g and h respectively, we get a new set of literals: $\{h(a, g(f(b), f(c))) = d, h(b, g(f(a), f(c))) \neq d, a = b\}$. This set of literals can be proved unsatisfiable using only congruence closure.

33.2.2.2. Arithmetic

Let $\Sigma_{\mathcal{Z}}$ be the signature $(0, 1, +, -, \leq)$. Let the theory $\mathcal{T}_{\mathcal{Z}}$ consist of the model that interprets these symbols in the usual way over the integers.¹⁰ This theory is also known as *Presburger arithmetic*.¹¹ We can define the theory $\mathcal{T}_{\mathcal{R}}$ to consist of the model that interprets these same symbols in the usual way over the reals.

Let $\mathcal{T}'_{\mathcal{Z}}$ be the extension of $\mathcal{T}_{\mathcal{Z}}$ with an arbitrary number of uninterpreted constants (and similarly for $\mathcal{T}'_{\mathcal{R}}$). The question of satisfiability for conjunctions of ground formulas in either of these theories is decidable. Ground satisfiability in $\mathcal{T}'_{\mathcal{R}}$ is actually decidable in polynomial time [Kar84], though exponential methods such as those based on simplex often perform best in practice (see, e.g. [DdM06b]). On the other hand, ground $\mathcal{T}'_{\mathcal{Z}}$ -satisfiability is NP-complete [Pap81].

Two important related problems have to do with restricting the syntax of arithmetic formulas in these theories. *Difference logic* formulas require that every

⁹See [MZ03a] for an earlier related survey.

¹⁰Of course, additional symbols can be included for numerals besides 0 and 1 or for $<$, $>$, and \geq , but these add no expressive power to the theory, so we omit them for the sake of simplicity.

¹¹In Presburger arithmetic, the domain is typically taken to be the natural numbers rather than the integers, but it is straightforward to translate a formula with integer variables to one where variables are interpreted over \mathcal{N} and vice-versa by adding (linearly many) additional variables or constraints.

atom be of the form $a - b \bowtie t$ where a and b are uninterpreted constants, \bowtie is either $=$ or \leq , and t is an integer (i.e. either a sum of 1's or the negation of a sum of 1's). Fast algorithms for difference logic formulas have been studied in [NO05c]. A slight variation on difference logic is UTVPI (“unit two variable per inequality”) formulas which in addition to the above pattern also allow $a + b \bowtie t$. Algorithms for UTVPI formulas have been explored in [LM05, SS05].

An obvious extension of the basic arithmetic theories discussed so far is to add multiplication. Unfortunately, this dramatically increases the complexity of the problem, and so is often avoided in practice. In fact, the integer case becomes undecidable even for conjunctions of ground formulas [Mat71]. The real case is decidable but is doubly-exponential [DH88].

There are obviously many practical uses of decision procedures for arithmetic and solvers for these or closely related theories have been around for a long time. In particular, when modeling and reasoning about systems, arithmetic is useful for modeling finite sets, program arithmetic, manipulation of pointers and memory, real-time constraints, physical properties of the environment, etc.

33.2.2.3. Arrays

Let $\Sigma_{\mathcal{A}}$ be the signature $(read, write)$. Let $\Lambda_{\mathcal{A}}$ be the following axioms:

$$\begin{aligned} &\forall a \forall i \forall v (read(write(a, i, v), i) = v) \\ &\forall a \forall i \forall j \forall v (i \neq j \rightarrow read(write(a, i, v), j) = read(a, j)) \end{aligned}$$

Then the theory $\mathcal{T}_{\mathcal{A}}$ of *arrays* is the set of all models of these axioms. It is common also to include the following *axiom of extensionality*:

$$\forall a \forall b ((\forall i (read(a, i) = read(b, i))) \rightarrow a = b)$$

We will denote the resulting theory $\mathcal{T}_{\mathcal{A}ex}$. The satisfiability of ground formulas over $\mathcal{T}'_{\mathcal{A}}$ or $\mathcal{T}'_{\mathcal{A}ex}$ is NP-complete [SDBL01]. Theories of arrays are commonly used to model actual array data structures in programs. They are also often used as an abstraction for memory. The advantage of modeling memory with arrays is that the size of the model depends on the number of accesses to memory rather than the size of the memory being modeled. In many cases, this leads to significant efficiency gains.

33.2.2.4. Fixed-width bit-vectors

A natural theory for high-level reasoning about circuits and programs is a theory of bit-vectors. Various theories of bit-vectors have been proposed and studied [CMR97, Möl97, BDL98, BP98, EKM98, BRTS08]. Typically, constant symbols are used to represent vectors of bits, and each constant symbol has an associated bit-width that is fixed for that symbol. The function and predicate symbols in these theories may include extraction, concatenation, bit-wise Boolean operations, and arithmetic operations. For non-trivial theories of bit-vectors, it is easy to see that the satisfiability problem is NP-complete by a simple reduction to SAT. Bit-vectors provide a more compact representation and often allow

problems to be solved more efficiently than if they were represented at the bit level [BKO⁺07, BCF⁺07, GD07].

33.2.2.5. Inductive data types

An *inductive data type* (IDT) defines one or more *constructors*, and possibly also *selectors* and *testers*. A simple example is the IDT *list*, with constructors *cons* and *null*, selectors *car* and *cdr*, and testers *is_cons* and *is_null*. The *first order signature* of an IDT associates a function symbol with each constructor and selector and a predicate symbol with each tester. The standard model for such a signature is a term model built using only the constructors. For IDTs with a single constructor, a conjunction of literals is decidable in polynomial time using an algorithm by Oppen [Opp80a]. For more general IDTs, the problem is NP complete, but reasonably efficient algorithms exist in practice [BST07]. IDTs are very general and can be used to model a variety of things, e.g., enumerations, records, tuples, program data types, and type systems.

33.3. Eager Encodings to SAT

The *eager approach* to SMT solving involves translating the original formula to an equisatisfiable Boolean formula in a single step. In order to generate a small SAT problem, several optimizations are performed in this translation. As one might expect, some optimizations are computationally expensive and thus there is a trade-off between the degree of optimization performed and the amount of time spent therein. In fact, the translation procedure is much like an optimizing compiler, with the “high-level program” being the original SMT problem and the “low-level object code” being the generated SAT problem. This section describes the main ideas in the eager approach and surveys the state of the art.

33.3.1. Overview

The translations used in the eager approach are, by their very nature, theory-specific. We survey here the transformations for a combination of two theories: $\mathcal{T}_{\mathcal{E}}$ and $\mathcal{T}_{\mathcal{Z}}$. These theories, plus an extension of the basic syntax to include restricted lambda expressions (see below), form the core logic of the original UCLID decision procedure [LS04, Ses05], which is the main tool implementing the eager approach. The UCLID logic has sufficed for a range of applications, from microprocessor design verification [LB03] to analyzing software for security vulnerabilities [Ses05].

As mentioned, the theories of interest for this section are $\mathcal{T}_{\mathcal{E}}$ and $\mathcal{T}_{\mathcal{Z}}$, with signatures as given in §33.2.2. In particular, we assume a signature Σ containing 0, 1, +, −, ≤, and any number of uninterpreted functions and predicates.

Lambda expressions. For additional expressiveness, in this section we consider an extension of the core logical syntax (as given in Figure 33.1) to include lambda expressions. Assuming an infinite set \mathcal{V} of *integer variables*, the extended syntax is given in Figure 33.2.

Notice that the use of lambda expressions is quite restricted. In particular, there is no way in the logic to express any form of iteration or recursion. An

t	$::= c$ $ \textit{int-var}$ $ \textit{function-expr}(t_1, \dots, t_n)$ $ \textit{ite}(\varphi, t_1, t_2)$	where $c \in \Sigma^F$ with arity 0
φ	$::= A$ $ \textit{predicate-expr}(t_1, \dots, t_n)$ $ t_1 = t_2 \mid \perp \mid \top \mid \neg\varphi_1$ $ \varphi_1 \rightarrow \varphi_2 \mid \varphi_1 \leftrightarrow \varphi_2$ $ \varphi_1 \vee \varphi_2 \mid \varphi_1 \wedge \varphi_2$	where $A \in \Sigma^P$ with arity 0
$\textit{int-var}$	$::= v$	where $v \in \mathcal{V}$
$\textit{function-expr}$	$::= f$ $ \lambda \textit{int-var}, \dots, \textit{int-var}. t$	where $f \in \Sigma^F$ with arity $n > 0$
$\textit{predicate-expr}$	$::= p$ $ \lambda \textit{int-var}, \dots, \textit{int-var}. \varphi$	where $p \in \Sigma^P$ with arity $n > 0$

Figure 33.2. Extended syntax with restricted lambda expressions.

integer variable x is said to be *bound* in expression E when it occurs inside a lambda expression for which x is one of the argument variables. We say that an expression is *well-formed* when it contains no unbound variables.

Satisfiability and entailment are defined for well-formed formulas just as in §33.2.1 for formulas without lambdas. Well-formed formulas containing lambdas are considered to be semantically equivalent to their beta-reduced forms (see §33.3.1.2, below), which do not contain lambdas.

Lambda notation allows us to model the effect of a sequence of *read* and *write* operations on a memory (the *select* and *update* operations on an array) without the added complexity of the theory of arrays (\mathcal{T}_A). At any point of system operation, a memory can be represented by a function expression M denoting a mapping from addresses to values (for an array, the mapping is from indices to values). The initial state of the memory is given by an uninterpreted function symbol m_0 indicating an arbitrary memory state. The effect of a write operation with terms A and D denoting the address and data values yields a function expression M' :

$$M' = \lambda \textit{addr}. \textit{ITE}(\textit{addr} = A, D, M(\textit{addr}))$$

Reading from array M at address A simply yields the function application $M(A)$.

Multi-dimensional memories or arrays are easily expressed in the same way. Moreover, lambda expressions can express *parallel-update* operations, which update multiple memory locations in a single step. The details are outside the scope of this chapter, and can be found elsewhere [Ses05].

33.3.1.1. Operation

Suppose that we are given a formula F_{orig} in the syntax of Figure 33.2. We decide the satisfiability of F_{orig} by performing a three-stage satisfiability-preserving translation to a Boolean formula F_{bool} , and then invoking a SAT solver on F_{bool} .

The three stages of translation are as follows:

1. All lambda expressions are eliminated, resulting in a formula F_{norm} . This stage is described in §33.3.1.2.
2. Function and predicate applications of non-zero arity are eliminated to get a formula F_{arith} . This stage is described in §33.3.1.3.
3. Formula F_{arith} is a quantifier-free linear integer arithmetic (Σ_Z -) formula. There is more than one way to translate F_{arith} to an equisatisfiable Boolean formula F_{bool} . We describe these techniques in §33.3.2–§33.3.4.

In addition to preserving satisfiability, the mapping between the eliminated symbols of a theory and the new symbols that replace them is maintained. For satisfiable problems, this facilitates model generation from a satisfying assignment generated by the SAT solver. For unsatisfiable problems, it permits the generation of higher level proof information from a Boolean proof of unsatisfiability.

33.3.1.2. Eliminating Lambdas

Recall that the syntax of lambda expressions does not permit recursion or iteration. Therefore, each lambda application in F_{orig} can be expanded by *beta-substitution*, i.e., by replacing each argument variable with the corresponding argument term. Denote the resulting formula by F_{norm} .

This step can result in an exponential blow-up in formula size. Suppose that all expressions in our logic are represented as directed acyclic graphs (DAGs) so as to share common sub-expressions. Then, the following example shows how we can get an exponential-sized DAG representation of F_{norm} starting from a linear-sized DAG representation of F_{orig} .

Example 33.3.1. Let F_{orig} be defined recursively by the following set of expressions:

$$\begin{aligned}
 F_{orig} &\doteq P(L_1(b)) \\
 L_1 &\doteq \lambda x . f_1(L_2(x), L_2(g_1(x))) \\
 L_2 &\doteq \lambda x . f_2(L_3(x), L_3(g_2(x))) \\
 &\vdots \\
 L_{n-1} &\doteq \lambda x . f_{n-1}(L_n(x), L_n(g_{n-1}(x))) \\
 L_n &\doteq g_n
 \end{aligned}$$

Notice that the representation of F_{orig} is linear in n . Suppose we perform beta-substitution on L_1 . As a result, the sub-expression $L_1(b)$ gets transformed to $f_1(L_2(b), L_2(g_1(b)))$. Next, if we expand L_2 , we get four applications of L_3 , viz., $L_3(b)$, $L_3(g_1(b))$, $L_3(g_2(b))$, and $L_3(g_2(g_1(b)))$. Notice that there were originally only two applications of L_3 .

Continuing the elimination process, after $k - 1$ elimination steps, we will get 2^{k-1} distinct applications of L_k . This can be formalized by observing that after $k - 1$ steps each argument to L_k is comprised of applications of functions from a distinct subset of $\mathcal{P}(\{g_1, g_2, \dots, g_{k-1}\})$. Thus, after all lambda elimination steps, F_{norm} will contain 2^{n-1} distinct applications of g_n , and hence is exponential in the size of F_{orig} . \square

In practice, however, this exponential blow-up is rarely encountered. This is because the recursive structure in most lambda expressions, including those for memory (array) operations, tends to be linear. For example, here is the lambda expression corresponding to the result of the memory write (store) operation:

$$\lambda addr . ITE(addr = A, D, M(addr))$$

Notice that the “recursive” use of M occurs only in one branch of the ITE expression.

33.3.1.3. Eliminating Function Applications

The second step in the transformation to a Boolean formula is to eliminate applications of function and predicate symbols of non-zero arity. These applications are replaced by symbolic constants, but only after encoding enough information to maintain functional consistency (the congruence property).

There are two different techniques of eliminating function (and predicate) applications. The first is a classic method due to Ackermann [Ack54] that involves creating sufficient instances of the congruence axiom to preserve satisfiability. The second is a technique introduced by Bryant et al. [BGV01] that exploits the polarity of equations and is based on the use of ITE expressions. We briefly review each of these methods.

Ackermann’s method. We illustrate Ackermann’s method using an example. Suppose that function symbol f has three occurrences: $f(a_1)$, $f(a_2)$, and $f(a_3)$. First, we generate three fresh symbolic constants xf_1 , xf_2 , and xf_3 to replace all instances of these applications in F_{norm} .

Then, the following set of functional consistency constraints for f is generated:

$$\left\{ a_1 = a_2 \implies xf_1 = xf_2, \quad a_1 = a_3 \implies xf_1 = xf_3, \quad a_2 = a_3 \implies xf_2 = xf_3 \right\}$$

In a similar fashion, functional consistency constraints are generated for each function and predicate symbol in F_{norm} . Denote the conjunction of all these constraints by F_{cong} . Then, F_{arith} is the formula $F_{cong} \wedge F_{norm}$.

The Bryant-German-Velev method. The function elimination method proposed by Bryant, German, and Velev exploits a property of function applications called *positive equality* [BGV01]. (This discussion assumes that we are working with the concept of validity rather than satisfiability, but the ideas remain unchanged except for a flipping of polarities.) The general idea is to determine the polarity of each equation in the formula, i.e., whether it appears under an even (positive) or odd (negative) number of negations. Applications of uninterpreted functions can then be classified as either p-function applications, i.e., used only under positive equalities, or g-function applications, i.e., general function applications that appear under other equalities or under inequalities. The p-function applications can be encoded in propositional logic with fewer Boolean variables than the g-function applications, thus greatly simplifying the resulting SAT problem. We omit the details.

In order to exploit positive equality, Bryant et al. eliminate function applications using a nested series of ITE expressions. As an example, if function symbol

f has three occurrences: $f(a_1)$, $f(a_2)$, and $f(a_3)$, then we would generate three new symbolic constants xf_1 , xf_2 , and xf_3 . We would then replace all instances of $f(a_1)$ by xf_1 , all instances of $f(a_2)$ by $ITE(a_2 = a_1, xf_1, xf_2)$, and all instances of $f(a_3)$ by $ITE(a_3 = a_1, xf_1, ITE(a_3 = a_2, xf_2, xf_3))$. It is easy to see that this preserves functional consistency.

Predicate applications can be removed by a similar process. In eliminating applications of some predicate p , we introduce symbolic Boolean constants xp_1, xp_2, \dots . Function and predicate applications in the resulting formula F_{arith} are all of zero arity.

Lahiri et al. [LBGT04] have generalized the notion of positive equality to apply to both polarities and demonstrate that further optimization is possible, albeit at the cost of incurring a time overhead.

33.3.1.4. Summary

We conclude this section with observations on the worst-case blow-up in formula size in going from the starting formula F_{orig} to the quantifier-free arithmetic formula F_{arith} . The lambda elimination step can result in a worst-case exponential blow-up, but is typically only linear. In going from the lambda-free formula F_{norm} to F_{arith} , the worst-case blow-up is only quadratic. Thus, if the result of lambda expansion is linear in the size of F_{orig} , F_{arith} is at most quadratic in the size of F_{orig} .

We next consider the two main classes of methods for transforming F_{arith} to an equisatisfiable Boolean formula F_{bool} : the *small-domain encoding* method and the *direct encoding* method.

33.3.2. Small-domain encodings

The formula F_{arith} is a quantifier-free $\Sigma_{\mathcal{Z}}$ -formula, and so, we are concerned with $\mathcal{T}_{\mathcal{Z}}$ -satisfiability of quantifier-free $\Sigma_{\mathcal{Z}}$ -formulas. Recall that this problem is NP-complete (as discussed in 33.2.2). In the remainder of this section, we assume satisfiability is with respect to $\mathcal{T}_{\mathcal{Z}}$ and that all formulas are quantifier-free $\Sigma_{\mathcal{Z}}$ -formulas.

A formula is constructed by combining linear constraints with Boolean operators (such as \wedge , \vee , \neg). Formally, the i^{th} constraint is of the form

$$\sum_{j=1}^n a_{i,j} x_j \geq b_i$$

where the coefficients and the constant terms are integer constants and the variables¹² x_1, x_2, \dots, x_n are integer-valued.

If there is a satisfying solution to a formula, there is one whose size, measured in bits, is polynomially bounded in the problem size [BT76, vzGS78, KM78, Pap81]. Problem size is traditionally measured in terms of the parameters m , n , $\log a_{\max}$, and $\log b_{\max}$, where m is the total number of constraints in the formula, n is the number of variables (integer-valued symbolic constants), and

¹²The word “variable” is used in this section instead of “symbolic constant” as it is the more common term used in literature on solving integer linear arithmetic constraints.

$a_{\max} = \max_{(i,j)} |a_{i,j}|$ and $b_{\max} = \max_i |b_i|$ are the maximums of the absolute values of coefficients and constant terms respectively.

The above result implies that we can use an enumerative approach to deciding the satisfiability of a formula, where we restrict our search for satisfying solutions to within the bound on the problem size mentioned above. This approach is referred to as the *small-domain encoding* (SD) method.

In this method, given a formula $F_{\mathcal{Z}}$, we first compute the polynomial bound S on solution size, and then search for a satisfying solution to $F_{\mathcal{Z}}$ in the bounded space $\{0, 1, \dots, 2^S - 1\}^n$. However, a naïve implementation of a SD-based decision procedure fails for formulas encountered in practice. The problem is that the bound on solution size, S , is $\mathcal{O}(\log m + \log b_{\max} + m[\log m + \log a_{\max}])$. In particular, the presence of the $m \log m$ term means that, for problems involving thousands of constraints and variables, as often arises in practice, the Boolean formulas generated are beyond the capacity of even the best current SAT solvers.

In this section, we describe how the small-domain encoding method can be made practical by considering special cases of formulas. Since we consider arbitrary Boolean combinations of these constraints, the decision problems are NP-complete no matter how simple the form of the linear constraint.

33.3.2.1. Equalities

When all linear constraints are equalities (or disequalities) over integer variables, the fragment of $\mathcal{T}_{\mathcal{Z}}$ is called *equality logic*. For this fragment, we have the following “folk theorem” that is easily obtained:

Theorem 33.3.2. For an equality logic formula with n variables, $S = \log n$.

The key proof argument is that any satisfying assignment can be translated to the range $\{0, 1, 2, \dots, n - 1\}$, since we can only tell *whether* variable values differ, not by how much.

This bound yields a search space of size $\mathcal{O}(n^n)$, which can be far too large in many cases. Several optimizations are possible. The most obvious is to divide the set of variables into equivalence classes so that two variables that appear in the same equality fall into the same class. Then a separate bound on solution size can be derived for each equivalence class. This optimization is clearly applicable for arbitrary linear constraints, not just equalities.

The *range allocation* method [PRSS02] is another effective technique for reducing the size of the search space. This method operates by first building a constraint graph representing equalities and disequalities between variables in the formula, with separate types of edges representing equalities and disequalities in the negation normal form. Connected components of this graph correspond to equivalence classes mentioned above. Furthermore, the only major restriction on satisfying solutions comes from cycles that contain exactly one disequality edge. Pnueli et al. [PRSS02] give a graph-based algorithm that assigns, to each variable that participates in both equality and disequality constraints, a set of values large enough to consider all possible legal truth assignments to the constraints containing it. The resulting set of values assigned to each variable can be of cardinality smaller than n , thus often resulting in a more compact search space than n^n .

However, the worst case solution size is still n , and the search space can still be $\Theta(n^n)$.

33.3.2.2. Difference Logic

Recall that *difference logic* requires every atom to be of the form $x_i - x_j \bowtie b_t$ where x_i and x_j are variables, \bowtie is either $=$ or \leq , and b_t is an integer. Note that a constraint of the form $x_i \bowtie b_t$ can be written as $x_i - x_0 \bowtie b_t$ where x_0 is a special “variable” denoting zero. Also note that an equality can be written as a conjunction of two inequalities, while a strict inequality $<$ can be rewritten as a *le* inequality by rounding the constant term down.

We will refer to such atoms as *difference constraints*. They are also referred to in the literature as *difference-bound constraints* or *separation predicates*, and difference logic has also been termed as *separation logic*. We will use DL as an acronym for difference logic.

A fundamental construct used in the SAT-encoding of difference logic is the *constraint graph*. This graph is a weighted, directed multigraph built from the set of m difference constraints involving n variables as follows:

1. A vertex v_i is introduced for each variable x_i , including for x_0 .
2. For each difference constraint of the form $x_i - x_j \geq b_t$, we add a directed edge from v_i to v_j of weight b_t .

The resulting structure has m edges and $n + 1$ vertices. It is, in general, a multigraph since there can be multiple constant (right-hand side) terms for a given left-hand side expression $x_i - x_j$.

The following theorem states the bound on solution size for difference logic.

Theorem 33.3.3. Let F_{diff} be a DL formula with n variables, excluding x_0 . Let b_{max} be the maximum over the absolute values of all difference constraints in F_{diff} . Then, F_{diff} is satisfiable if and only if it has a solution in $\{0, 1, 2, \dots, d\}^n$ where $d = n \cdot (b_{max} + 1)$.

The proof can be obtained by an analysis of the constraint graph \mathcal{G} . The main insight is that any satisfying assignment for a formula with constraints represented by \mathcal{G} can have a spread in values that is at most the weight of the longest path in \mathcal{G} . This path weight is at most $n \cdot (b_{max} + 1)$. The bound is tight, the “+1” in the second term arising from a “rounding” of inequalities from strict to non-strict.

The above bound can also be further optimized. Equivalence classes can be computed just as before. The range allocation approach has also been extended to apply to difference logic, although the analysis involved in computing ranges can take worst-case exponential time [TSSP04]. On the plus side, the range allocation approach can, in some cases, exponentially reduce the size of the search space.

33.3.2.3. UTVPI Constraints

UTVPI constraints include difference constraints as well as *sum constraints* of the form $x_i + x_j \bowtie b_t$. UTVPI constraints over integer variables are also called *generalized 2SAT constraints*. Useful optimization problems, such as the minimum vertex cover and the maximum independent set problems, can be modeled

using UTVPI constraints [HMNT93], and some applications of constraint logic programming and automated theorem proving also generate UTVPI constraints (e.g., see [JMSY94, BCLZ04]).

The bound on solution size for UTVPI constraints is only a slight increase over that for difference logic.

Theorem 33.3.4. Let F_{utvpi} be a UTVPI formula with n variables. Let b_{\max} be the maximum over the absolute values of all constraints in F_{utvpi} . Then, F_{utvpi} is satisfiable if and only if it has a solution in $\{0, 1, 2, \dots, d\}^n$ where $d = 2 \cdot n \cdot (b_{\max} + 1)$.

The theorem can be proved using results from polyhedral theory [Ses05, SSB07]. A UTVPI formula can be viewed as a union of polyhedra defined by UTVPI hyperplanes. The vertices of these polyhedra are half-integral. The main step in the proof is to show that if a satisfying solution exists (i.e., there is an integer point inside some polyhedron in the union), then there is a solution that can be obtained by rounding some vertex of a polyhedron in the union. Since the above bound works for the vertices of the UTVPI polyhedra, it suffices for searching for integer solutions also.

33.3.2.4. Sparse, Mostly-Difference Constraints

The most general case is when no restricting assumptions can be made on the structure of linear constraints. In this case, we can still improve the “typical-case” complexity of SAT-encoding by exploiting the structure of constraints that appear in practical problems of interest.

It has been observed [Ses05, Pra77, DNS03] that formulas arising in software verification have:

1. *Mainly Difference Constraints:* Of the m constraints, $m - k$ are difference constraints, where $k \ll m$.
2. *Sparse Structure:* The k non-difference constraints are sparse, with at most w variables per constraint, where w is “small”. The parameter w is termed the *width* of the constraint.

Seshia and Bryant [SB05] exploited above special structure to obtain a bound on solution size that is parameterized in terms of k and w in addition to m , n , a_{\max} and b_{\max} . Their main result is stated in the following theorem.

Theorem 33.3.5. Let $F_{\mathcal{Z}}$ be a quantifier-free $\Sigma_{\mathcal{Z}}$ -formula. If $F_{\mathcal{Z}}$ is satisfiable, there is a solution to $F_{\mathcal{Z}}$ whose l_{∞} norm is bounded by $d = (n + 2)\Delta$, where $\Delta = s(b_{\max} + 1)(a_{\max} w)^k$ and $s = \min(n + 1, m)$.

The proof of the above theorem is based on a theorem given by Borosh, Treybig, and Flahive [BFT86] bounding integer solutions of linear systems of the form $A\mathbf{x} \geq \mathbf{b}$, where \mathbf{x} is of length n . Their result is as follows. Consider the augmented matrix $[A|\mathbf{b}]$. Let Δ be the maximum of the absolute values of all minors of this augmented matrix. Then, the linear system has a satisfying solution if and only if it has one with all entries bounded by $(n + 2)\Delta$. Seshia and Bryant used the special structure of sparse, mostly-difference constraints to obtain a bound on the value of Δ .

Several optimizations are possible to reduce the size of the bound given in Theorem 33.3.5, including computing equivalence classes of variables, rewriting constraints to reduce the size and number of non-zero coefficients, a “shift-of-origin” transformation to deal with large constant terms, etc. For brevity, these are omitted here and can be found elsewhere [Ses05].

33.3.2.5. Summary

Table 33.1 summarizes the value of d for all the classes of linear constraints explored in this section. We can clearly see that the solution bound for arbitrary

Table 33.1. Solution bounds for classes of linear constraints. The classes are listed top to bottom in increasing order of expressiveness.

Class of Linear Constraints	Solution Bound d
Equality constraints	n
Difference constraints	$n \cdot (b_{\max} + 1)$
UTVPI constraints	$2 \cdot n \cdot (b_{\max} + 1)$
Arbitrary linear constraints	$(n + 2) \cdot \min(n + 1, m) \cdot (b_{\max} + 1) \cdot (w \cdot a_{\max})^k$

formulas is conservative. For example, if all constraints are difference constraints, the expression for d simplifies to $(n + 2) \cdot \min(n + 1, m) \cdot (b_{\max} + 1)$. This is $n + 2$ times as big as the bound obtainable for difference logic in isolation; however, the slack in the bound is a carry-over from the result of Borosh, Treybig, and Flahive [BFT86]. For UTVPI constraints too, the bound derived for arbitrary formulas is much looser. In the worst case, it is looser by an exponential factor: if k is $\mathcal{O}(m)$, a_{\max} is 1, and w is 2, then the bound is $\mathcal{O}((n + 2) \cdot \min(n + 1, m) \cdot (b_{\max} + 1) \cdot 2^m)$, whereas the results of §33.3.2.3 tell us that the solution bound $d = 2 \cdot n \cdot (b_{\max} + 1)$ suffices.

33.3.3. Direct encoding of theory axioms

A decision procedure based on the direct encoding method operates in three steps:

1. Replace each unique constraint in the linear arithmetic formula F_{arith} with a fresh Boolean variable to get a Boolean formula F_{bvar} .
2. Generate a Boolean formula F_{cons} that constrains values of the introduced Boolean variables so as to preserve the arithmetic information in F_{arith} .
3. Invoke a SAT solver on the Boolean formula $F_{bvar} \wedge F_{cons}$.

The direct encoding approach has also been termed as *per-constraint encoding*.

For integer linear arithmetic, the formula F_{cons} expresses so-called *transitivity constraints*. For equality logic, Bryant and Velev [BV00] showed how to generate transitivity constraints efficiently so that the size of F_{cons} is in the worst-case only cubic in the size of the number of equalities in F_{arith} . Their transitivity constraint generation algorithm operates on the constraint graph (as introduced in §33.3.2.1). It avoids enumeration of cycles by introducing *chordal edges*, thereby avoiding an exponential blow-up in the number of transitivity constraints.

Strichman et al. [SSB02] generalized the above graph-based approach to difference logic. In this case, the constraint graph is just as in §33.3.2.2. Again, cycle enumeration is avoided by the introduction of new edges. However, in the case of difference logic, the number of added edges can be exponential in the original constraint graph, in the worst case [Ses05]. Even so, in many practical instances, the number of transitivity constraints is small and the resulting SAT problem is easily solved. Various heuristic optimizations are possible based on the Boolean structure of the formula [Str02b].

Strichman [Str02a] also extended the above scheme to operate on an arbitrary linear arithmetic formula (over the integers or the rationals). The “transitivity constraints” are generated using the Fourier-Motzkin variable elimination procedure (the Omega test variant [Pug91], in the case of integers). It is well-known that Fourier-Motzkin can generate doubly-exponentially many new constraints in the worst case [Cha93]. Thus, the worst-case size of F_{cons} is doubly-exponential in the size of F_{arith} . This worst-case behavior does seem to occur in practice, as evidenced by the results in Strichman’s paper [Str02a] and subsequent work.

We summarize the complexity of the direct encoding method for the three classes of linear arithmetic formulas in Table 33.2.

Table 33.2. Worst-case size of direct encoding. The classes are listed top to bottom in increasing order of expressiveness.

Class of Linear Constraints	Worst-case size of F_{cons}
Equality constraints	Cubic
Difference constraints	Exponential
Arbitrary linear constraints	Doubly exponential

33.3.4. Hybrid eager approaches

In §33.3.2 and §33.3.3, we have introduced two very distinct methods of deciding a linear arithmetic formula via translation to SAT. This naturally gives rise to the following question: Given a formula, which encoding technique should one use to decide *that* formula the fastest? This question is an instance of the automated algorithm selection problem.

On first glance, it might seem that the small-domain encoding would be best, since it avoids the potential exponential or doubly-exponential blowup in SAT problem size that the direct encoding can suffer in the worst case. However, this blowup is not always a problem because of the special structure of the generated SAT instance. The form of a transitivity constraint is $b_1 \wedge b_2 \implies b_3$ where b_1, b_2, b_3 are Boolean variables encoding linear constraints. If the polarities of these variables are chosen appropriately, the resulting constraint is either a Horn constraint or can be transformed into one by variable renaming. Thus, the overall SAT encoding is a “mostly-HornSAT” problem: i.e., the vast majority of clauses are Horn clauses. It has been observed for difference logic that the generated SAT problems are solved quickly in practice in spite of their large size [Ses05].

The question on the choice of encoding has been studied in the context of difference logic [Ses05]. It has been found that this question cannot be resolved entirely in favor of either method. One can select an encoding method based on formula characteristics using a rule generated by machine learning from past examples (formulas) [SLB03, Ses05]. Moreover, parts of a single formula corresponding to different variable classes can be encoded using different encoding methods. The resulting hybrid encoding algorithm has been empirically shown to be more robust to variation in formula characteristics than either of the two techniques in isolation [Ses05]. This hybrid algorithm is the first successful use of automated algorithm selection based on machine learning in SMT solvers.

33.3.5. Eager encoding for bit-vector arithmetic

The theory of fixed-width (finite-precision) bit-vector arithmetic naturally lends itself to the eager encoding approach. The obvious encoding to SAT involves replacing each bit-vector variable in the SMT formula by a vector of Boolean variables, and each bit-vector operator by a corresponding bit-level circuit implementation, thus reducing the original SMT formula to an equi-satisfiable Boolean formula. This approach is commonly termed *bit-blasting*. Bit-blasting remains a workhorse of SMT solving for bit-vector arithmetic, but it does not suffice to solve the more challenging bit-vector formulas. Therefore, researchers have devised several strategies for solving bit-vector formulas before resorting to bit-blasting, or to enhance the effectiveness of bit-blasting. The UCLID solver demonstrated the use of under-approximations of the domains of bit-vector variables (similar to small-domain encoding) and over-approximations of the bit-vector constraints (similar to a version of the direct encoding) to effectively solve bit-vector formulas [BKO⁺07]. The Beaver SMT solver [JLS09], developed in the UCLID project, uses a combination of event-driven bit-vector constraint propagation, specialized bit-vector rewrite rules, optimized encodings of non-linear bit-vector operations, and the use of logic optimization methods on the bit-blasted translations. Boolector [BB09] solves a combination of bit-vectors and arrays by combining rewrite rules, under-approximations, bit-blasting and on-demand checking of consistency with the theory of arrays. Boolector can also reason about combinations of bit-vectors, arrays, and lambda expressions using similar techniques [PNB15]. It has also been found that combining eager and lazy encoding approaches can be effective in the solving of bit-vector arithmetic [BKO⁺07, HBJ⁺14].

33.4. Integrating Theory Solvers into SAT Engines

The alternative to the eager approach, as described above, is the *lazy* approach in which efficient SAT solvers are integrated with decision procedures for first-order theories (or *Theory Solvers* or *T-solvers*) [AG93, WW99, ACG99, dMRS02, ABC⁺02, BDS02a, GHN⁺04, NO05c, YM06]). Systems based on this approach are called *lazy SMT solvers*, and include ArgoLib [MJ04], Ario [SS05], Barcelogic [NO05a], CVC3 [BT07], Fx7 [ML06], ICS [FORS01], MATHSAT [BBC⁺05a], Simplify [DNS03], TSAT++ [ACGM04], Verifun [FJOS03], YICES [DdM06a], and Z3 [dMB08].

33.4.1. Theory Solvers and their desirable features

In its simplest form, a theory solver for a theory \mathcal{T} (\mathcal{T} -solver) is a procedure which takes as input a collection of \mathcal{T} -literals μ and decides whether μ is \mathcal{T} -satisfiable. In order for a \mathcal{T} -solver to be effectively used within a lazy SMT solver, the following features are often important or even essential. In the following, we assume an SMT solver has been called on a \mathcal{T} -formula φ .

Model generation: when the \mathcal{T} -solver is invoked on a \mathcal{T} -consistent set μ , it is able to produce a \mathcal{T} -model \mathcal{I} witnessing the consistency of μ , i.e., $\mathcal{I} \models_{\mathcal{T}} \mu$.

Conflict set generation: when the \mathcal{T} -solver is invoked on a \mathcal{T} -inconsistent set μ , it is able to produce the (possibly minimal) subset η of μ which has caused its inconsistency. η is called a *theory conflict set* of μ .

Incrementality: the \mathcal{T} -solver “remembers” its computation status from one call to the next, so that, whenever it is given as input a set $\mu_1 \cup \mu_2$ such that μ_1 has just been proved \mathcal{T} -satisfiable, it avoids restarting the computation from scratch.

Backtrackability: it is possible for the \mathcal{T} -solver to undo steps and return to a previous state in an efficient manner.

Deduction of unassigned literals: when the \mathcal{T} -solver is invoked on a \mathcal{T} -consistent set μ , it can also perform deductions of the form $\eta \models_{\mathcal{T}} l$, where $\eta \subseteq \mu$ and l is a literal on a not-yet-assigned atom in φ .¹³

Deduction of interface equalities: when returning **Sat**, the \mathcal{T} -solver can also perform deductions of the form $\mu \models_{\mathcal{T}} e$ (if \mathcal{T} is convex) or $\mu \models_{\mathcal{T}} \bigvee_j e_j$ (if \mathcal{T} is not convex) where e, e_1, \dots, e_n are equalities between variables or terms occurring in atoms in μ . We call such equalities *interface equalities* and denote the interface equality ($v_i = v_j$) by e_{ij} . Deductions of interface equalities are also called *e_{ij} -deductions*. Notice that here the deduced equalities need not occur in the input formula φ .

\mathcal{T} -solvers will be discussed in more detail in §33.5.

33.4.2. A generalized DPLL schema

Different variants of lazy SMT procedures have been presented. Here we consider variants in which the Boolean abstraction φ^p of the input formula φ is fed into a DPLL-based SAT solver (henceforth referred to as a DPLL solver). Note that since most DPLL solvers accept only CNF, if φ^p has arbitrary Boolean structure, it is first converted into an equisatisfiable CNF formula using standard techniques (see Chapter 2).

In its simplest integration schema [BDS02a, dMRS02], called “*offline*” schema [FJOS03],¹⁴ the Boolean abstraction φ^p of the input formula is fed to a DPLL solver, which either decides that φ^p is unsatisfiable, and hence φ is \mathcal{T} -unsatisfiable, or it returns a satisfying assignment μ^p ; in the latter case, the set of literals μ

¹³Notice that, in principle, every \mathcal{T} -solver has deduction capabilities, as it is always possible to call \mathcal{T} -solver($\mu \cup \{-l\}$) for every unassigned literal l [ACG99]. We call this technique *plunging* [DNS03]. In practice, plunging is very inefficient.

¹⁴The offline approach is also called the “lemmas on demand” approach in [dMRS02].

```

1.  SatValue  $\mathcal{T}$ -DPLL ( $\mathcal{T}$ -formula  $\varphi$ ,  $\mathcal{T}$ -assignment &  $\mu$ ) {
2.      if ( $\mathcal{T}$ -preprocess( $\varphi, \mu$ ) == Conflict);
3.      return Unsat;
4.       $\varphi^p = \mathcal{T}2\mathcal{B}(\varphi)$ ;  $\mu^p = \mathcal{T}2\mathcal{B}(\mu)$ ;
5.      while (1) {
6.           $\mathcal{T}$ -decide_next_branch( $\varphi^p, \mu^p$ );
7.          while (1) {
8.              status =  $\mathcal{T}$ -deduce( $\varphi^p, \mu^p$ );
9.              if (status == Sat) {
10.                  $\mu = \mathcal{B}2\mathcal{T}(\mu^p)$ ;
11.                 return Sat; }
12.             else if (status == Conflict) {
13.                 blevel =  $\mathcal{T}$ -analyze_conflict( $\varphi^p, \mu^p$ );
14.                 if (blevel == 0)
15.                     return Unsat;
16.                 else  $\mathcal{T}$ -backtrack(blevel,  $\varphi^p, \mu^p$ );
17.             }
18.             else break;
19.         } } }

```

Figure 33.3. An online schema for \mathcal{T} -DPLL based on modern DPLL.

corresponding to μ^p is given as input to the \mathcal{T} -solver. If μ is found to be \mathcal{T} -consistent, then φ is \mathcal{T} -consistent. If not, $\neg\mu^p$ is added as a clause to φ^p , and the SAT solver is restarted from scratch on the resulting formula. Notice that here DPLL is used as a black-box.

In a more sophisticated schema [AG93, GS96, ACG99, WW99, ABC⁺02, FJOS03, GHN⁺04, BBC⁺06], called “*online*” [FJOS03], DPLL is modified to work directly as an enumerator of truth assignments, whose \mathcal{T} -satisfiability is checked by a \mathcal{T} -solver. This schema evolved from that of the DPLL-based procedures for modal logics (see Sections 32.3 and 32.4). Figure 33.3 shows an online \mathcal{T} -DPLL procedure based on a modern DPLL engine [ZMMM01, ZM02]. The inputs φ and μ are a \mathcal{T} -formula and a reference to an (initially empty) set of \mathcal{T} -literals respectively. The DPLL solver embedded in \mathcal{T} -DPLL reasons on and updates φ^p and μ^p , and \mathcal{T} -DPLL maintains some data structure encoding the set $Lits(\varphi)$ and the bijective mapping $\mathcal{T}2\mathcal{B}/\mathcal{B}2\mathcal{T}$ on literals.¹⁵

\mathcal{T} -preprocess simplifies φ into a simpler formula, and updates μ if necessary, so as to preserve the \mathcal{T} -satisfiability of $\varphi \wedge \mu$. If this process produces some conflict, then \mathcal{T} -DPLL returns Unsat. \mathcal{T} -preprocess combines most or all of the Boolean preprocessing steps of DPLL with some theory-dependent rewriting steps on the \mathcal{T} -literals of φ . (The latter are described in §33.4.3.1. and §33.4.3.2.)

\mathcal{T} -decide_next_branch selects the next literal to split on as in standard DPLL (but it may also take into consideration the semantics in \mathcal{T} of the literals being selected.)

\mathcal{T} -deduce, in its simplest version, behaves similarly to standard BCP in DPLL: it iteratively deduces Boolean literals l^p implied by the current assignment

¹⁵We implicitly assume that all functions called in \mathcal{T} -DPLL have direct access to $Lits(\varphi)$ and to $\mathcal{T}2\mathcal{B}/\mathcal{B}2\mathcal{T}$, and that both $\mathcal{T}2\mathcal{B}$ and $\mathcal{B}2\mathcal{T}$ require constant time for mapping each literal.

(i.e., s.t. $\varphi^p \wedge \mu^p \models_p l^p$, “ \models_p ” being propositional entailment) and updates φ^p and μ^p accordingly, until one of the following conditions occur:

- (i) μ^p propositionally violates φ^p ($\mu^p \wedge \varphi^p \models_p \perp$). If so, \mathcal{T} -deduce behaves like deduce in DPLL, returning Conflict.
- (ii) μ^p propositionally satisfies φ^p ($\mu^p \models_p \varphi^p$). If so, \mathcal{T} -deduce invokes the \mathcal{T} -solver on μ : if the latter returns Sat, then \mathcal{T} -deduce returns Sat; otherwise, \mathcal{T} -deduce returns Conflict.
- (iii) no more literals can be deduced. If so, \mathcal{T} -deduce returns Unknown. A slightly more elaborate version of \mathcal{T} -deduce can invoke the \mathcal{T} -solver on μ also at this intermediate stage: if the \mathcal{T} -solver returns Unsat, then \mathcal{T} -deduce returns Conflict. (This enhancement, called *early pruning*, is discussed in §33.4.3.3.)

A much more elaborate version of \mathcal{T} -deduce can be implemented if the \mathcal{T} -solver is able to perform deductions of unassigned literals. (This enhancement, called \mathcal{T} -propagation, is discussed in §33.4.3.4.)

\mathcal{T} -analyze_conflict is an extension of analyze_conflict of DPLL [ZM02, ZMMM01]: if the conflict produced by \mathcal{T} -deduce is caused by a Boolean failure (case (i) above), then \mathcal{T} -analyze_conflict produces a Boolean conflict set η^p and the corresponding value of `blevel` [ZMMM01, ZM02]; if instead the conflict is caused by a \mathcal{T} -inconsistency revealed by \mathcal{T} -solver (case (ii) or (iii) above), then the result of \mathcal{T} -analyze_conflict is the Boolean abstraction η^p of the theory conflict set $\eta \subseteq \mu$ produced by the \mathcal{T} -solver, or a mixed Boolean+theory conflict set computed by a backward-traversal of the implication graph starting from the conflicting clause $\neg\eta^p$ (see §33.4.3.5). If the \mathcal{T} -solver is not able to return a theory conflict set, the whole assignment μ may be used, after removing all Boolean literals from μ . Once the conflict set η^p and `blevel` have been computed, \mathcal{T} -backtrack behaves analogously to backtrack in DPLL: it adds the clause $\neg\eta^p$ to φ^p , either temporarily or permanently, and backtracks up to `blevel`. (These features, called \mathcal{T} -backjumping and \mathcal{T} -learning, are discussed in §33.4.3.5.)

\mathcal{T} -DPLL differs from the DPLL schema of [ZMMM01, ZM02] because it exploits:

- an extended notion of *deduction of literals*: not only *Boolean deduction* ($\mu^p \wedge \varphi^p \models_p l^p$), but also *theory deduction* ($\mu \models_{\mathcal{T}} l$);
- an extended notion of *conflict*: not only *Boolean conflicts* ($\mu^p \wedge \varphi^p \models_p \perp$), but also *theory conflicts* ($\mu \models_{\mathcal{T}} \perp$), or even *mixed Boolean+theory conflicts* ($(\mu \wedge \varphi) \models_{\mathcal{T}} \perp$). See §33.4.3.5.

Example 33.4.1. Consider the formulas φ and φ^p shown in Figure 33.4. Suppose \mathcal{T} -decide_next_branch selects, in order, $\mu^p := \{\neg B_5, B_8, B_6, \neg B_1\}$ (in c_4, c_7, c_6 , and c_1). \mathcal{T} -deduce cannot unit-propagate any literal. Assuming the enhanced version of step (iii), it invokes the \mathcal{T} -solver on $\mu := \{\neg(3x_1 - x_3 \leq 6), (x_3 = 3x_5 + 4), (x_2 - x_4 \leq 6), \neg(2x_2 - x_3 > 2)\}$. Suppose the enhanced \mathcal{T} -solver not only returns Sat, but also deduces $\neg(3x_1 - 2x_2 \leq 3)$ (c_3 and c_5) as a consequence of the first and last literals. The corresponding Boolean literal $\neg B_3$, is then added to μ^p and propagated (\mathcal{T} -propagation). As a result, A_1, A_2 and B_2 are unit-propagated from c_5, c_3 and c_2 .

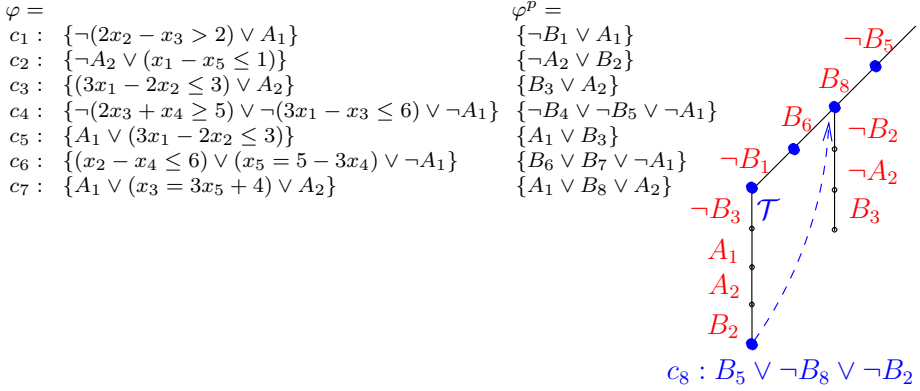

Figure 33.4. Boolean search (sub)tree in the scenario of Example 33.4.1. (A diagonal line, a vertical line and a vertical line tagged with “ \mathcal{T} ” denote literal selection, unit propagation and \mathcal{T} -propagation respectively; a bullet “ \bullet ” denotes a call to the \mathcal{T} -solver.)

Let μ^p be the resulting assignment $\{\neg B_5, B_8, B_6, \neg B_1, \neg B_3, A_1, A_2, B_2\}$. By step (iii), \mathcal{T} -deduce invokes the \mathcal{T} -solver on μ' : $\{\neg(3x_1 - x_3 \leq 6), (x_3 = 3x_5 + 4), (x_2 - x_4 \leq 6), \neg(2x_2 - x_3 > 2), \neg(3x_1 - 2x_2 \leq 3), (x_1 - x_5 \leq 1)\}$ which is inconsistent because of the 1st, 2nd, and 6th literals. As a result, the \mathcal{T} -solver returns *Unsat*, and hence \mathcal{T} -deduce returns *Conflict*. Next, \mathcal{T} -analyze_conflict and \mathcal{T} -backtrack learn the corresponding Boolean conflict clause

$$c_8 =_{def} B_5 \vee \neg B_8 \vee \neg B_2$$

and backtrack, popping from μ^p all literals up to $\{\neg B_5, B_8\}$, and then unit-propagating $\neg B_2$ on c_8 (\mathcal{T} -backjumping and \mathcal{T} -learning). Then, starting from $\{\neg B_5, B_8, \neg B_2\}$, $\neg A_2$ and B_3 are also unit-propagated (on c_2 and c_3 respectively).

As in standard DPLL, an excessive number of \mathcal{T} -learned clauses may cause an explosion in the size of φ . Thus, many lazy SMT tools introduce techniques for deleting \mathcal{T} -learned clauses when necessary. Moreover, like in standard DPLL, \mathcal{T} -DPLL can be *restarted* from scratch in order to avoid dead-end portions of the search space. The learned clauses prevent \mathcal{T} -DPLL from repeating the same steps twice. Most lazy SMT tools implement restarting mechanisms as well.

33.4.3. Enhancements to the schema

We describe some of the most effective techniques which have been proposed in order to optimize the interaction between the DPLL solver and the \mathcal{T} -solver. (We refer the reader to [Seb07] for a much more extensive and detailed survey.) Some of them derive from those developed in the context of DPLL-based procedures for modal logics (see Section 32.4.1).

33.4.3.1. Normalizing \mathcal{T} -atoms.

As discussed in Section 32.4.1, in order to avoid the generation of many trivially-unsatisfiable assignments, it is wise to preprocess \mathcal{T} -atoms so as to map as many as possible \mathcal{T} -equivalent literals into syntactically-identical ones. This can be achieved by applying some rewriting rules, like, e.g.:

- *Drop dual operators:* $(x_1 < x_2), (x_1 \geq x_2) \implies \neg(x_1 \geq x_2), (x_1 \geq x_2)$.
- *Exploit associativity:* $(x_1 + (x_2 + x_3) = 1), ((x_1 + x_2) + x_3) = 1 \implies (x_1 + x_2 + x_3 = 1)$.
- *Sort:* $(x_1 + x_2 - x_3 \leq 1), (x_2 + x_1 - 1 \leq x_3) \implies (x_1 + x_2 - x_3 \leq 1)$.
- *Exploit \mathcal{T} -specific properties:* $(x_1 \leq 3), (x_1 < 4) \implies (x_1 \leq 3)$ if x_1 represents an integer.

The applicability and effectiveness of these mappings depends on the theory \mathcal{T} .

33.4.3.2. Static learning

On some specific kinds of problems, it is possible to quickly detect *a priori* small and “obviously \mathcal{T} -inconsistent” sets of \mathcal{T} -atoms in φ (typically pairs or triplets). Some examples are:

- *incompatible values* (e.g., $\{x = 0, x = 1\}$),
- *congruence constraints* (e.g., $\{(x_1 = y_1), (x_2 = y_2), f(x_1, x_2) \neq f(y_1, y_2)\}$),
- *transitivity constraints* (e.g., $\{(x - y \leq 2), (y - z \leq 4), \neg(x - z \leq 7)\}$),
- *equivalence constraints* (e.g., $\{(x = y), (2x - 3z \leq 3), \neg(2y - 3z \leq 3)\}$).

If so, the clauses obtained by negating the literals in such sets (e.g., $\neg(x = 0) \vee \neg(x = 1)$) can be added to the formula before the search starts. Then, whenever all but one of the literals in the set are assigned to true, the negation of the remaining literal is assigned deterministically by unit propagation. This prevents the solver from generating any assignment which include the inconsistent set. This technique may significantly reduce the Boolean search space, and hence the number of calls to the \mathcal{T} -solver, producing significant speed-ups [ACG99, ACKS02, BBC⁺05a, YM06].

Intuitively, one can think of static learning as suggesting some small and “obvious” \mathcal{T} -valid lemmas relating some \mathcal{T} -atoms of φ , which drive DPLL in its Boolean search. Notice that, unlike the extra clauses added in “per-constraint” eager approaches [SSB02, SLB03] (see §33.3), the clauses added by static learning refer only to atoms which *already occur in the original formula*, so that the Boolean search space is not enlarged. Notice also that these clauses are not needed for correctness or completeness: rather, they are used only for pruning the Boolean search space.

33.4.3.3. Early pruning

Another optimization, here generically called *early pruning* – *EP*,¹⁶ is to introduce intermediate calls to the \mathcal{T} -solver while an assignment μ is still under construction (in the \mathcal{T} -DPLL scheme of §33.4.2, this corresponds to the “slightly more

¹⁶Also called *intermediate assignment checking* in [GS96] and *eager notification* in [BDS02a].

elaborate version” of step (iii) of \mathcal{T} -deduce). If \mathcal{T} -solver(μ) returns **Unsat**, then all possible extensions of μ are unsatisfiable, so \mathcal{T} -DPLL can immediately return **Unsat** and backtrack, possibly avoiding a very large amount of useless search.

In general, EP may dramatically reduce the Boolean search space, and hence of the number of calls to the \mathcal{T} -solver. Unfortunately, as EP may cause useless calls to the \mathcal{T} -solver, the benefits of the pruning effect may be partly counterbalanced by the overhead introduced by the extra calls. Many different improvements to EP and strategies for interleaving calls to the \mathcal{T} -solver with Boolean reasoning steps have been proposed [WW99, SBD02, GHN⁺04, ABC⁺02, ACGM04, NO05c, BBC⁺05b, CM06a].

33.4.3.4. \mathcal{T} -propagation

As discussed in §33.4.1, for some theories it is possible to implement the \mathcal{T} -solver so that a call to \mathcal{T} -solver(μ) returning **Sat** can also perform one or more deduction(s) of the form $\eta \models_{\mathcal{T}} l$, where $\eta \subseteq \mu$ and l is a literal on an unassigned atom in φ . If this is the case, then the \mathcal{T} -solver can return l to \mathcal{T} -DPLL, so that l^p is added to μ^p and unit-propagated [ACG99, ABC⁺02, GHN⁺04, NO05c]. This process, which is called \mathcal{T} -propagation,¹⁷ may result in new literals being assigned, leading to new calls to the \mathcal{T} -solver, followed by additional new assignments being deduced, and so on, so that together, \mathcal{T} -propagation and unit propagation may produce a much larger benefit than either of them alone. As with early-pruning, there are different strategies by which \mathcal{T} -propagation can be interleaved with unit-propagation [ACG99, ABC⁺02, GHN⁺04, BBC⁺05a, NO05c, CM06a, NOT06].

Notice that when the \mathcal{T} -solver deduces $\eta \models_{\mathcal{T}} l$, it can return this deduction to \mathcal{T} -DPLL, which can then add the \mathcal{T} -deduction clause ($\eta^p \rightarrow l^p$) to φ^p , either temporarily or permanently. The \mathcal{T} -deduction clause can be used during the rest of the search, with benefits analogous to those of \mathcal{T} -learning (see §33.4.3.5).

33.4.3.5. \mathcal{T} -backjumping and \mathcal{T} -learning

As hinted in §33.4.2, we assume that, when the \mathcal{T} -solver is invoked on a \mathcal{T} -inconsistent assignment μ , it is able to return also the conflict set $\eta \subseteq \mu$ causing the \mathcal{T} -unsatisfiability of μ (see §33.4.1). If so, \mathcal{T} -DPLL can use η^p as if it were a Boolean conflict set to drive the backjumping and learning mechanism of DPLL: the conflict clause $\neg\eta^p$ is added to φ^p either temporarily or permanently (\mathcal{T} -learning) and the procedure backtracks to the branching point suggested by η^p (\mathcal{T} -backjumping) [Hor98, PS98, WW99, dMRS02, SBD02, ABC⁺02, GHN⁺04, BBC⁺05a]. Modern implementations inherit the backjumping mechanism of current DPLL tools: \mathcal{T} -DPLL learns the conflict clause $\neg\eta^p$ and backtracks to the highest point in the stack where one $l^p \in \eta^p$ is not assigned, and unit propagates $\neg l^p$ on $\neg\eta^p$. Intuitively, DPLL backtracks to the highest point where it would have done something different if it had known in advance the conflict clause $\neg\eta^p$ from the \mathcal{T} -solver.

As hinted in §33.4.2, it is possible to use either a theory conflict set η (i.e., $\neg\eta$ is a \mathcal{T} -valid clause) or a *mixed Boolean+theory conflict set* η' , i.e., a set η'

¹⁷Also called *forward reasoning* in [ACG99], *enhanced early pruning* in [ABC⁺02], *theory propagation* in [NOT05, NO05c], and *theory-driven deduction* or \mathcal{T} -deduction in [BBC⁺05a].

s.t. an inconsistency can be derived from $\eta' \wedge \varphi$ by means of a combination of Boolean and theory reasoning ($\eta' \wedge \varphi \models_{\mathcal{T}} \perp$). Such conflict sets/clauses can be obtained starting from the theory conflict clause $\neg\eta^p$ by backward-traversal of the implication graph, until one of the standard conditions (e.g., 1UIP) is achieved. Notice that it is possible to learn *both* clauses $\neg\eta$ and $\neg\eta'$.

Example 33.4.2. The scenario depicted in Example 33.4.1 represents a form of \mathcal{T} -backjumping and \mathcal{T} -learning, in which the conflict clause c_8 is a $\mathcal{T}_{\mathcal{R}}$ -conflict clause (i.e., $\mathcal{B}2\mathcal{T}(c_8)$ is $\mathcal{T}_{\mathcal{R}}$ -valid). However, \mathcal{T} -analyze_conflict could instead look for a mixed Boolean+theory conflict clause by treating c_8 as a conflicting clause and backward-traversing the implication graph. This is done by starting with c_8 and performing resolution with each of the clauses that triggered the assignments leading to the conflict, but in the reverse order that the assignments occurred (in this case, clauses c_2 and c_3 , the antecedent clauses of B_2 and A_2 respectively, and the \mathcal{T} -deduction clause c_9 which “caused” the propagation of $\neg B_3$):

$$\begin{array}{c}
 c_8: \text{theory conflicting clause} \\
 \frac{\overbrace{B_5 \vee \neg B_8 \vee \neg B_2} \quad \overbrace{\neg A_2 \vee B_2}^{c_2}}{B_5 \vee \neg B_8 \vee \neg A_2} \quad \overbrace{B_3 \vee A_2}^{c_3}}{B_5 \vee \neg B_8 \vee B_3} \quad \overbrace{B_5 \vee B_1 \vee \neg B_3}^{c_9}}{B_5 \vee \neg B_8 \vee B_1} \\
 c'_8: \text{mixed Boolean+theory conflict clause}
 \end{array}$$

The result is the mixed Boolean+theory conflict clause $c'_8 : B_5 \vee \neg B_8 \vee B_1$. (Notice that, $\mathcal{B}2\mathcal{T}(c'_8) = (3x_1 - x_3 \leq 6) \vee \neg(x_3 = 3x_5 + 4) \vee (2x_2 - x_3 > 2)$ is not $\mathcal{T}_{\mathcal{R}}$ -valid.) If c'_8 is chosen, then \mathcal{T} -backtrack pops from μ^p all literals up to $\{\neg B_5, B_8\}$, and then unit-propagates B_1 on c'_8 , and hence A_1 on c_1 .

As with static learning, the clauses added by \mathcal{T} -learning refer only to atoms which already occur in the original formula, so that no new atom is added. [FJOS03] proposed an interesting generalization of \mathcal{T} -learning, in which learned clause may contain also new atoms. [BBC⁺05c, BBC⁺06] used a similar idea to improve the efficiency of Delayed Theory Combination (see §33.6.3). [WGG06] proposed similar ideas for a SMT tool for difference logic, in which new atoms can be generated selectively according to an ad-hoc heuristic.

33.4.3.6. Generating partial assignments

Due to the two-watched-literal scheme [MMZ⁺01], in modern implementations, DPLL returns Sat only when all variables are assigned truth values, thus returning *total* assignments. Thus, when a *partial* assignment μ is found which satisfies φ , this causes an unnecessary sequence of decisions and unit-propagations for assigning the remaining variables. In SAT, this scenario causes no extra Boolean search, because every extension of μ propositionally satisfies φ , so the overhead introduced is negligible. In SMT, however, many total assignments extending μ may be \mathcal{T} -inconsistent even though μ is \mathcal{T} -consistent, so that many useless Boolean branches and calls to \mathcal{T} -solvers may be required.

In order to overcome these problems, it is sufficient to implement some device monitoring the satisfaction of all original clauses in φ . Although this may cause some overhead in handling the Boolean component of reasoning, it may also reduce the overall Boolean search space and hence the number of subsequent calls to the \mathcal{T} -solver.

33.4.3.7. Pure-literal filtering

If we have non-Boolean \mathcal{T} -atoms occurring only positively [resp. negatively] in the input formula, we can safely drop every negative [resp. positive] occurrence of them from an assignment μ whenever μ is to be checked by the \mathcal{T} -solver [WW99, GGT01, ABC⁺02, BBC⁺05b, Seb07].¹⁸ We call this technique *pure-literal filtering*.¹⁹

There are a couple of potential benefits of this behavior. Let μ' be the filtered version of μ . First, μ' might be \mathcal{T} -satisfiable despite μ being \mathcal{T} -unsatisfiable. If so, and if μ (and hence μ') propositionally satisfies φ , then \mathcal{T} -DPLL can stop, potentially saving a lot of search. Second, if μ' (and hence μ) is \mathcal{T} -unsatisfiable, then checking the consistency of μ' rather than that of μ can be faster and result in smaller conflict sets, improving the effectiveness of \mathcal{T} -backjumping and \mathcal{T} -learning.

Moreover, this technique is particularly useful in some situations. For instance, many \mathcal{T} -solvers for $\mathcal{T}_{\mathcal{Z}}$ and its difference logic fragment cannot efficiently handle disequalities, so that they are forced to split them into a disjunction of strict inequalities. For example, the disequality $(x_1 - x_2 \neq 3)$ would be replaced by $(x_1 - x_2 > 3) \vee (x_1 - x_2 < 3)$. This causes an enlargement of the search, because the two disjuncts must be investigated separately. In many problems, however, it is common for most equalities to $(t_1 = t_2)$ occur with positive polarity only. For such equalities, pure-literal filtering avoids adding $(t_1 \neq t_2)$ to μ when $(t_1 = t_2)^p$ is assigned to false by \mathcal{T} -DPLL, so that no split is needed [ABC⁺02].

33.4.4. An abstract framework

The DPLL procedure and its variants and extensions, including \mathcal{T} -DPLL, can also be described more abstractly as transition systems. This allows one to ignore unimportant control and implementation details and provide the essence of each variant in terms of a set of state transition rules and a rule application strategy.

Following the *Abstract DPLL Modulo Theories* framework first introduced in [NOT05], the variants of \mathcal{T} -DPLL discussed in the previous subsection can be described abstractly as a transition relation over states of the form Fail or $\mu \parallel \varphi$, where φ is a (ground) CNF formula, or, equivalently, a finite set of clauses, and μ is a *sequence* of (ground) literals, each marked as a *decision* or a non-decision literal. As in §33.4.1, the set μ represents a partial assignment of truth values to the atoms of φ . The transition relation is specified by a set of *transition rules*, given below. In the rules, we denote the concatenation of sequences of literals

¹⁸If both \mathcal{T} -propagation and pure-literal filtering are implemented, then the filtered literals must be dropped not only from the assignment, but also from the list of literals which can be \mathcal{T} -deduced, so that to avoid the \mathcal{T} -propagation of literals which have been filtered away.

¹⁹Also called *triggering* in [WW99, ABC⁺02].

by simple juxtaposition (e.g., $\mu \mu' \mu''$), treating single literals as one element sequences and denoting the empty sequence with \emptyset . To denote that a literal l is annotated as a decision literal in a sequence we write it as l^\bullet . A literal l is *undefined* in μ if neither l nor $\neg l$ occurs in μ . We write $S \Longrightarrow S'$ as usual to mean that two states S and S' are related by the transition relation \Longrightarrow and say that there is a *transition* from S to S' . We call any sequence of transitions of the form $S_0 \Longrightarrow S_1 \Longrightarrow S_2 \Longrightarrow \dots$ a *derivation*.

Definition 33.4.3 (Transition Rules). The following is a set of rules for *Abstract \mathcal{T} -DPLL*. Except for **Decide**, all the rules that introduce new literals annotate them as non-decision literals.

$$\text{Propagate : } \mu \parallel \varphi, c \vee l \Longrightarrow \mu l \parallel \varphi, c \vee l \text{ if } \begin{cases} \mu \models_p \neg c \\ l \text{ is undefined in } \mu \end{cases}$$

$$\text{Decide : } \mu \parallel \varphi \Longrightarrow \mu l^\bullet \parallel \varphi \text{ if } \begin{cases} l \text{ or } \neg l \text{ occurs in } \varphi \\ l \text{ is undefined in } \mu \end{cases}$$

$$\text{Fail : } \mu \parallel \varphi, c \Longrightarrow \text{Fail} \text{ if } \begin{cases} \mu \models_p \neg c \\ \mu \text{ contains no decision literals} \end{cases}$$

$$\text{Restart : } \mu \parallel \varphi \Longrightarrow \emptyset \parallel \varphi$$

$$\mathcal{T}\text{-Propagate : } \mu \parallel \varphi \Longrightarrow \mu l \parallel \varphi \text{ if } \begin{cases} \mu \models_{\mathcal{T}} l \\ l \text{ or } \neg l \text{ occurs in } \varphi \\ l \text{ is undefined in } \mu \end{cases}$$

$$\mathcal{T}\text{-Learn : } \mu \parallel \varphi \Longrightarrow \mu \parallel \varphi, c \text{ if } \begin{cases} \text{each atom of } c \text{ occurs in } \mu \parallel \varphi \\ \varphi \models_{\mathcal{T}} c \end{cases}$$

$$\mathcal{T}\text{-Forget : } \mu \parallel \varphi, c \Longrightarrow \mu \parallel \varphi \text{ if } \{ \varphi \models_{\mathcal{T}} c \}$$

\mathcal{T} -Backjump :

$$\mu l^\bullet \mu' \parallel \varphi, c \Longrightarrow \mu k \parallel \varphi, c \text{ if } \begin{cases} \mu l^\bullet \mu' \models_p \neg c, \text{ and there is} \\ \text{some clause } c' \vee l' \text{ such that:} \\ \varphi, c \models_{\mathcal{T}} c' \vee l' \text{ and } \mu \models_p \neg c', \\ l' \text{ is undefined in } \mu, \text{ and} \\ l \text{ or } \neg l \text{ occurs in } \mu l^\bullet \mu' \parallel \varphi \end{cases}$$

The clauses c and $c' \vee l'$ in the \mathcal{T} -Backjump rule are respectively the *conflicting* clause and the *backjump* clause of the rule.

The rules **Propagate**, **Decide**, **Fail** and **Restart**, operate at the propositional level. The other rules involve the theory \mathcal{T} and have rather general preconditions. While all of these preconditions are decidable whenever the \mathcal{T} -satisfiability of sets of ground literals is decidable, they might be expensive to check in their full generality.²⁰ However, there exist restricted applications of these rules that are both efficient and enough for completeness [NOT06]. Given a ground CNF formula φ , the purpose of the rules above is to extend and modify an originally empty sequence until it determines a total, satisfying assignment for φ or the **Fail** rule becomes applicable.

²⁰In particular, the precondition of \mathcal{T} -Backjump seems problematic on a first look because it relies on the computability of the backjump clause $c' \vee l'$.

Example 33.4.4. The computation discussed in Example 33.4.2 can be described by the following derivation in Abstract \mathcal{T} -DPLL, where φ is again the formula consisting of the $\mathcal{T}_{\mathcal{R}}$ -clauses c_1, \dots, c_7 in Figure 33.4 and c_8 is the clause abstracted by $B_5 \vee \neg B_8 \vee \neg B_2$. For space constraints, instead of φ 's literals we use their propositional abstraction here, and use \Longrightarrow^+ to denote multiple transitions.

1–4.	$\emptyset \parallel \varphi \Longrightarrow^+$	$\neg B_5 \bullet B_8 \bullet B_6 \bullet \neg B_1 \bullet \parallel \varphi$	(by Decide)
5.	\Longrightarrow	$\neg B_5 \bullet B_8 \bullet B_6 \bullet \neg B_1 \bullet \neg B_3 \parallel \varphi$	(by \mathcal{T} -Propagate)
6–8.	\Longrightarrow^+	$\neg B_5 \bullet B_8 \bullet B_6 \bullet \neg B_1 \bullet \neg B_3 A_1 A_2 B_2 \parallel \varphi$	(by Propagate)
9.	\Longrightarrow	$\neg B_5 \bullet B_8 \bullet B_6 \bullet \neg B_1 \bullet \neg B_3 A_1 A_2 B_2 \parallel \varphi, c_8$	(by \mathcal{T} -Learn)
10.	\Longrightarrow	$\neg B_5 \bullet B_8 \bullet B_1 \parallel \varphi, c_8$	(by \mathcal{T} -Backjump)
11.	\Longrightarrow	$\neg B_5 \bullet B_8 \bullet B_1 A_1 \parallel \varphi, c_8$	(by Propagate)

Recall that clause c_8 in Step 9 is a theory lemma added in response to the \mathcal{T} -inconsistency of the assignment produced by Step 8. In step 10, \mathcal{T} -Backjump is applied with conflicting clause $c = c_8$ and backjump clause $c' \vee l' = B_5 \vee \neg B_8 \vee B_1$ with $l' = B_1$. The backjump clause is derived as explained in Example 33.4.2.

Let us say that a state is \mathcal{T} -compatible if it is *Fail* or has the form $\mu \parallel \varphi$ where μ is \mathcal{T} -consistent. The transition rules can be used to decide the \mathcal{T} -satisfiability of an input formula φ_0 by generating a derivation

$$\emptyset \parallel \varphi_0 \Longrightarrow_{\mathcal{B}} S_1 \Longrightarrow_{\mathcal{B}} \dots \Longrightarrow_{\mathcal{B}} S_n, \quad (33.1)$$

where S_n is a \mathcal{T} -compatible state to which none of the rules *Propagate*, *Decide*, *Fail*, or *\mathcal{T} -Backjump* applies. We call such a derivation *exhausted*.

To generate from $\emptyset \parallel \varphi_0$ only derivations like (33.1) above it is enough to impose a few, rather weak, restrictions on a rule application strategy. Roughly speaking, these restrictions rule out only derivations with subderivations consisting exclusively of \mathcal{T} -Learn and \mathcal{T} -Forget steps, and derivations that do not apply *Restart* with increased periodicity.²¹

A rule application strategy is *fair* if it conforms to these restrictions and stops (extending) a derivation only when the derivation is exhausted. Every fair strategy is *terminating*, *sound*, and *complete* in the following sense (see [NOT06] for details).

Termination: Starting from a state $\emptyset \parallel \varphi_0$, the strategy generates only finite derivations.

Soundness: If φ_0 is \mathcal{T} -satisfiable, every exhausted derivation of $\emptyset \parallel \varphi_0$ generated by the strategy ends with a state of the form $\mu \parallel \varphi$ where μ is a (\mathcal{T} -consistent) total, satisfying assignment for φ .

Completeness: If φ_0 is not \mathcal{T} -satisfiable, every exhausted derivation of $\emptyset \parallel \varphi_0$ generated by the strategy ends with *Fail*.

In the setting above, fair strategies stop a derivation for a \mathcal{T} -satisfiable φ_0 only once they compute a *total* assignment for φ_0 's atoms. A more general setting can be obtained, with similar results, by defining a finite derivation to be exhausted if its last state is \mathcal{T} -compatible and, when the state is $\mu \parallel \varphi$, the assignment μ

²¹In fact, the actual restrictions are even weaker. See Theorem 3.7 of [NOT06] for details.

propositionally satisfies φ . We refer back to the discussion in §33.4.3.6 for why this can be more convenient computationally.

The rule set in Definition 33.4.3 is not minimal. For instance, there are fair strategies that use only \mathcal{T} -Propagate or only \mathcal{T} -Learn in addition to Decide, Fail, Propagate and \mathcal{T} -Backjump. The rule set is not exhaustive either because it models only the most common (and experimentally most useful) operations found in lazy SMT solvers. We explain how below, focusing on the less trivial rules.

Decide. This rule represents a case split by adding an undefined literal of φ , or its negation, to μ . The added literal l is annotated as a *decision literal*, to denote that if μl cannot be extended to a model of φ then an alternative extension of μ must be considered—something done with the \mathcal{T} -Backjump rule.²²

\mathcal{T} -Propagate. This rule performs the kind of theory propagation described in §33.4.3.4 by adding to the current assignment μ any undefined literal l that is \mathcal{T} -entailed by μ . The rule's precondition maintains the invariant that every atom in an assignment occurs in the initial formula of the derivation. This invariant is crucial for termination.

\mathcal{T} -Backjump. This rule models the kind of *conflict-driven* backjumping described in §33.4.3.5. As defined, the rule is only triggered by a propositional conflict with one of the current clauses ($\mu \models_p \neg c$). This is for simplicity and uniformity, and without loss of generality thanks to the \mathcal{T} -Propagate and \mathcal{T} -Learn rules. Using those rules, any conflict involving the theory \mathcal{T} is reducible to a propositional conflict. For instance, if the current assignment μ has a \mathcal{T} -inconsistent subset η , then $\emptyset \models_{\mathcal{T}} \neg\eta$. The theory lemma $\neg\eta$ can then be added to the current clause set φ by one application of \mathcal{T} -Learn and then play the role of clause c in \mathcal{T} -Backjump.

\mathcal{T} -Backjump is triggered by the existence of a conflicting clause, but in order to undo (the effect of) an earlier decision step it needs a backjump clause $c' \vee l'$, which synthesizes the reason of the conflict, indicating the level to backjump to and the literal to put in place of the decision literal for that level. This clause is the dual of the conflict set η discussed in §33.4.3.5; that is, $c' \vee l' = \neg\eta$.

\mathcal{T} -Learn. This rule allows the addition to the current formula φ of an arbitrary clause c that is \mathcal{T} -entailed by φ and consists of atoms in the current state. It can be used to model the static learning techniques described in §33.4.3.2 as well as the usual conflict-driven lemma learning that adds backjump clauses, or any other technique that takes advantage of theory consequences of φ . In particular, it can be used to model uniformly all the early pruning techniques described in §33.4.3.3. This is because any backjumping motivated by the \mathcal{T} -inconsistency of the current assignment μ can be modeled as the discovery and learning of a theory lemma c that is propositionally falsified by μ , followed by an application of \mathcal{T} -Backjump with c as the conflicting clause. The rule does not model the learning of clauses containing *new* literals, which is done by some SMT solvers, as seen in

²²Note that the precondition of Decide does not include a check on whether Propagate, say, applies to l or its negation. This is intentional since such control considerations are best left to a rule application strategy.

§33.4.3.5. An extension of Abstract \mathcal{T} -DPLL that allows that is discussed later in §33.5.2.

We can now describe some of the approaches for implementing \mathcal{T} -DPLL solvers discussed in §33.4.2 in terms of Abstract \mathcal{T} -DPLL. (See [NOT06] for more details.)

Offline integrations of a theory solver and a DPLL solver are modeled by a class of rule application strategies that do not use the \mathcal{T} -Propagate rule. Whenever a strategy in this class produces a state $\mu \parallel \varphi$ irreducible by Decide, Fail, Propagate, or \mathcal{T} -Backjump, the sequence μ is a satisfying assignment for the formula φ_0 in the initial state $\emptyset \parallel \varphi_0$, but it may not be \mathcal{T} -consistent. If it is not, there exists a $\eta \subseteq \mu$ such that $\emptyset \models_{\mathcal{T}} \neg\eta$. The strategy then adds the theory lemma $\neg\eta$ (the blocking clause) with one \mathcal{T} -Learn step and applies Restart, repeating the same cycle above until a \mathcal{T} -compatible state is generated. With an incremental \mathcal{T} -solver it might be more convenient to check the \mathcal{T} -consistency of μ in a state $\mu \parallel \varphi$ even if the state is reducible by one of the four rules above. In that case, it is possible to learn a blocking clause and restart earlier. Strategies like these are sound and complete. To be fair, and so terminating, they must not remove (with \mathcal{T} -Forget) any blocking clause.

A strategy can take advantage of an online SAT-solver by preferring backjumping to systematic restarting after μ is found \mathcal{T} -inconsistent. This is done by first learning a lemma $\neg\eta$ for some $\eta \subseteq \mu$, and then *repairing* μ using that lemma. In fact, since $\neg\eta$ is a conflicting clause by construction, either \mathcal{T} -Backjump or Fail applies—depending respectively on whether μ contains decision literals or not. To be fair, strategies that apply \mathcal{T} -Backjump/Fail instead of Restart do not need to keep the blocking clause once they use it as the conflicting clause for backjumping.

Any fair strategy above remains fair if it is modified to interleave arbitrary applications of \mathcal{T} -Propagate. Stronger results are possible if \mathcal{T} -Propagate is applied eagerly (in concrete, if it has higher priority than Decide). In that case, it is impossible to generate \mathcal{T} -inconsistent assignments, and so it is unnecessary for correctness to learn any blocking clauses, or any theory lemmas at all.

33.5. Theory Solvers

The lazy approach to SMT as described above relies on combining a SAT solver with a *theory solver* for some theory \mathcal{T} . The role of the theory solver is to accept a set of literals and report whether the set is \mathcal{T} -satisfiable or not. Typically, theory solvers are *ad hoc*, with specialized decision procedure tailored to the theory in question. For details on such procedures for some common theories, we refer the reader to the references given in §33.2.2. Because different theories often share some characteristics, a natural question is whether there exist general or parameterized methods that have broader applicability. This section discusses several such approaches that have been developed: Shostak's method (§33.5.1), splitting on demand (§33.5.2), layered theory solvers (§33.5.3), and rewriting-based theory solvers (§33.5.4).

33.5.1. Shostak's method

Shostak's method was introduced in a 1984 paper [Sho84] as a general method for combining the theory of equality with one or more additional theories that satisfy certain specific criteria. The original paper lacks rigor and contains serious errors, but work since then has shed considerable light on the original claims [CLS96, RS01, SR02, KC03, BDS02b, Gan02]. We summarize some of the most significant results here. We start with some definitions.

Definition 33.5.1. A set \mathcal{S} of equations is said to be in *solved form* iff the left-hand side of each equation in \mathcal{S} is a ground constant which appears only once in \mathcal{S} . We will refer to these constants appearing only on the left-hand sides as *solitary* constants.

A set \mathcal{S} of equations in solved form defines an idempotent substitution: the one which replaces each solitary constant with its corresponding right-hand side. If S is a term or set of terms, we denote the result of applying this substitution to S by $\mathcal{S}(S)$.

Definition 33.5.2. Given a formula F and a formula G , we define $\gamma_F(G)$ as follows:

1. Let G' be the formula obtained by replacing each free constant symbol in G that does not appear in F with a fresh variable.
2. Let \bar{v} be the set of all fresh variables introduced in the previous step.
3. Then, $\gamma_F(G) = \exists \bar{v}. G'$.

Definition 33.5.3. A consistent theory \mathcal{T} with signature Σ is a *Shostak* theory if the following conditions hold.

1. Σ does not contain any predicate symbols.
2. There exists a *canonizer* *canon*, a computable function from Σ -terms to Σ -terms, with the property that $\models_{\mathcal{T}} s = t$ iff $\text{canon}(s) \equiv \text{canon}(t)$.
3. There exists a *solver* *solve*, a computable function from Σ -equations to sets of formulas defined as follows:
 - (a) If $\models_{\mathcal{T}} s \neq t$, then $\text{solve}(s = t) \equiv \{\perp\}$.
 - (b) Otherwise, $\text{solve}(s = t)$ returns a set \mathcal{S} of equations in solved form such that $\models_{\mathcal{T}} (s = t) \leftrightarrow \gamma_{s=t}(\mathcal{S})$.

The main result in Shostak's paper is that given a Shostak theory \mathcal{T} , a simple algorithm can be used to determine the satisfiability of conjunctions of Σ -literals. Algorithm *S1* (shown in Figure 33.5) makes use of the properties of a Shostak theory to check the joint satisfiability of an arbitrary set of equalities, Γ , and an arbitrary set of disequalities, Δ , in a Shostak theory with canonizer *canon* and solver *solve*.

Algorithm *S1* is sound and complete whenever Δ contains at most one disequality or if \mathcal{T} satisfies the additional requirement of being convex (as defined in §33.2.1.2).

```

S1( $\Gamma$ ,  $\Delta$ , canon, solve)
1.  $\mathcal{S} := \emptyset$ ;
2. WHILE  $\Gamma \neq \emptyset$  DO BEGIN
3.   Remove some equality  $s = t$  from  $\Gamma$ ;
4.    $s^* := \mathcal{S}(s)$ ;  $t^* := \mathcal{S}(t)$ ;
5.    $\mathcal{S}^* := \text{solve}(s^* = t^*)$ ;
6.   IF  $\mathcal{S}^* = \{ \perp \}$  THEN RETURN FALSE;
7.    $\mathcal{S} := \mathcal{S}^*(\mathcal{S}) \cup \mathcal{S}^*$ ;
8. END
9. IF canon( $\mathcal{S}(s)$ )  $\equiv$  canon( $\mathcal{S}(t)$ ) for some  $s \neq t \in \Delta$  THEN RETURN FALSE;
10. RETURN TRUE;

```

Figure 33.5. Algorithm S1: A simple satisfiability checker based on Shostak's algorithm

Example 33.5.4. Perhaps the most obvious example of a Shostak theory is $T'_{\mathcal{R}}$. A simple canonizer for this theory can be obtained by imposing an order on all ground constants and combining like terms. For example, $\text{canon}(c + 3b - a - 5c) \equiv -a + 3b + (-4c)$. Similarly, a solver can be obtained simply by solving for one of the constants in an equation (returning \perp if no solution exists). For this theory, Algorithm *S1* corresponds to Gaussian elimination with back-substitution. Consider the following set of literals: $\{a + 3b - 2c = 1, a - b - 6c = 1, b + a \neq a - c\}$. The following table shows the values of Γ , \mathcal{S} , $s^* = t^*$, and \mathcal{S}^* on each iteration of Algorithm *S1* starting with $\Gamma = \{a + 3b - 2c = 1, a - b - 6c = 1\}$:

Γ	\mathcal{S}	$s^* = t^*$	\mathcal{S}^*
$a + 3b - 2c = 1$ $a - b - 6c = 1$	\emptyset	$a + 3b - 2c = 1$	$a = 1 - 3b + 2c$
$a - b - 6c = 1$	$a = 1 - 3b + 2c$	$1 - 3b + 2c - b - 6c = 1$	$b = -c$
\emptyset	$a = 1 + 5c$ $b = -c$		

Now, notice that $\text{canon}(\mathcal{S}(b + a)) \equiv \text{canon}(-c + 1 + 5c) \equiv 1 + 4c$ and $\text{canon}(\mathcal{S}(a - c)) \equiv \text{canon}(1 + 5c - c) \equiv 1 + 4c$. Since $b + a \neq a - c \in \Delta$, the algorithm returns FALSE indicating that the original set of literals is unsatisfiable in \mathcal{T} .

33.5.1.1. Combining Shostak theories

Besides providing a satisfiability procedure for a single Shostak theory \mathcal{T} , the original paper makes several additional claims. The first is that a variation of Algorithm *S1* can be used to decide the satisfiability of any theory \mathcal{T}' , where \mathcal{T}' is the extension of \mathcal{T} after adding an arbitrary number of constant and function symbols. In other words, there is an algorithm for the *combination* of \mathcal{T} with the theory of equality. This claim has been clarified and proved to be correct in later work [RS01, Gan02], and we do not elaborate on it here.

The second claim regarding combinations of theories is that given any two Shostak theories, their canonizers and solvers can be combined to obtain a decision procedure for the combined theories. While it is true that canonizers can be

combined (see [KC03, SR02]), it was shown in [KC03] that solvers can almost never be combined, and thus Shostak’s method as originally presented does not provide a way to combine theories (beyond simple combinations of a single Shostak theory with the theory of equality). In [SR02], a correct method for combining Shostak theories is given. However, the method does not combine theory solvers as proposed by Shostak, but relies, instead, on the Nelson-Oppen framework covered in §33.6.1.

33.5.2. Splitting on demand

Thus far, we have assumed that a theory solver \mathcal{T} -solver for a theory \mathcal{T} takes as input a set of literals and outputs true if the set is \mathcal{T} -consistent and false otherwise. For some important theories, determining the \mathcal{T} -consistency of a conjunction of literals requires *internal* case splitting (i.e. case splitting within the \mathcal{T} -solver).

Example 33.5.5. In the theory $\mathcal{T}_{\mathcal{A}}$ of arrays introduced in §33.2.2, consider the following set of literals: $read(write(A, i, v), j) = x, read(A, j) = y, x \neq v, x \neq y$. To see that this set is unsatisfiable, notice that if $i = j$, then $x = v$ because the value read should match the value written in the first equation. On the other hand, if $i \neq j$, then $x = read(A, j)$ and thus $x = y$. Deciding the $\mathcal{T}_{\mathcal{A}}$ -consistency of larger sets of literals may require a significant amount of such reasoning by cases.

Because theories like $\mathcal{T}_{\mathcal{A}}$ require internal case splits, solving problems with general Boolean structure over such theories using the framework developed in §33.4 results in a system where case splitting occurs in two places: in the Boolean DPLL (SAT) engine as well as inside the theory solver. In order to simplify the implementation of theory solvers for such theories, and to centralize the case splitting in a single part of the system, it is desirable to allow a theory solver \mathcal{T} -solver to *demand* that the DPLL engine do additional case splits before determining the \mathcal{T} -consistency of a partial assignment. For flexibility—and because it is needed by actual theories of interest—the theory solver should be able to demand case splits on literals that may be unfamiliar to the DPLL engine and may possibly even contain fresh constant symbols. Here, we give a brief explanation of how this can be done in the context of the abstract framework given in §33.4.4. Details can be found in [BNOT06a].

Recall that in the abstract framework, the \mathcal{T} -Learn rule allows the theory solver to add an arbitrary clause to those being processed by the DPLL engine, so long as all the atoms in that clause are already known to the DPLL engine. Our approach will be to relax this restriction. It is not hard to see, however, that this poses a potential termination problem. We can overcome this difficulty so long as for any input formula ϕ , the set of all literals needed to check the \mathcal{T} -consistency of ϕ is finite. We formalize this notion by introducing the following definition.

Definition 33.5.6. \mathcal{L} is a *suitable literal-generating function* if for every finite set of literals L :

1. \mathcal{L} maps L to a new finite set of literals L' such that $L \subseteq L'$.
2. For each atomic formula α , $\alpha \in \mathcal{L}(L)$ iff $\neg\alpha \in \mathcal{L}(L)$.

3. If L' is a set of literals and $L \subseteq L'$, then, $\mathcal{L}(L) \subseteq \mathcal{L}(L')$ (monotonicity).
4. $\mathcal{L}(\mathcal{L}(L)) = \mathcal{L}(L)$ (idempotence).

For convenience, given a formula ϕ , we denote by $\mathcal{L}(\phi)$ the result of applying \mathcal{L} to the set of all literals appearing in ϕ . In order to be able to safely use splitting on demand for a theory solver \mathcal{T} -solver, we must be able to show the existence of a suitable literal-generating function \mathcal{L} such that: for every input formula ϕ , the set of all literals on which the \mathcal{T} -solver may demand case splits when starting with a conjunction of literals from ϕ is contained in $\mathcal{L}(\phi)$. For example, for \mathcal{T}_A , $\mathcal{L}(\phi)$ could contain atoms of the form $i = j$, where i and j are array indices occurring in ϕ . Note that there is no need to explicitly construct $\mathcal{L}(\phi)$. It is enough to know that it exists.

As mentioned above, it is sometimes useful to demand case splits on literals containing new constant symbols. The introduction of new constant symbols poses potential problems not only for termination, but also for soundness. This is because the abstract framework relies on the fact that whenever $\emptyset \parallel \phi$ reduces in one or more steps to $\mu \parallel \phi'$, the formulas ϕ and ϕ' are \mathcal{T} -equivalent. This is no longer true if we allow the introduction of new constant symbols. Fortunately, it is sufficient to ensure \mathcal{T} -equisatisfiability of ϕ and ϕ' . With this in mind, we can give a new transition rule called **Extended \mathcal{T} -Learn** which replaces \mathcal{T} -Learn and allows for the desired additional flexibility.

Definition 33.5.7. The *Extended DPLL Modulo Theories system*, consists of the rules of §33.4.4 except that the \mathcal{T} -Learn rule is replaced by the following²³ rule:

Extended \mathcal{T} -Learn

$$\mu \parallel \phi \quad \Longrightarrow \quad \mu \parallel \phi, c \quad \mathbf{if} \quad \left\{ \begin{array}{l} \text{each atom of } c \text{ occurs in } \phi \text{ or in } \mathcal{L}(\mu) \\ \phi \models_{\mathcal{T}} \gamma_{\phi}(c) \end{array} \right.$$

The key observation is that an implementation using **Extended \mathcal{T} -Learn** has more flexibility when a state $\mu \parallel \phi$ is reached that is final with respect to the basic rules **Propagate**, **Decide**, **Fail**, and **\mathcal{T} -Backjump**. Whereas before it would have been necessary to determine the \mathcal{T} -consistency of μ when such a state was reached, the **Extended \mathcal{T} -Learn** rule allows the possibility of *delaying* a response by demanding that additional case splits be done first. As shown in [BNOT06a], the extended framework retains soundness and completeness. Furthermore, the properties of \mathcal{L} ensure that a delayed response cannot be delayed indefinitely, and thus the framework also ensures termination under similar conditions as the original framework.

Example 33.5.8. A careful examination of the decision procedure for \mathcal{T}_A given in [SDBL01] reveals the following:

1. Each term can be categorized as an *array* term, an *index* term, a *value* term, or a *set* term.
2. No new array terms are ever introduced by the inference rules.
3. At most one new index term for every pair of array terms is introduced.
4. Set terms are made up of some finite number of index terms.
5. The only new value terms introduced are of the form $read(a, i)$ where a is an array term and i is an index term.

²³The definition of γ was given in §33.5.1.

It follows that the total number of possible terms that can be generated by the procedure starting with any finite set of literals is finite. Because there are only a finite number of predicates, it then follows that this set of rules is literal-bounded.

In general, a similar analysis must be done for every theory before it can be integrated with the Extended DPLL Modulo Theories framework as described above. It should also be pointed out that the extended framework requires a DPLL engine that is capable of dealing with a dynamically expanding set of literals. However, because the splitting on demand approach can result in drastically simpler theory solvers, it remains an attractive and useful implementation strategy.

The approach can be refined to work with several theory solvers when the background theory \mathcal{T} is a combination of the solver's theories [BNOT06b, BNOT06a]. Then, the lemma generation mechanism is also used to achieve a sound and complete cooperation among the theory solvers, in the spirit of the Nelson-Oppen combination method described in §33.6. In this form, splitting on demand is implemented in the CVC, CVC Lite and CVC3 systems [SBD02, BB04, BT07]. A major requirement of the refinement is that each theory solver must be aware that it is being combined with others so that it can generate suitable lemmas necessary for the cooperation. An alternative approach to achieving inter-solver cooperation through the DPLL engine that does not have this requirement is described in some detail in §33.6.3.

33.5.3. Layered theory solvers

Sometimes, a theory \mathcal{T} has the property that a fully general solver for \mathcal{T} is not always needed: rather, the unsatisfiability of an assignment μ can often be established in less expressive, but much easier, sub-theories. Thus, the \mathcal{T} -solver may be organized in a *layered hierarchy* of solvers of increasing solving capabilities [ABC⁺02, BBC⁺05a, SS05, CM06b, BCF⁺07]. The general idea consists of stratifying the problem over N layers L_0, L_1, \dots, L_{N-1} of increasing complexity, and searching for a solution “at as simple a level as possible”. If one of the simpler solvers finds a conflict, then this conflict is used to prune the search at the Boolean level; if it does not, the next solver in the sequence is activated.

Since L_{n+1} refines L_n , if the set of literals is not satisfiable at level L_n , then it is not at L_{n+1}, \dots, L_{N-1} . If indeed a model S exists at L_n , either n equals $N-1$, in which case S solves the problem, or a refinement of S must be searched for at L_{n+1} . In this way, much of the reasoning can be performed at a high level of abstraction. This results in increased efficiency during the search for a solution, since the later solvers, which are often responsible for most of the complexity, are avoided whenever possible.

The schema can be further enhanced by allowing each layer L_i to infer novel equalities and inequalities and to pass them down to the next layer L_{i+1} , so as to better drive its search [SS05, SS06, CM06b].

33.5.4. Rewriting-based theory solvers

Another approach for building theory solvers relies on the power and flexibility of modern automated theorem provers, in particular, provers based on the *superposition calculus* [NR01], a modern version of the resolution calculus for first-order

logic with equality. This calculus is based on term rewriting techniques and comes equipped with powerful redundancy criteria that allow one to build very effective control strategies for reducing the search space.

The superposition-based approach to SMT, first proposed in [ARR03] and then further elaborated upon in [ABRS05, BGN⁺06a, BE07a, BE07b], applies to theories \mathcal{T} that are axiomatizable by a finite (and relatively small) set of first-order clauses, such as for instance the theory of arrays in §33.2.2. The main idea is to instrument a superposition prover with specialized control strategies which, together with the axioms of \mathcal{T} , effectively turn the prover into a decision procedure for ground \mathcal{T} -satisfiability.

An advantage of the approach is a simplified proof of correctness, even in the case of combined theories, which reduces to a routine proof of termination of the application of the various superposition rules (see, e.g., [ARR03] for details). Another potential advantage is the reuse of efficient data structures and algorithms for automated deduction implemented in state-of-the-art theorem provers. The main disadvantage is that to get additional features typically required in SMT such as model generation, incrementality, and so on, one may need to modify the theorem prover in ways not foreseen by the original implementors, possibly at the cost of a considerable (re)implementation effort. While this approach has generated an active stream of interesting theoretical work, its practical impact has been limited so far by a scarcity of robust and competitive implementations.

33.6. Combining Theories

We mentioned that in SMT one is often faced with formulas involving several theories at once. This is particularly true in software verification, where proof obligations are formulas talking about several datatypes, each modeled by its own theory. We have seen that for many of these theories the ground satisfiability problem is decidable, and often by efficient theory solvers. Hence, a natural question is whether it is possible to combine theory solvers for several *component* theories $\mathcal{T}_1, \dots, \mathcal{T}_n$ *modularly* into a theory solver that decides ground satisfiability modulo their combination $\mathcal{T}_1 \oplus \dots \oplus \mathcal{T}_n$.

In general, the answer is negative, simply because there exist theories with a decidable ground satisfiability problem whose combination has an undecidable ground satisfiability problem (see, e.g., [BGN⁺06b]). Positive results are however possible by imposing restrictions on the component theories and their combination. A successful combination method for theory solvers is due to Nelson and Oppen [NO79]. The success of the method is based on the fact that its restrictions on the theories are not very strong in practice, and lead to efficient implementations. It is fair to say that most work in theory combination in SMT is based on extensions and refinements of Nelson and Oppen's work (see, e.g., [TH96, Rin96, BDS02c, TR03, TZ04, Ghi04, TZ05, RRZ05, GNZ05, BBC⁺06, GNRZ06, CK06, BNOT06a, KGGT07]).

In this section, we present a declarative non-deterministic combination framework, first presented in [Opp80b], that captures the essence of the original combination procedure by Nelson and Oppen in [NO79], and briefly discuss a few

variants and extensions. Then we describe how an efficient implementation of this framework can be incorporated into the lazy approach to SMT.

For simplicity, we consider just the case of combining two theories and their solvers since the case of more theories is analogous. Therefore, let Σ_1, Σ_2 be two signatures and let \mathcal{T}_i be a Σ_i theory for $i = 1, 2$. The combination of \mathcal{T}_1 and \mathcal{T}_2 will be the theory $\mathcal{T}_1 \oplus \mathcal{T}_2$ as defined in §33.2.1.3.

33.6.1. A Logical Framework for Nelson-Oppen Combination

The original Nelson-Oppen method applies to theories \mathcal{T}_1 and \mathcal{T}_2 with disjoint signatures and each equipped with a theory solver deciding a ground \mathcal{T}_i -satisfiability problem. The gist of the method is to take a ground formula of signature $\Sigma_1 \cup \Sigma_2 \cup C$, where C is a set of constant symbols not in $\Sigma_1 \cup \Sigma_2$, convert it into an equisatisfiable conjunction $\varphi_1 \wedge \varphi_2$ with each φ_i of signature $\Sigma_i \cup C$, and feed each φ_i to \mathcal{T}_i 's theory solver. The two solvers cooperate by exchanging entailed constraints about their respective formulas until one of them has enough information to decide the satisfiability in $\mathcal{T}_1 \oplus \mathcal{T}_2$ of the original formula.

Any version of the Nelson-Oppen method is more conveniently described by considering only $(\Sigma_1 \cup \Sigma_2 \cup C)$ -formulas φ that are just *conjunctions of literals*. This restriction is without loss of generality both in theory, via a preliminary conversion to disjunctive normal form, and in practice, as we will see in §33.6.3. Now, queries like φ cannot be processed directly by either theory solver unless they have the *pure form* $\varphi_1 \wedge \varphi_2$ where each φ_i is a $(\Sigma_i \cup C)$ -formula—possibly \top . Even then, however, using the theory solvers in isolation is not enough because it is possible for $\varphi_1 \wedge \varphi_2$ to be $\mathcal{T}_1 \oplus \mathcal{T}_2$ -unsatisfiable while each φ_i is \mathcal{T}_i -satisfiable. By a simple application of Craig's interpolation lemma [Cra57] this situation happens precisely when there is a first-order formula ψ over the signature C such that $\varphi_1 \models_{\mathcal{T}_1} \psi$ and $\varphi_2 \wedge \psi \models_{\mathcal{T}_2} \perp$. Note that Craig's lemma tells us here that $=$ is the only predicate symbol and the elements of C are the only function symbols occurring in ψ . But it does not provide any indication of whether ψ has quantifiers or not, and which ones. One of the main theoretical contributions of Nelson and Oppen's work was to show that, under the right conditions, ψ is actually ground. Moreover, it is also computable.

The Nelson-Oppen method is not limited to formulas in pure form because any ground formula can be (efficiently) turned into an equisatisfiable pure form by a suitable *purification procedure*. The procedure most commonly used (and its correctness proof) is straightforward but to describe it we need some definitions and notation first.

Let $\Sigma = \Sigma_1 \cup \Sigma_2 \cup C$ and fix $i \in \{1, 2\}$. A Σ -term t is an *i-term* if its top function symbol is in $\Sigma_i \cup C$. A Σ -literal α is an *i-literal* if its predicate symbol is in $\Sigma_i \cup C$ or if it is of the form $(\neg)s = t$ and both s and t are *i-terms* or $i = 1$.²⁴ A subterm of an *i-atom* α is an *alien* subterm of α if it is a *j-term*, with $j \neq i$, and all of its superterms in t are *i-terms*. An *i-term* or *i-literal* is *pure* (or also, *i-pure*) if it only contains symbols from $\Sigma_i \cup C$. Note that the constants in C are the only terms that are both a 1-term and a 2-term, and that an equation is pure

²⁴This means that any literal $(\neg)s = t$ where s and t are not both *i-terms* for some i is considered to be a 1-term. This choice is arbitrary and immaterial.

whenever one of its members is a constant of C and the other is a pure term. The purification procedure consists of the following steps.

Purification Procedure. Let φ be a conjunction of Σ -literals.

1. **Abstract alien subterms.** Apply to completion the following transformation to φ : replace an alien subterm t of a literal of φ with a fresh constant c from C and add (conjunctively) the equation $c = t$ to φ .
2. **Separate.** For $i = 1, 2$, let φ_i be the conjunctions of all the i -literals in (the new) φ .²⁵

It is not hard to see that this procedure always terminates, runs in time linear in the size of φ , and produces a formula $\varphi_1 \wedge \varphi_2$ that is equisatisfiable with φ . More precisely, every model of $\varphi_1 \wedge \varphi_2$ is also a model of φ , and for every model \mathcal{A} of φ there is a model of $\varphi_1 \wedge \varphi_2$ that differs from \mathcal{A} at most in the interpretation of the new constants introduced in the abstraction step above.

The constraint propagation mechanism of the original Nelson-Oppen procedure can be abstracted by a preliminary non-deterministic guess of a truth assignment for all possible *interface equalities*, that is, equations between the (uninterpreted) constants shared by φ_1 and φ_2 . To describe that, it is convenient to introduce the following notion [TH96].

Let R be any equivalence relation over a finite set S of terms. The *arrangement of S induced by R* is the formula

$$ar_R(S) := \bigwedge_{(s,t) \in R} (s = t) \wedge \bigwedge_{(s,t) \notin R} s \neq t$$

containing all equations between R -equivalent terms and all disequations between non- R -equivalent terms of S .

The combination procedure below just guesses an arrangement of the shared constants in a pure form $\varphi_1 \wedge \varphi_2$ of φ , adds it to each φ_i , and then asks the corresponding theory solver to check the satisfiability of the extended φ_i .

The Combination Procedure. Let φ be a conjunction of Σ -literals.

1. **Purify input.** For $i = 1, 2$, let φ_i be the i -pure part of φ 's pure form.
2. **Guess an arrangement.** Where C_0 is the set of all the constant symbols occurring in both φ_1 and φ_2 , choose an arrangement $ar_R(C_0)$.
3. **Check pure formulas.** Return “satisfiable” if $\varphi_i \wedge ar_R(C_0)$ is \mathcal{T}_i -satisfiable for $i = 1$ and $i = 2$; return “unsatisfiable” otherwise.

We call any arrangement guessed in Step 2 of the procedure above an *arrangement for φ* . The procedure is trivially terminating, even if all possible arrangements are considered in step 2.²⁶ It is also refutationally sound for *any*

²⁵Note that (dis)equations between constants of C end up in both φ_1 and φ_2 .

²⁶Observe that there is always a finite, albeit possibly very large, set of arrangements for any finite set of terms.

signature-disjoint theories \mathcal{T}_1 and \mathcal{T}_2 : for such theories, φ is $\mathcal{T}_1 \oplus \mathcal{T}_2$ -unsatisfiable if the procedure returns “unsatisfiable” for every possible arrangement for φ . The procedure, however, is not complete without further assumptions on \mathcal{T}_1 and \mathcal{T}_2 ; that is, in general there could be arrangements for which it returns “satisfiable” even if φ is in fact $\mathcal{T}_1 \oplus \mathcal{T}_2$ -unsatisfiable. A sufficient condition for completeness is that both theories be *stably infinite* [Opp80b].

Definition 33.6.1. Let Σ be a signature and C an infinite set of constants not in Σ . A Σ -theory T is *stably infinite* if every \mathcal{T} -satisfiable ground formula of signature $\Sigma \cup C$ is satisfiable in a model of \mathcal{T} with an infinite universe.

Proposition 33.6.2 (Soundness and completeness). If \mathcal{T}_1 and \mathcal{T}_2 are signature-disjoint and both stably infinite, then the combination procedure returns “unsatisfiable” for an input φ and every possible arrangement for φ iff φ is $\mathcal{T}_1 \oplus \mathcal{T}_2$ -unsatisfiable.

The first (correct) proof of the result above was given in [Opp80b]. More recent proofs based on model-theoretic arguments can be found in [TH96, MZ03b, Ghi04], among others.²⁷ The completeness result in the original paper by Nelson and Oppen [NO79] is incorrect as stated because it imposes no restrictions on the component theories other than that they should be signature-disjoint. The completeness proof however is incorrect only because it implicitly assumes there is no loss of generality in considering only infinite models, which is however not the case unless the theories are stably infinite.

We remark that the stable infiniteness requirement is not an artifice of a particular completeness proof. The combination method is really incomplete without it, as shown for instance in [TZ05]. This is a concern because non-stably infinite theories of practical relevance do exist. For instance, all the theories of a single finite model, such as the theory of bit-vectors (or of strings) with some maximum size, are not stably infinite.

Current practice and recent theoretical work have shown that it is possible to lift the stable infiniteness requirement in a number of ways provided that the combination method is modified to include the propagation of certain cardinality constraints, in addition to equality constraints between shared constants [FG04, TZ05, FRZ05, RRZ05, KGGT07]. More importantly, recent research has shown (see [FRZ05, RRZ05, KGGT07]) that the vexation of the requirement is greatly reduced or disappears in practice if one frames SMT problems within a sorted (i.e., typed) logic, a more natural kind of logic for SMT applications than the classical, unsorted logic traditionally used. The main idea is that, in SMT, combined theories are usually obtained by combining the theory of some parametric data type $T(\alpha_1, \dots, \alpha_n)$ with the theories of particular instances of the type parameters $\alpha_1, \dots, \alpha_n$. A simple example would be the combined theory of lists of real numbers, say, where the type $\text{List}(\text{Real})$ is obtained by instantiating with the type Real the parameter α in the parametric type $\text{List}(\alpha)$.

With combined theories obtained by type parameter instantiation, the theories of the instantiated parameters can be arbitrary, as long as entailed cardinality constraints on the parameter types are propagated properly between theory

²⁷While those papers consider only theories specified by a set of axioms, their proofs also apply to theories specified as sets of models.

solvers. For instance, in the theory of lists of Booleans, say, a pure formula φ_1 of the form

$$l_1 \neq l_2 \wedge l_1 \neq l_3 \wedge l_2 \neq l_3 \wedge \text{tail}(l_1) = \text{nil} \wedge \text{tail}(l_2) = \text{nil} \wedge \text{tail}(l_3) = \text{nil},$$

stating that l_1, l_2, l_3 are distinct lists of length 1, entails the existence of at least 3 distinct values for the element type `Bool`. If φ_1 above is part of the formula sent to the list solver, its entailed minimal cardinality constraint on the `Bool` type must be communicated to the theory solver for that type. Otherwise, the unsatisfiability of φ_1 in the combined theory of `List(Bool)` will go undetected. A description of how it is possible to propagate cardinality constraints conveniently for theories of typical parametric datatypes, such as lists, tuples, arrays and so on, can be found in [RRZ05]. A discussion on why in a typed setting parametricity and not stable infiniteness is the key notion to consider for Nelson-Oppen style combination is provided in [KGGT07].

33.6.2. The Nelson-Oppen Procedure

The original Nelson-Oppen procedure can be seen as a concrete, and improved, implementation of the non-deterministic procedure in the previous subsection.

The first concrete improvement concerns the initial purification step on the input formula. Actually purifying the input formula is unnecessary in practice provided that each theory solver accepts literals containing alien subterms, and treats the latter as if they were free constants. In that case, interface equalities are actually equalities between certain alien subterms.²⁸ A description of the Nelson-Oppen procedure without the purification step is provided in [BDS02b].

A more interesting improvement is possible when each component theory \mathcal{T}_i is convex—as defined in §33.2.1.2. Then, it is enough for each theory solver to propagate recursively and to completion all the interface equalities entailed by its current pure half of the input formula. In concrete, this requires each solver to be able to infer entailed interface equalities and to pass them to the other solver (for addition to its pure half) until one of the two detects an unsatisfiability, or neither has any new equalities to propagate. In the latter case, it is safe to conclude that the input formula is satisfiable in the combined theory.

When one of the two theories, or both, are non-convex, exchanging just entailed interface equalities is no longer enough for completeness. The solver for the non-convex theory must be able to infer, and must propagate, also any *disjunction* of interface equality entailed by its pure half of the formula. Correspondingly, the other solver must be able to process such disjunctions, perhaps by case splits, in addition to the conjunction of literals in the original input.

For convex theories—such as, for instance $\mathcal{T}_{\mathcal{E}}$ —computing the interface equalities entailed by a conjunction φ of literals can be done very efficiently, typically as a by-product of checking φ 's satisfiability (see, e.g., [NO03, NO05b]). For non-convex theories, on the other hand, computing entailed disjunctions of equalities can be rather expensive both in practice and in theory. For instance, for the difference logic fragment of $\mathcal{T}_{\mathcal{Z}}$, this entailment problem is NP-complete even if the satisfiability of conjunctions of literals can be decided in polynomial time [LM05].

²⁸While this simple fact was well understood by earlier implementors of the Nelson-Oppen procedure—including its authors—it was (and still is) often overlooked by casual readers.

33.6.3. Delayed Theory Combination

Delayed Theory Combination (DTC) is a general method for tackling the problem of theory combination within the context of lazy SMT [BBC⁺05c, BBC⁺06]. As in §33.6.1, we assume that $\mathcal{T}_1, \mathcal{T}_2$ are two signature-disjoint stably-infinite theories with their respective \mathcal{T}_i -solvers. Importantly, no assumption is made about the capability of the \mathcal{T}_i -solvers of deducing (disjunctions of) interface equalities from the input set of literals (e_{ij} -deduction capabilities, see §33.4.1): for each \mathcal{T}_i -solver, every intermediate situation from complete e_{ij} -deduction (like in deterministic Nelson-Oppen) to no e_{ij} -deduction capabilities (like in non-deterministic Nelson-Oppen) is admitted.

In a nutshell, in DTC the embedded DPLL engine not only enumerates truth-assignments for the atoms of the input formula, but also “nondeterministically guesses” truth values for the equalities that the \mathcal{T} -solvers are not capable of inferring, and handles the case-split induced by the entailment of disjunctions of interface equalities in non-convex theories. The rationale is to exploit the full power of a modern DPLL engine by delegating to it part of the heavy reasoning effort previously assigned to the \mathcal{T}_i -solvers.

An implementation of DTC [BBC⁺06, BCF⁺06b] is based on the online integration schema of Figure 33.3, exploiting early pruning, \mathcal{T} -propagation, \mathcal{T} -backjumping and \mathcal{T} -learning. Each of the two \mathcal{T}_i -solvers interacts only with the DPLL engine by exchanging literals via the truth assignment μ in a stack-based manner, so that there is no direct exchange of information between the \mathcal{T}_i -solvers. Let \mathcal{T} be $\mathcal{T}_1 \cup \mathcal{T}_2$. The \mathcal{T} -DPLL algorithm is modified in the following ways [BBC⁺06, BCF⁺06b]:²⁹

- \mathcal{T} -DPLL must be instructed to assign truth values not only to the atoms in φ , but also to the interface equalities not occurring in φ . $\mathcal{B}2\mathcal{T}$ and $\mathcal{T}2\mathcal{B}$ are modified accordingly. In particular, \mathcal{T} -`decide_next_branch` is modified to select also new interface equalities not occurring in the original formula.
- μ^p is partitioned into three components $\mu_{\mathcal{T}_1}^p, \mu_{\mathcal{T}_2}^p$ and μ_e^p , s.t. $\mu_{\mathcal{T}_i}$ is the set of i -pure literals and μ_e is the set of interface (dis)equalities in μ .
- \mathcal{T} -`deduce` is modified to work as follows: for each \mathcal{T}_i , $\mu_{\mathcal{T}_i}^p \cup \mu_e^p$ is fed to the respective \mathcal{T}_i -solver. If both return `Sat`, then \mathcal{T} -`deduce` returns `Sat`, otherwise it returns `Conflict`.
- Early-pruning is performed; if some \mathcal{T}_i -solver can deduce atoms or single interface equalities, then \mathcal{T} -propagation is performed. If one \mathcal{T}_i -solver performs the deduction $\mu^* \models_{\mathcal{T}_i} \bigvee_{j=1}^k e_j$, s.t. $\mu^* \subseteq \mu_{\mathcal{T}_i} \cup \mu_e$, each e_j being an interface equality, then the deduction clause $\mathcal{T}2\mathcal{B}(\mu^* \rightarrow \bigvee_{j=1}^k e_j)$ is learned.
- \mathcal{T} -`analyze_conflict` and \mathcal{T} -`backtrack` are modified so as to use the conflict set returned by one \mathcal{T}_i -solver for \mathcal{T} -backjumping and \mathcal{T} -learning. Importantly, such conflict sets may contain interface equalities.

In order to achieve efficiency, other heuristics and strategies have been further suggested in [BBC⁺05c, BBC⁺06, BCF⁺06b, DdM06a, dMB07].

Example 33.6.3. [BCF⁺06b] Consider the set of $\mathcal{T}_{\mathcal{E}} \cup \mathcal{T}_{\mathcal{Z}}$ -literals $\mu =_{def} \mu_{\mathcal{E}} \wedge \mu_{\mathcal{Z}}$ of Figure 33.6. We assume that both the $\mathcal{T}_{\mathcal{E}}$ and $\mathcal{T}_{\mathcal{Z}}$ solvers have no e_{ij} -deduction

²⁹For simplicity, we assume φ is pure, although this condition is not necessary, as in [BDS02b].

Figure 33.6. The DTC search tree for Example 33.6.3 on $\mathcal{T}_Z \cup \mathcal{T}_E$, with no e_{ij} -deduction. v_1, \dots, v_6 are interface terms. $\mu'_{\mathcal{T}_i}, \mu''_{\mathcal{T}_i}, \mu'''_{\mathcal{T}_i}$ denote appropriate subsets of $\mu_{\mathcal{T}_i}$, $\mathcal{T}_i \in \{\mathcal{T}_E, \mathcal{T}_Z\}$.

capabilities. For simplicity, we also assume that both \mathcal{T}_i -solvers always return conflict sets which do not contain redundant interface disequalities $\neg e_{ij}$. (We adopt here a strategy for DTC which is described in detail in [BCF⁺06b].) In short, \mathcal{T} -DPLL performs a Boolean search on the e_{ij} 's, backjumping on the conflicting clauses $C_{13}, C_{56}, C_{23}, C_{24}$ and C_{14} , which in the end causes the unit-propagation of $(v_1 = v_4)$. Then, \mathcal{T} -DPLL selects a sequence of $\neg e_{ij}$'s without generating conflicts, and concludes that the formula is $\mathcal{T}_1 \cup \mathcal{T}_2$ -satisfiable. Notice that the backjumping steps on the clauses C_{13}, C_{56} , and C_{23} mimic the effects of performing e_{ij} -deductions.

By adopting \mathcal{T} -solvers with different e_{ij} -deduction power, one can trade part or all the e_{ij} -deduction effort for extra Boolean search. [BCF⁺06b] shows that, if the \mathcal{T} -solvers have full e_{ij} -deduction capabilities, then no extra Boolean search on the e_{ij} 's is required; otherwise, the Boolean search is controlled by the quality of the conflict sets returned by the \mathcal{T} -solvers: the more redundant interface disequalities are removed from the conflict sets, the more Boolean branches are pruned. If the conflict sets do not contain redundant interface disequalities, the extra effort is reduced to one branch for each deduction saved, as in Example 33.6.3.

As seen in §33.5.2, the idea from DTC of delegating to the DPLL engine part or most of the, possibly very expensive, reasoning effort normally assigned to the \mathcal{T}_i -solvers (e_{ij} -deduction, case-splits) is pushed even further in the splitting on demand approach. As far as multiple theories are concerned, the latter approach differs from DTC in the fact that the interaction is controlled by the \mathcal{T}_i -solvers, not by the DPLL engine. Other improvements of DTC are currently implemented

in the MATHSAT [BBC⁺06], YICES [DdM06a], and Z3 [dMB07] lazy SMT tools. In particular, [DdM06a] introduced the idea of generating e_{ij} 's on-demand, and [dMB07] that of having the Boolean search on e_{ij} 's driven by a model under construction.

33.6.4. Ackermann's expansion

When combining one or more theories with \mathcal{T}_E , one possible approach is to eliminate uninterpreted function symbols by means of Ackermann's expansion [Ack54]. The method works as described in §33.3.1.3 by replacing every function application occurring in the input formula φ with a fresh variable and then adding to φ all the needed functional congruence constraints. The formula φ' obtained is equisatisfiable with φ , and contains no uninterpreted function symbols. [BCF⁺06a] presents a comparison between DTC and Ackermann's expansion.

Example 33.6.4. Consider the $\mathcal{T}_E \cup \mathcal{T}_Z$ conjunction μ of Example 33.6.3 [BCF⁺06b]. Applying Ackermann's expansion we obtain the conjunction of \mathcal{T}_Z -literals:

$$\begin{aligned} \mu_E &: \neg(v_f(v_1) = v_f(v_2)) \wedge \neg(v_f(v_2) = v_f(v_4)) \wedge (v_f(v_3) = v_5) \wedge (v_f(v_1) = v_6) \wedge \\ \mu_Z &: (v_1 \geq 0) \wedge (v_1 \leq 1) \wedge (v_5 = v_4 - 1) \wedge (v_3 = 0) \wedge (v_4 = 1) \wedge \\ &\quad (v_2 \geq v_6) \wedge (v_2 \leq v_6 + 1) \wedge \\ \text{Ack} &: ((v_1 = v_2) \rightarrow (v_f(v_1) = v_f(v_2))) \wedge ((v_1 = v_3) \rightarrow (v_f(v_1) = v_f(v_3))) \wedge \\ &\quad ((v_1 = v_4) \rightarrow (v_f(v_1) = v_f(v_4))) \wedge ((v_2 = v_3) \rightarrow (v_f(v_2) = v_f(v_3))) \wedge \\ &\quad ((v_2 = v_4) \rightarrow (v_f(v_2) = v_f(v_4))) \wedge ((v_3 = v_4) \rightarrow (v_f(v_3) = v_f(v_4))), \end{aligned} \tag{33.2}$$

which every \mathcal{T}_Z -solver finds \mathcal{T}_Z -satisfiable. (E.g., the \mathcal{T}_Z -model $v_2 = 2$, $v_3 = v_5 = v_6 = v_f(v_1) = v_f(v_3) = 0$, $v_1 = v_4 = v_f(v_2) = v_f(v_4) = 1$ satisfies it.)

33.7. Extensions and Enhancements

33.7.1. Combining eager and lazy approaches

The Ackermann expansion described above is one way to combine eager and lazy approaches. Other hybrids of eager and lazy encoding methods can also be effective.

For instance, consider the satisfiability problem for integer linear arithmetic and the small-domain encoding technique presented in §33.3.2. Due to the conservative nature of the bound derived, and in spite of the many optimizations possible, the computed solution bound can generate a SAT problem beyond the reach of current solvers. For example, this situation can arise for problem domains that do not generate sparse linear constraints.

One can observe that the derived bounds are dependent only on the “bag of constraints”, rather than on their specific Boolean combination in the input formula. Thus, there is hope that a smaller solution bound might suffice. Kroening et al. [KOSS04] have presented an approach to compute the solution bound incrementally, starting with a small bound and increasing it “on demand”. Figure 33.7 outlines this *lazy* approach to computing the solution bound. Given a \mathcal{T}_Z -formula

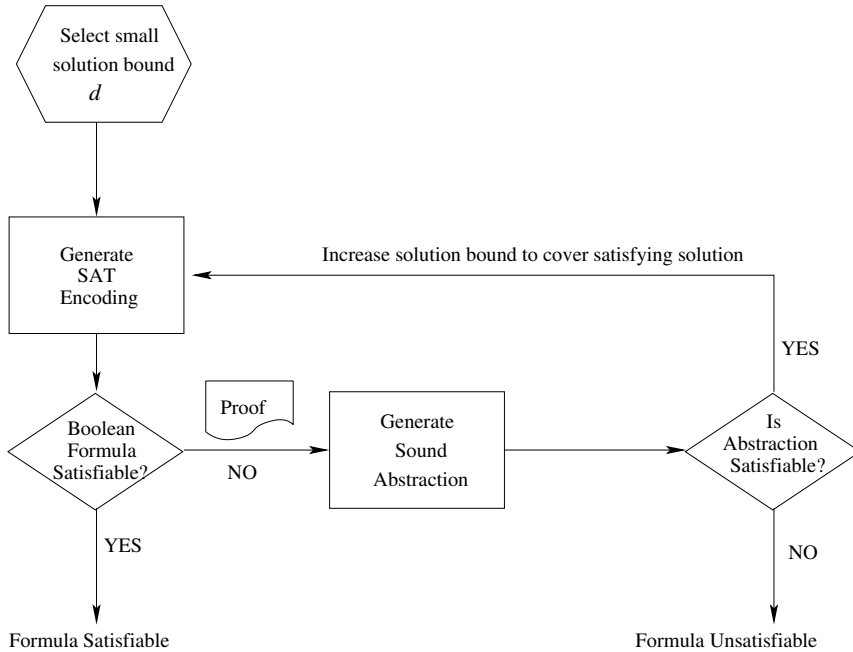

Figure 33.7. Lazy approach to computing solution bound

$F_{\mathcal{Z}}$, we start with an encoding size for each integer variable that is smaller than that prescribed by the conservative bound (say, for example, 1 bit per variable).

If the resulting Boolean formula is satisfiable, so is $F_{\mathcal{Z}}$. If not, the proof of unsatisfiability generated by the SAT solver is used to generate a *sound abstraction* $F'_{\mathcal{Z}}$ of $F_{\mathcal{Z}}$. A sound abstraction is a formula, usually much smaller than the original, such that if it is unsatisfiable, so is the original formula. A sound and complete decision procedure for quantifier-free formulas in $\mathcal{T}_{\mathcal{Z}}$ is then used on $F'_{\mathcal{Z}}$. If this decision procedure concludes that $F'_{\mathcal{Z}}$ is unsatisfiable, so is $F_{\mathcal{Z}}$. If not, it provides a counterexample which indicates the necessary increase in the encoding size. A new SAT-encoding is generated, and the procedure repeats.

The bound S on solution size that is derived in §33.3.2 implies an upper bound nS on the number of iterations of this lazy encoding procedure; thus the lazy encoding procedure needs only polynomially many iterations before it terminates with the correct answer. Of course, each iteration involves a call to a SAT solver as well as to the $\mathcal{T}_{\mathcal{Z}}$ -solver.

A key component of this lazy approach is the generation of the sound abstraction. While the details are outside the scope of this chapter, we sketch one approach here. (Details can be found in [KOSS04].) Assume that $F_{\mathcal{Z}}$ is in conjunctive normal form (CNF); thus, $F_{\mathcal{Z}}$ can be viewed as a set of clauses, each of which is a disjunction of linear constraints and Boolean literals. A subset of this set of clauses is a sound abstraction of $F_{\mathcal{Z}}$. This subset is computed by retaining only those clauses from the original set that contribute to the proof of unsatisfiability of the SAT-encoding.

If the generated abstractions are small, the sound and complete decision procedure used by this approach will run much faster than if it were fed the original formula. Thus, one can view this approach as an “accelerator” that can speed up any SMT solver. The approach is also applicable to other theories; for instance, it has been successfully extended to finite-precision bit-vector arithmetic [BKO⁺07].

33.7.2. Handling quantifiers

Because the Nelson-Oppen framework (§33.6.1) only works for quantifier-free formulas, SMT solvers have traditionally been rather limited in their ability to reason about quantifiers. A notable exception is the prover Simplify [DNS03] which uses *quantifier instantiation* on top of a Nelson-Oppen style prover. Several modern SMT solvers have adopted and extended these techniques [GBT07, BdM07, ML06].

The basic idea can be understood by extending the abstract framework described in §33.4.4 to include rules for quantifier instantiation. The main modification is to also allow closed quantified formulas wherever atomic formulas are allowed. Define a *generalized atomic formula* as either an atomic formula or a closed quantified formula. A *generalized literal* is either a generalized atomic formula or its negation; a *generalized clause* is a disjunction of generalized literals. The modified abstract framework is obtained simply by allowing literals and clauses to be replaced by their generalized counterparts. For instance, non-fail states become pairs $M \parallel F$, where M is a sequence of generalized literals and F is a conjunction of generalized clauses. With this understanding, the two rules below can be used to model quantifier instantiation. For simplicity and without loss of generality, we assume here that quantified literals in M appear only positively and that the bodies of quantified formulas are themselves in abstract CNF.

$$\begin{aligned} \exists\text{-Inst} : \quad M \parallel F &\implies M \parallel F, \neg\exists\mathbf{x}.\varphi \vee \varphi[\mathbf{x}/\mathbf{a}] \quad \text{if } \begin{cases} \exists\mathbf{x}.\varphi \text{ is in } M \\ \mathbf{a} \text{ are fresh constants} \end{cases} \\ \forall\text{-Inst} : \quad M \parallel F &\implies M \parallel F, \neg\forall\mathbf{x}.\varphi \vee \varphi[\mathbf{x}/\mathbf{s}] \quad \text{if } \begin{cases} \forall\mathbf{x}.\varphi \text{ is in } M \\ \mathbf{s} \text{ are ground terms} \end{cases} \end{aligned}$$

The $\exists\text{-Inst}$ rule essentially models skolemization and the $\forall\text{-Inst}$ rule models instantiation. It is also clear that termination can only be guaranteed by limiting the number of times the rules are applied. For a given existentially quantified formula, there is no benefit to applying $\exists\text{-Inst}$ more than once, but a universally quantified formula may need to be instantiated several times with different ground terms before unsatisfiability is detected. The main challenge then, in applying these rules, is to come up with an effective strategy for applying $\forall\text{-Inst}$. For some background theories (e.g., universal theories) completeness can be shown for exhaustive and fair instantiation strategies. In practice, however, the most effective techniques are incomplete and heuristic.

The most common approach is to select for instantiation only ground terms that are *relevant* to the quantified formula in question, according to some heuristic

relevance criteria. The idea is as follows: given a state $M \parallel F$ and an abstract literal $\forall x.\varphi$ in M , try to find a subterm t of $\forall x.\varphi$ properly containing x , a ground term g in M , and a subterm s of g , such that $t[x/s]$ is equivalent to g modulo the background theory \mathcal{T} (written $t[x/s] =_{\mathcal{T}} g$). In this case, we expect that instantiating x with s is more likely to be helpful than instantiating with other candidate terms. Following Simplify’s terminology, the term t is called a *trigger* (for $\forall x.\varphi$). In terms of unification theory, the case in which $t[x/s] =_{\mathcal{T}} g$ is a special case of \mathcal{T} -matching between t and g .

In general, in the context of SMT, given the complexity of the background theory \mathcal{T} , it may be very difficult if not impossible to determine whether a trigger and a ground term \mathcal{T} -match. As a result, most implementations use some form of $\mathcal{T}_{\mathcal{E}}$ -matching. For details on effective implementation strategies, we refer the reader to [DNS03, GBT07, BdM07, ML06].

33.7.3. Producing models

For some applications, it is desirable not only to know whether a formula is satisfiable, but if so, what a satisfying model is. In general, it may be challenging to capture all of the structure of an arbitrary first-order model. However, it is often sufficient to know how to assign values from some “standard” model to the ground terms in a formula. Several SMT solvers have implemented support for “models” of this kind.

One approach is to do additional work guessing values for ground terms and then to double-check that the formula is indeed satisfied. This is the approach followed by CVC3 [BT07].

An alternative approach is to instrument the \mathcal{T} -solver to continually maintain a value for every ground term associated with the theory. This is the strategy followed by the solvers YICES and Z3 [DdM06b, dMB07].

33.7.4. Producing proofs

In both SAT and SMT communities, the importance of having tools able to produce proofs of the (\mathcal{T} -)unsatisfiability of the input formulas has been recently stressed, due to the need for independently verifiable results, and as a starting point for the production of unsatisfiable cores (§33.7.5) and interpolants (§33.7.6).

A DPLL solver can be easily modified to generate a resolution proof of unsatisfiability for an input CNF formula, by keeping track of all resolution steps performed when generating each conflict clause, and by combining these subproofs iteratively into a proof of unsatisfiability whose leaves are original clauses. Techniques for translating a Boolean resolution proof into a more human-readable and verifiable format have been proposed, e.g., in [BB03, Amj07].

Similarly, a lazy SMT solver can be modified to generate a resolution proof of unsatisfiability for an input CNF formula, whose leaves are either clauses from the original formula or \mathcal{T} -lemmas (i.e. negations of \mathcal{T} -conflict sets and \mathcal{T} -deduction clauses returned by the \mathcal{T} -solver, see §33.4.3), which are \mathcal{T} -valid clauses. Such a resolution proof can be further refined by providing a proof for each \mathcal{T} -lemma in some theory-specific deductive framework (like, e.g. that in [McM05] for inequalities in $\mathcal{T}_{\mathcal{R}}$).

33.7.5. Identifying unsatisfiable cores

An *unsatisfiable core* (*UC*) of an unsatisfiable CNF formula φ is an unsatisfiable subset of the clauses in φ .

In SAT, the problem of finding small unsatisfiable cores has been addressed by many authors in recent years [LMS04, MLA⁺05, ZM03, OMA⁺04, Hua05, DHN06, Boo, GKS06, ZLS06] due to its importance in formal verification [McM02]. In particular, lots of techniques and optimizations have been introduced with the aim of producing small [ZM03, GKS06], minimal [OMA⁺04, Hua05, DHN06], or even minimum unsat cores [LMS04, MLA⁺05, ZLS06].

In SMT, despite the fact that finding unsatisfiable cores has been addressed explicitly in the literature only recently [CGS07], at least three SMT solvers (i.e. CVC3, MATHSAT, and YICES) support UC generation.³⁰ We distinguish three main approaches.

In the approach implemented in CVC3 and MATHSAT (*proof-based approach* hereafter), the UC is produced as a byproduct of the generation of resolution proofs. As in [ZM03], the idea is to return the set of clauses from the original problem which appear as leaves in the resolution proof of unsatisfiability. (\mathcal{T} -lemmas are not included as they are \mathcal{T} -valid clauses, so they play no role in the \mathcal{T} -unsatisfiability of the core.)

The approach used by YICES (*assumption-based approach* hereafter) is an adaptation of a method used in SAT [LMS04]: for each clause C_i in the problem, a new Boolean “selector” variable S_i is created; then, each C_i is replaced by $(S_i \rightarrow C_i)$; finally, before starting the search each S_i is forced to true. In this way, when a conflict at decision level zero is found by the DPLL solver, the conflict clause C contains only selector variables, and the UC returned is the union of the clauses whose selectors appear in C . Neither approach aims at producing minimal or minimum unsatisfiable cores, nor does anything to reduce their size.

In the *lemma-lifting approach* [CGS07] implemented in MATHSAT, a lazy SMT solver is combined with an external (and possibly highly-optimized) propositional core extractor. The SMT solver stores and returns the \mathcal{T} -lemmas it had to prove in order to refute the input formula; the external core extractor is then called on the Boolean abstraction of the original SMT problem and of the \mathcal{T} -lemmas. Clauses corresponding to \mathcal{T} -lemmas are removed from the resulting UC, and the remaining abstract clauses are refined back into their original form. The result is an unsatisfiable core of the original SMT problem. This technique is able to benefit from any size-reduction techniques implemented in the Boolean core extractor used.

33.7.6. Computing interpolants

A *Craig interpolant* (“interpolant” hereafter) of a pair of formulas (ψ, ϕ) s.t. $\psi \wedge \phi \models_{\mathcal{T}} \perp$ is a formula ψ' s.t.:

- $\psi \models_{\mathcal{T}} \psi'$,

³⁰Apart from [CGS07], the information reported here on the computation of unsatisfiable cores in these tools comes from personal knowledge of the tools (CVC3 and MATHSAT) and from private communications from the authors (YICES).

- $\psi' \wedge \phi \models_{\mathcal{T}} \perp$, and
- $\psi' \preceq \psi$ and $\psi' \preceq \phi$,

where $\alpha \preceq \beta$ denotes that all uninterpreted (in the signature of \mathcal{T}) symbols of α appear in β . Note that a quantifier-free interpolant exists if \mathcal{T} admits quantifier elimination [KMZ06] (e.g., in $\mathcal{T}_{\mathcal{Z}}$ a quantifier-free interpolant for (ψ, ϕ) may not exist).

The use of interpolation in formal verification was introduced by McMillan in [McM03] for purely-propositional formulas, and it was subsequently extended to handle $\mathcal{T}_{\mathcal{E}} \cup \mathcal{T}_{\mathcal{R}}$ -formulas in [McM05]. The technique, which is based on earlier work by Pudlák [Pud97], works as follows. (We assume w.l.o.g. that the formulas are in CNF.) An interpolant for (ψ, ϕ) is constructed from a resolution proof \mathcal{P} of the unsatisfiability of $\psi \wedge \phi$, according to the following steps:

1. for every clause C occurring as a leaf in \mathcal{P} , set $I_C \equiv C \downarrow \phi$ if $C \in \psi$, and $I_C \equiv \top$ if $C \in \phi$;
2. for every \mathcal{T} -lemma $\neg\eta$ occurring as a leaf in \mathcal{P} , generate an interpolant $I_{\neg\eta}$ for $(\eta \setminus \phi, \eta \downarrow \phi)$;
3. for every node C of \mathcal{P} obtained by resolving $C_1 \equiv p \vee \phi_1$ and $C_2 \equiv \neg p \vee \phi_2$, set $I_C \equiv I_{C_1} \vee I_{C_2}$ if p does not occur in ϕ , and $I_C \equiv I_{C_1} \wedge I_{C_2}$ otherwise;
4. return I_{\perp} as an interpolant for (ψ, ϕ) ;

where $C \downarrow \phi$ is the clause obtained by removing all the literals in C whose atoms do not occur in ϕ , and $C \setminus \phi$ that obtained by removing all the literals whose atoms do occur in ϕ . In the purely-Boolean case the algorithm reduces to steps 1., 3. and 4. only. Notice that step 2 of the algorithm is the only part which depends on the theory \mathcal{T} , so that the problem reduces to that of finding interpolants for (negated) \mathcal{T} -lemmas.

A number of techniques exist for theory-specific interpolation generation. For example, [McM05] provides a set of rules for constructing interpolants for \mathcal{T} -lemmas in $\mathcal{T}_{\mathcal{E}}$, for weak linear inequalities ($0 \leq t$) in $\mathcal{T}_{\mathcal{R}}$, and their combination. [YM05] uses a variant of the Nelson-Oppen procedure (§33.6.2) for generating interpolants for $\mathcal{T}_1 \cup \mathcal{T}_2$ using the interpolant-generation procedures of \mathcal{T}_1 and \mathcal{T}_2 as black-boxes. The combination $\mathcal{T}_{\mathcal{E}} \cup \mathcal{T}_{\mathcal{R}}$ can also be used to compute interpolants for other theories, such as those of lists, arrays, sets and multisets [KMZ06]. [RSS07] computes interpolants for \mathcal{T} -lemmas in $\mathcal{T}_{\mathcal{E}} \cup \mathcal{T}_{\mathcal{R}}$ by solving a system of Linear Programming (LP) constraints. [KW07] extends the *eager* SMT approach to the generation of interpolants. (The approach is currently limited to the theory of equality only, without uninterpreted functions.) [CGS08] presents some extensions to the work in [McM05], including an optimized interpolant generator for the full theory $\mathcal{T}_{\mathcal{R}}$, an ad hoc interpolant generator for difference logic, and an interpolant combination method based on Delayed Theory Combination (§33.6.3).

33.7.7. Recent advances

In the decade since the first version of this book chapter was written, the field of SMT solving has matured considerably. The literature in the intervening period

is too large for us to fully review here. We focus on just three directions that are producing exciting advances.

New theories: SMT solving has been extended to new background theories such as that of strings with operations such as concatenation, length, and membership in regular languages [LRT⁺16, BGZ17]. Even for existing theories, researchers are finding special cases where domain-specific structure can be exploited to obtain several orders of magnitude speed-up in solver time: a good example is solving Boolean combinations of (possibly non-linear) convex constraints over the reals [NPSSV10, SNSV⁺17, SNS⁺18].

From satisfiability to optimization: A natural extension of SMT solving is in the direction of optimization. In these variants, termed *optimization modulo theories*, one seeks to optimize a cost function while satisfying constraints represented as an SMT formula. While initial promising results have been obtained for special cases [MPP15, ST17], much more remains to be done on this topic.

SMT and synthesis: One of the exciting new applications of SMT solving in the past decade has been to the algorithmic synthesis of programs and other formal artifacts [JGST10, Ses15]. Recently several synthesis problems have been unified by the formalism of *syntax-guided synthesis* (SyGuS) [ABJ⁺13]. In the simplest version of SyGuS, one is given an SMT formula φ with an uninterpreted function f to be synthesized and a grammar of expressions for the implementation of this function, and one must determine whether there exists an expression which, when substituted for f in φ , causes it to become valid. The connection between SMT and SyGuS is synergistic. Clearly, determining whether a candidate solution to a SyGuS problem is correct involves solving an SMT problem. Additionally, SyGuS solvers are proving useful in solving synthesis sub-tasks within SMT solving such as generating terms with which to instantiate quantifiers [PNB17, NPR⁺18]. We anticipate this connection between SMT solving and synthesis will only deepen in the years to come.

Chapter 34

Stochastic Boolean Satisfiability

Stephen M. Majercik

34.1. Introduction

Stochastic satisfiability (SSAT) is an extension of satisfiability (SAT) that merges two important areas of artificial intelligence: logic and probabilistic reasoning. SSAT was initially suggested by Papadimitriou, who called it a “game against nature” [Pap85] and explored further by Littman, Majercik & Pitassi [LMP01]. SSAT is interesting both from a theoretical perspective—it is PSPACE-complete, an important complexity class—and from a practical perspective—a broad class of probabilistic planning problems can be encoded and solved as SSAT instances. In this chapter, we describe SSAT and its variants, their computational complexity, applications, analytical results, algorithms and empirical results, and related work. We conclude with a discussion of directions for future work.

34.2. Definitions and Notation

A stochastic satisfiability (SSAT) problem $\Phi = Q_1v_1 \dots Q_nv_n\phi$ is specified by:

1. a *prefix* $Q_1v_1 \dots Q_nv_n$ that orders a set of n Boolean variables $V = \{v_1, \dots, v_n\}$ and specifies the quantifier Q_i associated with each variable v_i , and
2. a *matrix* ϕ that is a Boolean formula constructed from these variables.

More specifically, the prefix $Q_1v_1 \dots Q_nv_n$ associates a quantifier Q_i , either existential (\exists) or “randomized” (\exists^{π_i}), with the variable v_i . An existentially (randomly) quantified variable is an *existential (randomized) variable*. A *sub-block* of variables in the prefix is any sequence of adjacent, similarly quantified variables; a *block* is a maximal sub-block. A block of existential (randomized) variables is an *existential (randomized) block*. We will use v_1, v_2, \dots for variables in general, x_1, x_2, \dots for existential variables, and y_1, y_2, \dots for randomized variables. An existential variable x_i is a standard Boolean variable, whereas a randomized variable y_i is a Boolean variable that has the value **true** with an arbitrary rational probability π_i . (A more restricted version of SSAT, in which all randomized variables are **true** with probability $1/2$, is defined in [LMP01].) $X \subseteq V$ is the set

of all existential variables in Φ and $Y \subseteq V$ is the set of all randomized variables in Φ . X_i is the subset of variables in the i^{th} existential block in the prefix of Φ and Y_i is the subset of variables in i^{th} randomized block in the prefix of Φ .

The matrix ϕ is assumed to be in conjunctive normal form (CNF), i.e. a set of m conjoined clauses, where each clause is a set of distinct disjoined literals. A *literal* l is either a variable v (a *positive* literal) or its negation \bar{v} (a *negative* literal). For a literal l , $|l|$ is the variable v underlying that literal and \bar{l} is the “opposite” of l , i.e. if l is v , \bar{l} is \bar{v} ; if l is \bar{v} , \bar{l} is v ; A literal l is **true** if it is positive and $|l|$ has the value **true**, or if it is negative and $|l|$ has the value **false**. A literal l is *existential* (*randomized*) if $|l|$ is existential (randomized). The probability that a randomized variable v has the value **true** (**false**) is denoted $\Pr[v]$ ($\Pr[\bar{v}]$). The probability that a randomized literal l is **true** is denoted $\Pr[l]$. As in a SAT problem, a clause is satisfied if at least one literal is **true**, and unsatisfied, or *empty*, if all its literals are **false**. The formula is satisfied if all its clauses are satisfied.

A partial assignment α of the variables V is a sequence of $k \leq n$ literals $l_1; l_2; \dots; l_k$ such that no two literals in α have the same underlying variable. Given l_i and l_j in an assignment α , $i < j$ implies that the assignment to $|l_i|$ was made before the assignment to $|l_j|$. A positive (negative) literal v (\bar{v}) in an assignment α indicates that the variable v has the value **true** (**false**). The notation $\Phi(\alpha)$ denotes the SSAT problem Φ' remaining when the partial assignment α has been applied to Φ ; that is:

1. clauses with **true** literals have been removed from the matrix,
2. **false** literals have been removed from the remaining clauses in the matrix,
3. all variables and associated quantifiers not in the remaining clauses have been removed from the prefix, and
4. the remaining variables and quantifiers in the prefix have been renumbered such that the index of the leftmost variable and its quantifier is 1 and the index of every other variable and quantifier is one more than the index of the immediately preceding variable and quantifier.

The notation $\phi(\alpha)$ denotes ϕ' , the matrix remaining when α has been applied. Similarly, given a set of literals L , such that no two literals in L have the same underlying variable, the notation $\Phi(L)$ denotes the SSAT problem Φ' remaining when the assignments indicated by the literals in L have been applied to Φ . And $\phi(L)$ denotes ϕ' , the matrix remaining when the assignments indicated by the literals in L have been applied. A literal $l \notin \alpha$ is *active* if some clause in $\phi(\alpha)$ contains l ; otherwise it is *inactive*.

Since the values of existential variables can be made contingent on the values of existentially and randomized variables that appear earlier in the prefix, the solution of an SSAT instance Φ takes the form of an *assignment tree* that specifies an assignment to each existential variable x_i for each possible instantiation of the randomized variables that precede x_i in the prefix. An optimal assignment tree, or *solution tree*, is one that yields the maximum probability of satisfaction of Φ . (A *decision* version of SSAT, which asks whether the probability of satisfaction exceeds a rational threshold $0 \leq \theta \leq 1$, is defined in [LMP01].) Formally, given an SSAT problem Φ , the maximum probability of satisfaction of Φ , denoted $\Pr^*[\Phi]$,

is defined according to the following recursive rules:

1. If ϕ contains an empty clause, $\text{Pr}^*[\Phi] = 0$.
2. If ϕ is the empty set of clauses, $\text{Pr}^*[\Phi] = 1$.
3. If the leftmost quantifier in the prefix of Φ is existential and the variable thus quantified is v , then $\text{Pr}^*[\Phi] = \max(\text{Pr}[\Phi(v)], \text{Pr}[\Phi(\bar{v})])$.
4. If the leftmost quantifier in ϕ is randomized and the variable thus quantified is v , then $\text{Pr}^*[\Phi] = (\text{Pr}[\Phi(v)] \times \text{Pr}[v]) + (\text{Pr}[\Phi(\bar{v})] \times \text{Pr}[\bar{v}])$.

34.2.1. Special Cases and Extensions of SSAT

Two special cases of SSAT, arrived at by placing restrictions on the type or ordering of the quantifiers, are of special interest. If all the variables are randomized, then Φ is a MAJSAT problem. (Papadimitriou [Pap85] referred to this as “Threshold SAT.”) Since none of the variables are existentially qualified, there is no optimal tree of existential variable assignments; the solution to a MAJSAT problem Φ is just $\text{Pr}^*[\Phi]$. If the prefix is composed of a single existential block followed by a single randomized block, then Φ is an E-MAJSAT problem. The solution to such a problem is an assignment α to X , the set of existential variables that maximizes $\text{Pr}[\Phi(\alpha)]$, where $\Phi(\alpha)$ is the MAJSAT problem that results when all the existential variables have been eliminated by applying α to Φ . Two other variants of SSAT are defined in [LMP01]:

- Alternating SSAT (ASSAT), a more constrained version of SSAT in which existential and randomized quantifiers strictly alternate, and
- Extended SSAT (XSSAT), called Extended SSAT in [LMP01], a further generalization of SSAT that includes universal quantifiers and encompasses SAT, QBF, SSAT, MAJSAT, and E-MAJSAT.

An XSSAT problem is essentially an SSAT problem in which variables can be universally quantified (\forall) as well as existentially and randomly quantified. A universally quantified variable is a *universal variable*. A block of universal variables is a *universal block*. We will use z_1, z_2, \dots for universal variables. $Z \subseteq V$ is the set of all universal variables in Φ . Z_i is the i^{th} universal block in the prefix of Φ .

The solution of an XSSAT instance Φ is an assignment of truth values to the existentially quantified variables that yields the maximum probability of satisfaction of Φ in the face of the demands of the universally quantified variables. If the leftmost variable in the prefix of XSSAT instance Φ is universally quantified ($Q_1 = \forall$), then $\text{Pr}^*[\Phi]$ must be such that the probability of satisfaction is attainable both when that variable is assigned the value **true** and when it is assigned the value **false**. Thus, $\text{Pr}^*[\Phi]$ for XSSAT instance Φ is defined according to the recursive rules stated above for an SSAT instance plus the following rule:

5. If the leftmost quantifier in the prefix of Φ is universal and the variable thus quantified is v , then $\text{Pr}^*[\Phi] = \min(\text{Pr}[\Phi(v)], \text{Pr}[\Phi(\bar{v})])$.

The decision version of XSSAT, which asks whether the probability of satisfaction exceeds a rational threshold $0 \leq \theta \leq 1$, is defined in [LMP01].) As noted in [LMP01], when an XSSAT instance Φ contains only existential and universal

quantifiers, the definition of $\text{Pr}^*[\Phi]$ is equivalent to the definition of satisfiability of a QBF instance. In fact, a QBF instance can be solved by replacing the universal quantifiers with randomized quantifiers whose associated probabilities are all strictly between 0 and 1, and checking whether the probability of satisfaction of the resulting SSAT instance is 1.

34.3. Complexity of SSAT and Related Problems

We briefly summarize some complexity results for SSAT; details can be found in [LMP01, Lit97, LGM98]. Each of SAT, MAJSAT, E-MAJSAT, SSAT, and QBF is complete for a particular complexity class, i.e. is “as hard as” any other problem in that class. A brief look at the satisfiability problems and the classes for which they are complete indicates the additional difficulty imposed by the introduction of randomized and universal quantifiers into the basic SAT problem. It also shows how these satisfiability problems relate to some standard propositional, probabilistic planning problems and belief network problems.

SAT is the prototypical NP-complete problem. An intuitive way to think about NP is that it is the class of decision problems for which one can guess and check an answer in time that is polynomial in the size of the problem. The problem of finding the most probable explanation (MPE) in a belief network [Dec96] is also NP-complete and, therefore, polynomially equivalent to SAT. A related problem from planning under uncertainty is determining whether there is some choice of actions such that the probability of the most likely trajectory through state space to the goal exceeds a given probability threshold.

MAJSAT is complete for the class PP (probabilistic polynomial time). By way of analogy with the earlier description of NP, one can think of PP as the class of decision problems for which one can guess and check an answer in time that is polynomial in the size of the problem and, if the correct answer is “yes,” the guessed answer will be correct with probability at least $1/2$. The problem of belief network inference is #P-complete [Rot96]. (roughly speaking, #P actually counts the number of satisfying assignments; PP just decides whether the probability of satisfaction is at least $1/2$.) In addition, any belief network (with rational conditional probability tables) can be represented as a Boolean formula. Plan evaluation in a probabilistic domain is a PP-complete planning problem [LGM98].

E-MAJSAT is NP^{PP} -complete [LGM98]. NP^{PP} is the class of decision problems for which one can guess a solution in time polynomial in the size of the problem (NP) and then perform a PP calculation to determine whether that answer is correct. The belief network problems of calculating a maximum a posteriori (MAP) hypothesis or a maximum expected utility (MEU) solution [Dec96] are NP^{PP} -complete. Finding optimal size-bounded plans in uncertain domains is also NP^{PP} -complete [LGM98]. One can think of the existential variables as corresponding to the hypothesis or plan and the randomized variables as corresponding to the uncertainty.

Finally, SSAT, ASSAT, and *XSSAT*, like QBF, are PSPACE-complete. PSPACE is the set of problems that can be solved using an amount of space that is polynomial in the size of the input. Solving a finite-horizon partially observable Markov decision process (POMDP) is also PSPACE-complete [PT87], when the

domain is specified compactly via probabilistic STRIPS operators or an equivalent representation [MGLA97], even if the domain is “fully observable” [LGM98]. Influence diagrams [Sha86] are a belief-network-like representation for the same type of problem.

34.4. Applications

The complexity results in Section 34.3 show that various planning problems can be efficiently transformed into a type of satisfiability problem (in time that is polynomial in the size of the problem). In fact, the most well-explored application of stochastic satisfiability is an extension of the deterministic-planning-as-satisfiability paradigm. (See Part 2, Chapter 19 for further discussion of planning and satisfiability.)

34.4.1. Planning

Three sound and complete probabilistic planners have been developed that solve a planning problem by converting the planning problem into a stochastic satisfiability problem and solving that problem instead. The stochastic satisfiability problem is designed so that the tree of existential variable assignments that yields $\Pr^* [\Phi]$ directly translates into the plan that has the highest probability of reaching the planning agent’s goal. All of these planners solve goal-oriented, finite-horizon, propositional probabilistic planning problems. MAXPLAN solves conformant planning problems by solving an E-MAJSAT encoding of the problem [ML98a]. ZANDER solves partially observable, contingent planning problems (partially observable Markov decision processes) by solving an SSAT encoding of the planning problem [ML03]. In Section 34.6.3.1, we describe these SSAT plan encodings and the technique ZANDER uses to solve them. Evidence that ZANDER is a viable alternative to the POMDP, partial order, and planning graph approaches to probabilistic planning is presented in [ML03]. Finally, DC-SSAT is a divide-and-conquer approach that takes advantage of the structure in the SSAT encoding of a completely observable planning problem to solve such planning problems 2-3 orders of magnitude faster than ZANDER using 2-3 orders of magnitude less space [MB05]. DC-SSAT is described in Section 34.6.3.2.

34.4.2. Belief Networks

[Rot96] showed that the problem of belief net inferencing can be reduced to MAJSAT, a type of SSAT problem. Thus, in principle, an SSAT solver could solve the inferencing problem by solving the MAJSAT encoding of that problem. That this approach would be an efficient alternative to standard belief net inferencing algorithms is supported by work in [BDP03c, BDP03a, BDP03b] that describes a DPLL-based approach to solving belief net inferencing problems that provides the same time and space performance guarantees as state-of-the-art exact algorithms and, in some cases, achieves an exponential speedup over existing algorithms.

34.4.3. Trust Management

SSAT has also shown promise in the development of algorithms for *trust management* (TM) systems. TM systems are application-independent infrastructures that can enforce access control policies within and between organizations to protect sensitive resources from access by unauthorized agents. State-of-the-art TM systems have significant limitations, e.g. difficulty in expressing partial trust, and a lack of fault tolerance that can lead to interruptions of service. [FK03] have shown that stochastic satisfiability can form the basis of a TM system that addresses these limitations, and work is in progress to develop efficient solution techniques for the SSAT problems generated by such a system.

34.5. Analytical Results

The structural properties of SAT problems have been studied extensively. For example, it is well-known that increasing the clause-to-variable ratio in random k -SAT problems produces an “easy-hardest-hard” pattern [SML96]). This pattern becomes particularly pronounced as the number of variables increases. It is conjectured that there exists a constant α_k such that a random k -SAT formula drawn from $\mathcal{F}_m^{k,n}$ (the distribution of formulas obtained by selecting independently m clauses of size k over n variables) is almost certainly satisfiable if $m/n < \alpha_k$ (as n gets large), and almost certainly unsatisfiable if $m/n > \alpha_k$. (See Part 1, Chapter 10 for a discussion of random k -SAT.)

The additional complexity introduced by the ordering of variables and quantifiers in the general SSAT problem has made it difficult to generate comparable analytical results for these problems. While there are no analytical results regarding the threshold behavior of random instances of general SSAT problems, however, there are some results for MAJSAT. [Fri97] showed that random SAT has a sharp 0–1 threshold (although the 0–1 threshold value α_k may be a function of n) and the ideas in that proof are general enough to extend to MAJSAT, i.e. there exists a function $\alpha_k(n)$ such that for any $\epsilon > 0$, there exists $t > 1$ such that a random MAJSAT instance with parameters (k, m, n, t) , where $m = (\alpha_k(n) - \epsilon)n$, is positive with high probability, while a random formula with parameters (k, m, n, t) , where $m = (\alpha_k(n) + \epsilon)n$, is not a positive instance with high probability, and moreover has zero satisfying truth assignments with high probability [LMP01]. This implies a 0–1 threshold although it does not specify the location of it.

[LMP01] describe some additional results for MAJSAT instances drawn from $\mathcal{F}_m^{k,n}$. These results are based on the decision version of the MAJSAT problem and hold only for instances in which, for each variable y_i , $\Pr[y_i] = 1/2$. A parameter t specifies a threshold probability of $1/2^{n-t}$. When $m \geq (\log_{8/7} 2)(n - t) \approx 5.19(n - t)$, a random 3-MAJSAT instance with m clauses and n variables almost certainly has fewer than 2^t satisfying assignments, and empirical estimates of the 0-1 threshold confirm the form of this inequality [LMP01]. Work by [KMPS95, KKKS98] shows that the actual number of satisfying assignments for most k -SAT formulas will be much smaller than the expected number of satisfying assignments and [LMP01], using results from [KMPS95], conclude that

when the matrix ϕ in a MAJSAT instance Φ is satisfiable, Φ will almost certainly be a positive instance when $t \leq ne^{-3m/n}$.

With respect to a lower bound on m as a function of t , assume that almost certainly, there are l disjoint clauses, C_1, C_2, \dots, C_l in a random MAJSAT formula with parameters k, m, n, t . Let $k = 3$. There are 2^{3l} total assignments for the l disjoint clauses. There are 7 ways to make each clause **true** for 3-CNF formulas. Since the clauses are disjoint, there are 7^l ways to make all the clauses true, so the exact number of assignments that make one or more clauses **false** is $2^{3l} - 7^l$, which is between $2^{3(l-1)}$ and 2^{3l} . This gives a lower bound on m as a function of t , since l can be chosen as a function of m and n such that almost certainly a 3-SAT random formula with m clauses over n variables contains at least l variable-disjoint clauses.

34.6. Algorithms and Empirical Results

Current algorithms for stochastic satisfiability include:

- 1) systematic algorithms for random problems and structured problems,
- 2) approximation algorithms for random problems and structured problems,
and
- 3) non-systematic algorithms for random problems.

In Section 34.6.2, we describe two sound and complete algorithms for solving arbitrary XSSAT problems. In Section 34.6.3, we describe two sound and complete algorithms for structured SSAT problems (SSAT encodings of probabilistic planning problems). In Sections 34.6.4 and 34.6.5, we describe approximation algorithms for random MAJSAT problems, random SSAT problems, and SSAT encodings of probabilistic planning problems. Finally, in Section 34.6.6, we describe a stochastic local search algorithm.

34.6.1. Decision Trees

We will use the idea of a *decision tree* to describe some of the following SSAT algorithms. A decision tree T over variables v_1, \dots, v_n is a binary decision tree where each internal node in the tree represents a variable v_i , and the two outgoing edges are labeled with the two possible values of v_i : **true** and **false**. Each leaf is labeled with either 0 or 1. Any complete assignment α to the variables is consistent with exactly one path of T . A decision tree T over v_1, \dots, v_n represents a CNF formula ϕ if for every truth assignment α , the value of the leaf node on the path consistent with α is equal to 0 if α does not satisfy ϕ and 1 if α does satisfy ϕ . A decision tree T for ϕ is *complete* if it is a full binary tree of height n . A given ϕ will have many decision trees that can represent it; some may be very small while others (such as the complete tree) can have exponential size in n .

A *canonical* decision tree for an XSSAT instance Φ is a decision tree T where the ordering of the variables along paths in T is consistent with the quantifier order. (Note that although the variables in a canonical decision tree must follow the ordering of the variables in the prefix, variables occurring in a block can be permuted within the block, both in Φ and in T , without altering the value.) Given

a canonical tree T for an XSSAT instance Φ , $\text{Pr}^*[\Phi]$ can be computed from T by labeling the intermediate nodes of T with rational numbers in a bottom-up fashion. A leaf is labeled 0 (1) if the assignment specified by the path to that leaf is unsatisfying (satisfying). Then, if node w representing variable v_i is unlabeled, and has children w_0 and w_1 with labels $L(w_0)$, $L(w_1)$, respectively, then:

1. if $Q_i = \exists$, then $L(w) = \max(L(w_0), L(w_1))$,
2. if $Q_i = \forall$, then $L(w) = \min(L(w_0), L(w_1))$,
3. if $Q_i = \forall$, then $L(w) = (L(w_0) * \text{Pr}[\bar{v}] + L(w_1) * \text{Pr}[v])$,

and $\text{Pr}^*[\Phi]$ is the label of the root.

Note that while a decision tree ignores the quantifier ordering, a canonical decision tree follows it exactly.

34.6.2. Systematic Algorithms

Two sound and complete algorithms for solving arbitrary SSAT problems (problems with no special structure) were described in [LMP01]. The first is a modification of the Davis-Putnam-Logemann-Loveland (DPLL) algorithm for solving SAT instances [DLL62] (the basis of most modern SAT engines). This DPLL-based algorithm, described in Section 34.6.2.1, solves XSSAT problems (and, thus, SSAT, E-MAJSAT, and MAJSAT problems as well). The second algorithm is also a DPLL-based algorithm for XSSAT problems and is guaranteed to solve an XSSAT instance in time that is efficient in the size of the smallest *decision tree* (defined in Section 34.6.2.2). As discussed in Section 34.6.2.2, however, this algorithm does not provide the basis for an efficient XSSAT algorithm.

34.6.2.1. A Davis-Putnam-Logemann-Loveland Algorithm

The Davis-Putnam-Logemann-Loveland (DPLL) algorithm for Boolean satisfiability [DLL62] searches for a satisfying assignment to a SAT instance by enumerating partial assignments and taking advantage of opportunities to prune assignments that could not lead to a satisfying assignment. DPLL needs to deal with only the implicitly existentially quantified variables in a SAT instance, but the algorithm can be extended to handle the addition of randomized quantifiers in an SSAT instance, and randomized and universal quantifiers in an XSSAT instance. Pruning rules for existentially and universally quantified variables are described in [DLL62] and [CGS98], respectively. These rules, plus pruning rules for randomly quantified variables are the basis for *evalssat*, an algorithm for XSSAT problems presented in [LMP01]. Since this algorithm is the basis of all the algorithms that have been developed for stochastic satisfiability, we will describe it in some detail.

The *evalssat* algorithm computes $\text{Pr}^*[\Phi]$ for XSSAT instance Φ from the definition of $\text{Pr}^*[\Phi]$ in Section 34.2.1. Thus, the basis of this algorithm is an enumeration of all assignments by assigning values to the variables in the order in which they occur in the prefix. The algorithm attempts to avoid enumerating all assignments, however, by using techniques adapted from the basic DPLL algorithm—*unit propagation* and *pure variable elimination*—as well as a *threshold pruning* technique similar to branch-and-bound techniques and techniques for

solving AND-OR and MINIMAX trees [Nil80]. Existential variable nodes are analogous to OR, or MAX, nodes, and randomized variable nodes are analogous to AND, or MIN, nodes. However, the probabilities associated with randomized variables (the opponent is nature) make the analogy somewhat inexact. The assignment trees searched by *evalssat* are more similar to MINIMAX trees with randomized nodes [Bal83], i.e. a sequence of alternating moves by opposing players mediated by random events.

Figure 34.1 provides pseudocode for DPLL-XSSAT, a modification of *evalssat* to accommodate randomized variables with arbitrary rational probabilities. The algorithm takes SSAT instance Φ and low and high probability thresholds θ_{\min} and θ_{\max} . It returns a value less than θ_{\min} if and only if the value of the XSSAT formula is less than θ_{\min} , a value greater than θ_{\max} if and only if the value of the XSSAT formula is greater than θ_{\max} , and otherwise the exact value of the XSSAT formula. Thus, it can be used to solve the XSSAT decision problem by setting $\theta_{\min} = \theta_{\max} = \theta$. It can also be used to compute the exact value of the formula by setting $\theta_{\min} = 0$ and $\theta_{\max} = 1$. Existing implementations of this algorithm also construct and return τ_{Φ} , the optimal assignment tree, but the construction of this tree is straightforward and, for the sake of clarity, we omit the details of this tree construction in the algorithm description. A proof of the correctness of *evalssat*, from which the correctness of DPLL-XSSAT follows, is provided in [LMP01].

Unit Propagation: A literal l is *unit* if it is the only literal in some clause (and we will refer to such a clause as a *unit clause*). If l is universal, the entire formula is **false** since it will not be the case that all values of $|l|$ make the formula **true** and $\Pr^*[\Phi] = 0$. If l is existential or randomized, then setting $|l|$ such that l is **false** immediately produces an empty clause and $\Pr^*[\Phi] = 0$. In this case, the algorithm can disregard the ordering of the variables in the prefix and choose the forced value. If l is existential, $\Pr^*[\Phi] = \Pr[\Phi(l)]$; if l is randomized, $\Pr^*[\Phi] = \Pr[\Phi(l)] \times \Pr[l]$.

Pure Variable Elimination: A literal l is *pure* if l is active and \bar{l} is inactive. If l is existential or universal, the algorithm can disregard the ordering of the variables in the prefix and choose the value consistent with the “goal” of the quantifier. If l is existential, the algorithm maximizes the probability of satisfaction by setting the value of $|l|$ to agree with l . If l is universal, the algorithm minimizes the probability of satisfaction by setting the value of $|l|$ to disagree with l . If l is randomized, there is no comparable simplification. Setting a pure randomized variable contrary to its sign in the formula can still yield a probability of satisfaction greater than 0, and this must be taken into account when computing the maximum probability of satisfaction.

Threshold Pruning: Threshold pruning, a mechanism absent from the DPLL algorithm for SAT, can boost efficiency by sometimes making it unnecessary to compute both $\Pr[\bar{v}_i]$ and $\Pr[v_i]$ when branching on a variable v_i . Threshold pruning computes *low* and *high* thresholds for the probability of satisfaction at each node in the solution tree (θ_{\min} and θ_{\max} in Figure 34.1). These thresholds delimit an interval outside of which it is unnecessary to compute the exact value of the probability of satisfaction (so threshold pruning cannot be used to solve instances in which the exact probability of satisfaction is required). Given a par-

```

     $p_1 = \text{DPLL-XSSAT}(\Phi(y_1), (\theta_{\min} - p_0 \Pr[\bar{y}_1]) / \Pr[y_1], (\theta_{\max} - p_0 \Pr[\bar{y}_1]) / \Pr[y_1])$ ;
    return  $p_0 \Pr[\bar{y}_1] + p_1 \Pr[y_1]$ ;

```

Figure 34.1. The DPLL-XSSAT algorithm generalizes the DPLL algorithm for satisfiability to solve XSSAT problems.

tial assignment α at a node, the solver can return the probability of satisfaction of the first branch explored (adjusted by the probability of that branch occurring if it is a randomized variable node) if that probability of satisfaction allows the solver to determine that $\Pr[\Phi(\alpha)]$ will fall outside the range $[\theta_{\min}, \theta_{\max}]$. In other words, the solver can leave the other branch of a variable unexplored when it is clear that 1) even the highest probability of satisfaction obtainable by exploring that branch will still leave the low threshold unattained, or 2) the probability of satisfaction that would be obtained by exploring that branch is not necessary to attain the high threshold. Threshold pruning also allows the solver to prune some subtrees in the \bar{l} subtree based on the probability of satisfaction associated with the l subtree (e.g. if $|l|$ is an existential variable, $\Pr[\Phi(\alpha; l)] = 0.6$, and the solver begins exploring the \bar{l} subtree, it can quit as soon as it determines that $\Pr[\Phi(\alpha; \bar{l})] < 0.6$ and that, therefore, l will be the better choice). Thresholds need to be adjusted in certain cases as the current partial assignment is extended, particularly in the case of randomized variable assignments. These adjustments are indicated in Figure 34.1; further details are available in [LMP01].

In [LMP01], *evalssat* with unit propagation, pure variable elimination, threshold pruning, and branching based on strict quantifier ordering, was tested on a set of 1,000 randomly generated formulas with $n = 20$ variables, $k = 3$ literals per clause, and 141 clauses. In these experiments, the decision version of the problems was solved and the probability of satisfaction threshold was expressed as $\theta = 1/2^{n-t}$ for integer t in the range 0 to n , i.e. 2^t satisfying assignments are required. The number of recursive calls required was used as the measure of the work required to solve an instance. We summarize the results of some of these tests here. Details of these tests and other test results are available in [LMP01].

MAJSAT problems exhibit the same easy-hardest-hard pattern as SAT problems as the clause-to-variable ratio is increased, although the peak difficulty appears to be higher than the peak for comparable SAT problems and occurs at a lower clause-to-variable ratio. The peak increases as the threshold probability of satisfaction increases since the threshold pruning rules apply less often to randomized variables as the threshold probability increases; i.e. it is less likely that the probability of satisfaction obtained from exploring the first branch of a randomized variable will be sufficient to make exploring the other branch unnecessary. In unsatisfiable MAJSAT instances (probability of satisfaction is 0), however, a higher threshold probability of satisfaction increases the effectiveness of threshold pruning, since, given the probability of satisfaction of 0 obtained from the first branch, even a probability of satisfaction of 1 from the second branch would be insufficient to attain the required probability of satisfaction.

The higher level of difficulty of MAJSAT instances relative to SAT instances was explored further in a set of experiments with E-MAJSAT problems. In E-MAJSAT problems, a single block of existential variables is followed by a single block of randomized variables, so these problems allow one to explore a range of problem types between SAT (n existential variables and 0 randomized variables) and MAJSAT (0 existential variables and n randomized variables). These experiments suggested that work increased logarithmically as the proportion of existential variables decreases, a result that runs counter to complexity class considerations since E-MAJSAT is in higher complexity class than MAJSAT. These

results suggest that MAJSAT is empirically more difficult than E-MAJSAT which is, in turn, empirically more difficult than SAT.

[LMP01] also compared SAT, E-MAJSAT, ASSAT, and MAJSAT problems of the same size. (The E-MAJSAT instances had equal numbers of existential and randomized variables.) For each problem type, the threshold value was chosen so as to maximize the difficulty of the instances (as observed empirically). Again, all classes exhibited the easy-hardest-hard pattern of difficulty as the clause-to-variable ratio increased. The same relative difficulty was observed for MAJSAT, E-MAJSAT, and SAT; the difficulty of ASSAT was very close to that of E-MAJSAT, once again suggesting that difficulty increases with the number of randomized variables (since E-MAJSAT and ASSAT problems with the same number of variables have the same number of existential and randomized variables). This makes sense since pure variable elimination cannot be applied to randomized variables and the threshold pruning rules are weaker for randomized quantifiers. The impact of quantifier type on problem difficulty has also been noted in QBF problems [GW98, CGS97].

Branching Heuristics: When the DPLL algorithm exhausts opportunities to apply unit resolution and pure variable elimination, it must select an unassigned variable v from the current simplified formula to branch on, i.e. check for satisfying assignments both when v is assigned `true` and when v is assigned `false`. The order in which variables are selected is critical—an appropriate branching heuristic can reduce the running time of the DPLL algorithm on SAT instances by several orders of magnitude—and there has been a great deal of research into efficient branching heuristics for SAT. (See Part 1, Chapter 8 for a discussion of branching heuristics for satisfiability.) [LMP01] showed that these SAT branching heuristics can be adapted for SSAT problems, but branching in these problems is more restricted. To ensure that the value of the formula is computed correctly, branching heuristics for SSAT must choose a variable from the leftmost quantifier block. Hence, branching heuristics have no impact in ASSAT instances, since each block contains only a single variable. This suggests that branching heuristics will be more effective as the block size increases.

This conjecture was tested in [LMP01] using six branching heuristics adapted from SAT branching heuristics: 1) choose a variable randomly, 2) find the literal l that satisfies the most clauses in the current formula and chooses the variable $|l|$, 3) 2-sided Jeroslow-Wang [HV95], which chooses a variable whose literals appear in a large number of short clauses, 4) positive, 2-sided Jeroslow-Wang [HV95]), which is Jeroslow-Wang applied to the subset of variables that appear in at least one clause containing all positive literals, 5) choose the variable that has many occurrences in small clauses (MOMS) [JW90], and 6) a heuristic that prefers variables that will lead to a maximal number of unit resolutions [BS97, Fre95, CA96]. In general, all but the random heuristic and the Jeroslow-Wang heuristic decreased the size of the DPLL tree constructed (as compared to the size of the tree when the variable ordering in the prefix was followed strictly). Although there were some anomalies, this improvement was positively correlated with block size. MOMS and the heuristic that tries to satisfy the most clauses were particularly effective; the success of the latter, which is computationally much simpler than all but the random heuristic, is surprising. Branching heuristics that take advantage

of the structure in SSAT encodings of planning problems are described in [ML03], but similar tests have not been conducted for such problems.

Nonchronological Backtracking: Nonchronological backtracking (NCB) is an important technique in most state-of-the-art SAT engines and has also been used for structured QBF problems [GNT03]. (See Part 1, Chapter 4 for more on nonchronological backtracking in satisfiability and Part 2, Chapter 30 for more on nonchronological backtracking in quantified Boolean formulas.) An NCB-augmented solver attempts to avoid exploring both values of a variable whenever possible. It does this by computing a *reason* whenever the current partial assignment α satisfies the formula or leads to a contradiction. A reason R is a subset of literals in α that is responsible for that result. When backtracking, the solver can sometimes use this reason to recognize situations in which exploring the second value of a particular variable v is unnecessary.

In an SSAT instance, a reason R is created at the end of a path in the solution tree when the solver has established that, given the current partial assignment α , either $(Pr(\Phi(\alpha)) = 0)$ or $(Pr(\Phi(\alpha)) = 1)$. A literal l from α is included in the reason only if changing the value of the underlying variable $|l|$ could have an impact on the result obtained at that leaf. If the probability of satisfaction at a leaf is 1, the solver does not need to check the other value of existential variables in the assignment, but *does* need to check the other value of any randomized variable to see if it will lower the probability of satisfaction. If the probability of satisfaction at a leaf is 0, there will be a clause which has just become empty that is responsible for this. The solver needs to check the other value of any existential *or* randomized variable that was initially in this clause to see if the probability of satisfaction of 0 can be improved, either by making a better choice in the case of an existential variable, or by discovering that the other value of a randomized variable leads to a probability of satisfaction greater than 0. The absence of a literal l in a reason (which is modified as the solver backtracks) indicates that changing the value of $|l|$ will not affect the probability of satisfaction, allowing the algorithm to avoid exploring that value. Rules for creating and modifying reasons in SSAT problems are described in [Maj04].

An SSAT solver augmented with this NCB mechanism was tested on random problems generated using a fixed-clause k -SSAT model similar to the k -QBF Model A of Gent and Walsh [GW99]. While tests on some randomly generated problems indicated that NCB can improve efficiency greatly, decreasing the median number of nodes visited and the median solution time by as much as five orders of magnitude in some problems, the number and type of problems in the test set are too limited to draw any general conclusions. In fact, tests on a second set of problems indicated that NCB becomes less effective as $Pr^*[\Phi]$ decreases, due to an increase in the size of the reasons, thereby reducing their effectiveness in reducing search. Furthermore, NCB degraded performance in tests on structured problems (SSAT encodings of probabilistic planning problems from [ML03]). These results are in sharp contrast to the effectiveness of NCB in solving structured SAT problems [BS97] and structured QBF problems [GNT03] (although [GNT03] do report some instances in which the overhead associated with NCB outweighs its benefits). This poor performance on SSAT encodings of planning problems may be due to the nature of the encoding, and it is possible

that other types of encodings [MR02] would improve the effectiveness of NCB. It is also possible that NCB would be more effective in SSAT instances with other types of structure.

Memoization: Memoization, a dynamic programming technique that caches solved subproblems and their solutions, can greatly increase the speed of an SSAT solver [ML98a]. An SSAT solver using memoization saves every subproblem encountered during the solution process along with its probability of satisfaction, thereby allowing the solver to avoid needless exploration of identical subtrees. Both MAXPLAN [ML98a] and current versions of ZANDER created by the author rely heavily on *memoization*. While memoization is memory intensive, it allows a solver to handle larger SSAT encodings of planning problems. In [Maj07], results are shown for three types of memoization in ZANDER: no memoization, memoization of all subproblems, and memoization of only those subproblems that are solved when both values of a variable are explored (i.e. do not memoize a subproblem that arises when a unit clause forces the value of a variable). Results indicated that the last option is usually the best one. For example, for a planning problem in which the SSAT encodings contained $9t$ variables and $31t - 1$, where t is the number of time steps in the plan, ZANDER with no memoization could find the optimal plans for both a 5-step problem and a 10-step problem. Using full memoization allowed ZANDER to find optimal plans up to 15 steps, and selective memoization ZANDER to find optimal plans up to 20 steps. At the 25-step level all variants of ZANDER exhausted memory.

Caching can be used to reduce the memory requirements of memoization. This approach uses a fixed amount of memory as a cache for subproblems and their probabilities of satisfaction along with a replacement policy to decide what subproblem to evict when the cache is full and a new subproblem needs to be stored. Two standard cache replacement policies—first-in-first-out (FIFO) and least-recently-used (LRU)—were tested and compared in [ML98b]. LRU outperformed FIFO by an average of approximately 18% across a range of cache sizes for a small planning problem. An approach that saved only “mid-size” problems (since large subproblems are unlikely to be reused and small subproblems can be quickly resolved), was ineffective on that problem. An approach that saved subproblems based on difficulty (size of DPLL subtree), was moderately effective, yielding up to a 37% decrease in CPU seconds compared to straight LRU caching. The optimal difficulty range, however, was determined experimentally and tests with other domains indicated that the range was problem dependent. Furthermore, the benefits of this modified LRU caching technique disappeared as the size of the planning problem increased.

Memoization has also been found to be useful in the context of DPLL algorithms for SAT [BIPS06], #SAT [BDP03b, SBB⁺04], and QBF [GKM04]. #SAT, the problem of counting the number of satisfying assignments in a SAT instance, is #P-complete and is thus closely related to *MAJSAT*, which is PP-complete. [BIPS06] formalize and analyze the complexity of proof systems for *formula caching* DPLL SAT algorithms that save unsatisfiable subproblems. *Component caching*, in which disjoint components of a subproblem, rather than the subproblem, are cached, has been shown to be particularly effective. [BDP03b] showed that component caching is theoretically competitive with the best known

#SAT algorithms and [SBB⁺04] showed that these theoretical results translate into competitive algorithms. They showed that component caching and clause learning can be effectively integrated in an algorithm to solve #SAT problems. Their algorithm is faster than *relsat* [BS97, BP00] by up to several orders of magnitude.

34.6.2.2. A Universal Search Algorithm for XSSAT

The worst-case running time of DPLL-XSSAT is exponential in the size of the formula. Given an unsatisfiable SAT instance that is known to require an exponential size resolution proof, DPLL-XSSAT produces a resolution refutation, so resolution lower bounds for specific formulas give exponential time lower bounds on the running time of DPLL-XSSAT. For random formulas over a broad range, the decision tree complexity of the underlying 3-CNF formula and, therefore, the running time of DPLL-XSSAT (or any decision-tree based algorithm) without pruning, will be exponential: [LMP01], based on results in [BKPS98], show the following:

Theorem 1. Let ϕ be a 3-CNF formula chosen uniformly at random from $\mathcal{F}_m^{k,n}$. For all n sufficiently large, for all m , $n \leq m \leq n^{5/4}$, with high probability any decision tree for ϕ requires exponential size in n .

where $\mathcal{F}_m^{k,n}$ denotes the distribution of formulas obtained by selecting independently m clauses of size k over n variables. A clause is generated by randomly selecting one of the n variables k times, rejecting duplicate selections, and randomly negating the variable with probability $1/2$.

Furthermore, DPLL-XSSAT is not guaranteed to search for the smallest tree. There is an algorithm, however, that is guaranteed to find a close-to-optimal size tree efficiently [LMP01]. Let Φ be an instance of XSSAT with κ consecutive blocks of variables X^1, \dots, X^κ . As described in Section 34.6.1, $\text{Pr}^*[\Phi]$ can be calculated by labeling a canonical decision tree for Φ in a way that is consistent with the recursive definition of $\text{Pr}^*[\Phi]$ given in Section 34.2.

The DPLL-XSSAT algorithm described in Section 34.6.2.1, however, can be generalized to search for a decision tree that is more general than a canonical decision tree (branches need not follow the precise quantifier ordering), but has the following properties: for every i, j , $i < j$, every variable in the block X^i is branched upon in the decision tree before every variable in the block X^j , with the possible exception of variables that appear in unit clauses or pure variables. A decision tree for Φ with these properties is a DPLL *decision tree*, or DPLL tree, for Φ . Thus, a DPLL tree falls in between a decision tree and a canonical decision tree, in the sense that while a decision tree ignores the quantifier ordering and a canonical decision tree follows the ordering exactly, a DPLL tree ignores the quantifier ordering only within blocks. The evaluation of a DPLL tree for Φ is obtained by evaluating each vertex, starting at the leaves, in the manner described in Section 34.6.1 for canonical decision trees.

Based on the work of [CEI96, BP96, BSW99], which shows that there is a relatively efficient deterministic procedure for finding a small tree-like resolution proof for a SAT instance, the following theorem is proved in [LMP01]:

Theorem 2. There is a deterministic algorithm that takes as input an XSSAT instance Φ with m clauses and n underlying variables and outputs T , a DPLL decision tree for ϕ . Moreover, the running time of the algorithm is at most $n^{O(\log s)}O(m)$, where s is the size of the smallest DPLL decision tree for Φ .

Thus, there is an efficient (quasi-polynomial) deterministic procedure for finding a small DPLL tree. The algorithm operates by dovetailing computations for all possible decision trees in a recursive fashion, terminating the computation of suboptimal subtrees as soon as their non-optimality becomes known; details are available in [LMP01]. Although this universal search algorithm has superior theoretical properties to the DPLL algorithm of Section 34.6.2.1, it is possible that the overhead of the dovetailed recursive calls would dominate for most instances.

Since a general decision tree does not respect the quantifier ordering, for a given XSSAT instance Φ , there may, in fact, be a decision tree that is smaller than the DPLL tree. This would suggest that an algorithm that efficiently constructs such a tree would be desirable. [LMP01], however, state a result from [Uma99] showing that an arbitrary decision tree cannot be used to evaluate an XSSAT formula efficiently unless an unexpected collapse of complexity classes occurs. There are decision trees somewhat less restricted than DPLL trees that could be used to evaluate an XSSAT formula [LMP01], but efficient algorithms to find such trees are so far lacking.

34.6.3. Systematic Algorithms For Structured Problems

There are currently three SSAT algorithms that are designed to take advantage of the structure in a particular type of SSAT problem: MAXPLAN [ML98a], ZANDER [ML03], and DC-SSAT [MB05]. Since the algorithm used by ZANDER generalizes the one used by MAXPLAN, we will only describe the ZANDER algorithm here.

34.6.3.1. ZANDER

ZANDER solves goal-oriented, finite-horizon, partially observable, probabilistic propositional contingent planning problems by converting the planning problem into an SSAT instance and solving that problem instead [ML03]. ZANDER works on partially observable probabilistic propositional planning domains consisting of a finite set of distinct *state propositions*, each of which may be **true** or **false** at any discrete time t . A *state* is an assignment of truth values to these propositions. A possibly probabilistic *initial state* is specified by a set of decision trees, one for each proposition. *Goal states* are specified by a partial assignment to the set of propositions; any state that extends this partial assignment is a goal state. Each of a finite set of *actions* probabilistically transforms a state at time step t into a state at time step $t + 1$ and so induces a probability distribution over the set of all states at time step $t + 1$. A set of *random propositions* encodes the uncertainty in the agent's actions and its knowledge of its current state. A subset of the set of state propositions is designated *observable* and a set of *observation propositions* is created corresponding to these observable state propositions. (Note that when the planning problem assumes complete observability, a subset

of state propositions can be declared observable without creating a separate set of observation propositions.) The task is to find an action for each time step t as a function of the value of observation propositions at time steps before step t and that maximizes the probability of reaching a goal state.

Given a plan horizon T , ZANDER time-indexes each proposition and action so the planner can reason about what happens when. Variables are created to record the status of actions and state and random propositions in a T -step plan by taking four separate cross products: actions and time steps 1 through T (existential variables), state propositions and time steps 0 through T (existential variables), random propositions and time steps 1 through T (randomized variables), and observation propositions and time steps 1 through T (randomized variables). The total number of variables in the CNF formula is $V = (A + S + R + O)T + P$, where A , S , R , and O are the number of actions, state propositions, random propositions, and observation propositions, respectively. Using these variables, ZANDER translates the planning problem into an SSAT problem by creating unit clauses that enforce initial and goal conditions, clauses that ensure that exactly one action is taken at each time step, clauses that model the (possibly probabilistic) effects of actions on state propositions, and frame axioms clauses that model lack of effect of some actions on some state propositions unchanged. There are, currently, four ways to encode this type of planning problem as an SSAT instance [MR02]: three of them restrict the plan to linear actions—a single action at each time step of the plan—whereas the fourth encoding allows parallel actions—more than one action at a given time step. The three linear-action encodings differ in the way they encode frame axioms: classical frame axioms, simple explanatory frame axioms, and complex explanatory frame axioms. These encodings, with the exception of the linear-action encoding with complex explanatory frame axioms, are similar to the encodings described in [KMS96] for deterministic planning as satisfiability. Empirically, linear-action encodings with simple explanatory frame axioms and parallel-action encodings are the most efficient, yielding solution times as much as three orders of magnitude faster than the linear-action encoding with classical frame axioms.

Essentially, ZANDER uses the SSAT solver described in Section 34.6.2.1, with some modifications, to find the assignment tree that specifies the assignments to existentially quantified action variables for all possible settings of the observation variables, such that the probability of satisfaction (which is also the probability that the plan will reach the goal) is maximized [ML03]. There are three important modifications:

1. Empirical results indicate that pure variable elimination does not provide significant improvement when solving SSAT encodings of planning problems—frequently, when a variable becomes pure, it also becomes unit and is eliminated through unit propagation—so ZANDER does not use this heuristic [ML03].
2. Randomized variables representing observations are intended to mark possible branch points in the plan, not to encode the probability of making that observation, which is encoded by a separate randomized variable. The algorithm needs to sum the probabilities of satisfaction over both branches of an observation variable. In [ML03], this is accomplished by associating

a probability of $1/2$ with each randomized variable representing an observation and adjusting the final probability of success upward by a factor of 2 for each observation variable. Current versions of ZANDER created by the author, however, sum the probabilities at each observation node directly.

3. The branching heuristic follows the time indexing of the variables when there are variables with different time indices in the same block, branching on variables with a lower time index first. In blocks in which all variables have the same time index (e.g. action variable blocks and observation variable blocks), however, ZANDER follows the arbitrary ordering imposed during the creation of the SSAT encoding of the planning problem.

Results reporting ZANDER's performance on a suite of test problems compared to seven other probabilistic planners are reported in [ML03].

34.6.3.2. DC-SSAT

The most significant advance in SSAT solvers since the DPLL-based algorithms described in Sections 34.6.2.1 and 34.6.3.1 is DC-SSAT, a sound and complete SSAT solver that uses a divide-and-conquer approach to take advantage of the structure in a COPP-SSAT problem, i.e. an SSAT encoding of a completely observable planning problem [MB05]. In such a problem, the agent has complete and accurate information about its environment, although the effects of its actions may be uncertain.

The key idea underlying DC-SSAT is to enlarge the size and scope of the units being manipulated by the solver. In order to solve an SSAT problem, any solver needs to consider, directly or indirectly, every possible satisfying assignment. ZANDER does this by exploring possible values for individual variables, DC-SSAT takes advantage the linear structure in a COPP-SSAT problem—variables in an existential block appear in clauses only with variables from the same existential block and variables from adjacent randomized blocks—to define an equivalence relation on the existential variables that partitions the SSAT problem into subproblems that are relatively independent. These subproblems are based on the structure of the particular SSAT instance being solved; the variable ordering in the prefix and the relationships among the variables induced by the clauses dictate the composition of these building blocks for the final solution.

DC-SSAT solves each of these subproblems using a DPLL-based algorithm to generate a set of *viable partial assignments* (VPAs) that satisfy the clauses in that subproblem, and then uses these VPAs to construct the solution to Φ . Note that DC-SSAT does not save redundant VPAs and each VPA saved is necessary to construct the solution. This is in contrast to ZANDER, which saves every solved subproblem, but often uses only a small percentage of cached subproblems. The VPAs saved by DC-SSAT almost always require 1-2 orders of magnitude less space than the subproblems saved by ZANDER. Roughly speaking, in the same way that ZANDER does a depth-first search on variable assignments, DC-SSAT does a depth-first search on VPAs. Intuitively, one can think of the solution tree for Φ as the best combination of VPAs that are compatible, as defined in [MB05]. A further optimization uses the VPAs generated by earlier subproblems to constrain the VPAs generated by the remaining subproblems.

DC-SSAT outperforms ZANDER by several orders of magnitude with respect to both time and space. The results of a comparison of DC-SSAT and ZANDER on a set of COPP-SSAT problems, adapted from [ML03, HSAHB99], are reported in [MB05]. Although DC-SSAT could be generalized to solve SSAT encodings of partially observable planning problems, the linear structure that DC-SSAT takes advantage of is not as pronounced in such problems—there are connections between non-adjacent blocks of variables—and this would likely reduce the effectiveness of this approach.

The DC-SSAT approach is similar to a number of other approaches. First, DC-SSAT is similar to SAT cut-set approaches that attempt to divide the SAT problem into subproblems by instantiating a subset of variables. In a COPP-SSAT problem, the variables shared by subproblems can be viewed as a cut-set that decomposes the problem. Instead of instantiating variables in the cut-set and propagating this information, however, DC-SSAT uses these variables as a conduit for information between adjacent subproblems. These variables can also be viewed as constraints for combining VPAs into a solution. This is due to the fact that, unlike a SAT problem, where the goal is to find satisfying assignments for the subproblems that can be linked through a common cut-set instantiation, DC-SSAT must find all satisfying assignments for each subproblem and determine the optimal combination of these. Because of the ordering on the variables and the structure of any possible solution, DC-SSAT can order the subproblems and use the solutions of earlier subproblems to restrict the search for solutions in subsequent subproblems. This interplay between subproblems, mediated by a subset of common variables, is similar to the *delayed cut variable binding* technique of [PV96] that tries to bind as few of the cut-set variables as possible while still satisfying the subproblems, searching among alternate assignments of the cut-set variables (starting with alternate assignments of the already instantiated cut-set variables) if this proves impossible.

Second, DC-SSAT is similar to the *bucket elimination* algorithm for solving SAT problems described in [Dec99]. In this approach, the clauses of the SAT instance are partitioned into n buckets (one for each variable) according to an arbitrary variable ordering v_1, v_2, \dots, v_n such that bucket i contains all the clauses whose highest literal is v_i . The algorithm then performs resolution on each bucket from bucket n down to bucket 1, putting resolvents in the appropriate bucket according to the variable ordering. When this *directional resolution* has been completed, a satisfying assignment, if one exists, can be generated without backtracking.

Finally, DC-SSAT is similar to the *component caching* approach to solving #SAT problems described in [SBB⁺04]. Unlike the component-caching algorithm, however, in which the solutions to disjoint problem components are computed and saved dynamically and used to calculate the solution to the original #SAT problem, DC-SSAT builds the solution to the COPP-SSAT problem using the solutions to components that share relatively few variables and that are created at the outset.

34.6.4. Approximation Algorithms

Approximation algorithms are often used to avoid the computation of exact answers to difficult optimization problems. MAJSAT instances are very naturally approximated using stochastic sampling (Section 34.6.4.1) and this sampling technique can be extended to provide an approximation algorithm for general SSAT instances (Section 34.6.6). Unfortunately, this approach does not reduce the complexity of solving the general SSAT problem defined in Section 34.2. Even approximating $\Pr^*[\Phi]$ for an instance of the general SSAT problem is hard. Condon et al. [CFLS97] showed that, given an SSAT instance Φ , there exists a constant $c > 0$ such that approximating $\Pr^*[\Phi]$ to within ratio 2^{-n^c} is PSPACE-hard (where n is the number of Boolean variables in Φ). However, SSAT encodings of finite-horizon probabilistic planning problems (described in Section 34.4.1) have relatively few quantifier alternations and the number of alternations is independent of the number of variables in the SSAT encoding, depending instead on the horizon (number of steps) in the encoded planning problem. It is not known whether the SSAT problem, restricted in this way, is also hard to approximate; APPSSAT, a technique for approximating the solution to such a problem is described in Section 34.6.5.

34.6.4.1. An Approximation Algorithm for Random MAJSAT Problems

The answer to a MAJSAT instance Φ can be approximated by generating some number of assignments to the random variables according to their probabilities and then estimating $\Pr^*[\Phi]$ from that sample. The following lemma directly gives an approximation algorithm for MAJSAT [LMP01]. Choose a set W of w assignments to the randomized variables proportional to their probability. The value of the policy is estimated as the sum of the probabilities of the satisfying sampled assignments divided by the sum of the probabilities of all the sampled assignments. Let v be the true value of $\Pr^*[\Phi]$ and \hat{v} be the estimate found via sampling. A direct application of Chernoff bounds shows that $w = O(\frac{1}{\epsilon^2} \log(\frac{1}{\delta}))$ samples are sufficient to produce an estimate no further than ϵ away from the true value with probability $1 - \delta$:

Lemma 3. Let $\epsilon > 0$ be a target approximation error. The probability that $|v - \hat{v}| > \epsilon$ is less than $2e^{-2\epsilon^2 w}$.

34.6.4.2. An Approximation Algorithm for Random SSAT Problems

As described in Section 34.6.4.1, approximating $\Pr^*[\Phi]$ for a MAJSAT is straightforward. The existence of existential variables in an SSAT instance makes it impossible to apply this sampling technique directly, but sampling can still be used to create an approximation algorithm. The `sampleevalssat` algorithm, presented in [LMP01], uses random sampling to select a subset of randomized variable instantiations. This subset of randomized variable instantiations limits the size of a possible solution by selecting a subset of paths to explore in the tree of assignments. In effect, this converts the SSAT problem to a (possibly exponentially larger) SAT problem. The `sampleevalssat` algorithm then systematically searches

```

sampleevalssat( $\Phi, W$ ) := {
  if  $\phi$  contains an empty clause:
    return 0;
  if  $\phi$  is the empty set of clauses:
    return 1;

  if  $Q_i = \exists$  {
    return max(sampleevalssat( $\Phi(\overline{x}_i), W$ ),
              sampleevalssat( $\Phi(x_i), W$ ))
  }
  else if  $Q_i = \forall$ , {
    Let  $W_0$  be the samples in  $W$  that assign  $x_i$  false
    Let  $W_1$  be the samples in  $W$  that assign  $x_i$  true
    return  $\frac{|W_0|}{|W|}$  sampleevalssat( $\Phi(\overline{x}_i), W_0$ ) +
           $\frac{|W_1|}{|W|}$  sampleevalssat( $\Phi(x_i), W_1$ )
  }
}

```

Figure 34.2. A stochastic sampling algorithm for SSAT problems.

for the existential variable assignments that maximize the probability of satisfaction of the partial tree formed by these samples. Given a sample W of size w of assignments to the randomized variables in an SSAT formula, the **sampleevalssat** algorithm (pseudocode from [LMP01] provided in Figure 34.2) computes the maximum possible $\text{Pr}^*[\Phi]$ given the sample W .

The running time of **sampleevalssat** is $w2^E$, where E is the number of existential variables in the formula, and [LMP01] also show that:

$$w = O\left(\frac{1}{\epsilon^2} \left(\log\left(\frac{P}{\delta}\right)\right)\right)$$

samples are sufficient to be sure with probability $1 - \delta$ of having an estimate no further than ϵ away from the true value, where P is the number of possible assignment trees for the SSAT instance. The number of samples needed to obtain an accurate estimate of the value of the formula $\text{Pr}^*[\Phi]$ with high probability is polynomial for SAT, MAJSAT, and E-MAJSAT, but exponential for ASSAT [LMP01].

Tests of **sampleevalssat** in [LMP01] on a set of problems drawn from $\mathcal{F}_m^{k,n}$ (the distribution of formulas obtained by selecting independently m clauses of size k over n variables), restricted to problems in which all n variables appear in the formula, over a range of number of quantifier alternations and a range of sample sizes show that the mean and variance of the squared error approach zero as the number of samples increases, approaching the set of all possible assignments to the randomized variables.

Many other researchers have explored approximations for probability-based problems. [KMN02] show how approximately optimal actions can be chosen with high probability in infinite-horizon discounted Markov decision processes. They show that it is sufficient to consider the first H actions in the sequence, for an appropriate choice of H . The space of all H -step action sequences is then evaluated

using random sampling. The `sampleevalssat` algorithm was directly inspired by this work [LMP01]. [Rot96] studied the complexity of inference in belief networks and showed that computing the probability of a query node (similar to evaluating a MAJSAT formula) is $\#P$ -complete. In addition, approximating the probability of a query node to within a multiplicative factor of its true value is just as hard as computing the exact value. In contrast, Lemma 3 in Section 34.6.4.1 shows that the complexity of getting within an *additive* factor for MAJSAT is polynomial.

34.6.5. Approximation Algorithms for Structured Problems

APPSSAT is an approximation technique for solving SSAT encodings of finite-horizon, goal-oriented, probabilistic propositional contingent planning problems [Maj07]. APPSSAT is an anytime planner based on ZANDER (see Sections 34.4.1 and 34.6.3.1). Unlike ZANDER, which, in effect, looks at randomized variable instantiations at a particular time step based on the instantiation of variables (particularly existential variables that encode actions) at previous times steps (i.e. earlier in the quantifier ordering), APPSSAT considers the most likely instantiations of the randomized variables that encode the uncertainty in the planning problem and incrementally constructs the optimal solution tree by updating the probabilities of the possible assignments paths in that tree as it processes the instantiations of the randomized variables. In a single iteration, APPSSAT: 1) selects the randomized variable instantiation with the next highest probability p , 2) uses a SAT solver to find all the satisfying assignments that extend this randomized variable assignment, 3) installs each such satisfying assignment into the solution tree and updates, as necessary, the probabilities of success of the actions and the optimal action at each point in the tree, and 4) uses a kind of threshold pruning to compute the probability of success of the optimal plan so far and compares it to the target threshold probability. Given more time, less likely instantiations are considered and the solution is revised as necessary.

APPSSAT, by enumerating complete instantiations of the randomized variables that encode domain uncertainty in descending order of probability, examines, in effect, the most likely outcomes of all actions at all time steps. Instantiating all the randomized variables also has the benefit of reducing the SSAT problem to a number of much simpler SAT problems that can be solved efficiently using a state-of-the-art SAT solver like zChaff [MMZ⁺01]. An alternate approach noted in [Maj07], but rejected due to considerations of excessive overhead, is to instantiate randomized variables based on the instantiation of variables (particularly action variables) at previous times steps.

In some cases, a solution constructed to address a relatively low percentage of possible instantiations will succeed for instantiations not explicitly considered as well, and may return an optimal or near-optimal solution. Experimental results indicated that this approach can sometimes find sub-optimal plans in cases in which ZANDER is unable to find the optimal (or any) plan. In a domain in which all the random variable instantiations are approximately equally likely, however, this approach will perform poorly. And, given APPSSAT's performance on the small test problems in [Maj07], it seems unlikely that this approach could scale up to large, real-world problems without significant modification.

34.6.6. Non-Systematic Algorithms for Random Problems

Non-Systematic search techniques, such as stochastic local search (SLS), consider a subset of potential solutions. SLS searches for a solution by starting with a candidate solution and iteratively exploring the solution space. In one iteration, SLS uses local information to stochastically select another candidate solution that is “close to” the current candidate (according to some metric) and moves to that candidate solution [HS05]. While not complete, SLS algorithms can often solve significantly larger instances of a problem than a systematic algorithm. SLS algorithms for SAT have been extensively investigated since the early success of such algorithms [SLM92, SKC96, MSK97]. (See Part 1, Chapter 6 for a discussion of local search techniques for satisfiability.) SLS techniques have also been incorporated in algorithms for QBF [GHR03, HR05].

Using SLS for SSAT problems is complicated by the fact that an SSAT solver needs to systematically consider all possible assignments to solve the SSAT problem exactly. The stochastic sampling algorithm, `sampleevalssat` (Section 34.6.4.2), however, has been used to create `randevalssat`, an algorithm that is both an approximation algorithm and a non-systematic algorithm for solving SSAT instances [LMP01]. Like the `sampleevalssat` algorithm, the `randevalssat` algorithm limits the size of a possible solution tree—and converts the problem to a lower complexity class problem (SAT)—by randomly sampling to select a subset of randomized variable instantiations. But, instead of systematically searching for the existential variable assignments that maximize the probability of satisfaction of the tree formed by these samples, `randevalssat` uses SLS to look for these existential variable assignments.

This is done by converting the sampled randomized variable instantiations into a two-level Boolean formula called a *treeSAT* formula. A satisfying assignment to the *treeSAT* formula corresponds to a setting of the decision variables that satisfies the original SSAT formula for every random variable instantiation sampled. In general, it will not be possible to find such a setting, so [LMP01] use stochastic local search. This is similar to the scenario-based approach to stochastic constraint programming of [TMW06], briefly described in Section 34.7. Tests on sets of problems drawn from $\mathcal{F}_m^{k,n}$ showed the mean and variance of the squared error decreasing as the number of samples increased, in some cases approaching the accuracy of `sampleevalssat` (Section 34.6.4.2) in less than 25% of the time.

There are a number of problems, however, with the `randevalssat` algorithm. First, like all SLS algorithms, `randevalssat` can get stuck in local optima. Second, the memory requirements of the algorithm to store the *treeSAT* formula can be prohibitively large. In fact, there are SSAT problems for which the algorithm needs provably large samples (see [LMP01] for an example of such a problem). Third, `randevalssat` does not return an answer whose correctness can be readily checked. Fourth, the algorithm returns a partial solution that specifies existential variable settings only for those randomized variable instantiations that were sampled. Finally, `randevalssat` is unsuited to solving SSAT encodings of planning problems (Section 34.6.3.1). The `randevalssat` algorithm would require the observations to be represented by randomized variables, so a random instantiation of the randomized variables describes an observation sequence as well as

an instantiation of the uncertainty in the domain. The observation sequence described, however, may not be observationally consistent, and these inconsistencies can make it impossible to find a solution, even if one exists. The APPSSAT algorithm (Section 34.6.5) suggests one way to deal with this problem.

Some of these issues could be addressed by using the probabilities of the random variables to direct the construction of the partial solution tree. A more substantial modification would be to iteratively build the partial solution tree by using the solution of the partial tree in a given iteration to construct a better partial solution tree (and solution) in the next iteration.

34.7. Stochastic Constraint Programming

We have cited related work in relevant sections throughout this chapter. Here we discuss *stochastic constraint programming* (SCP), a technique developed to model and solve combinatorial decision problems involving uncertainty [Wal02, TMW06]. SCP, a combination of traditional constraint satisfaction, stochastic integer programming, and stochastic satisfiability, generalizes the probabilistic planning as stochastic satisfiability paradigm by allowing variables with arbitrary domains and arbitrary constraints over those variables. A *stochastic constraint satisfaction program* (SCSP) is a decision form of stochastic constraint programming. As defined in [TMW06], an SCSP is a 6-tuple $\langle V, S, D, P, C, \theta \rangle$ where:

1. V is a set of *decision variables*,
2. S is a set of *stochastic variables*,
3. D is a function mapping each variable in V and S to a domain of possible values,
4. P is a function mapping each variables in S to a probability distribution for its domain,
5. C is set of *constraints* over V defined in the standard CSP manner,
6. $H \subseteq C$ is the set of *chance constraints*, i.e. constraints containing at least one stochastic variable, and
7. for each chance constraint $h \in H$, $0 \leq \theta_h \leq 1$ is a *threshold probability* specifying the probability with which that constraint must be satisfied.

In an m -stage SCSP, V and S are partitioned into disjoint subsets V_1, V_2, \dots, V_m and S_1, S_2, \dots, S_m . Each stage contains a set of decision variables and a set of stochastic variables, modeling the interaction between a set of decisions and an uncertain environment. In stage i , the decision variables in V_i are those variables whose values can be set by a solver (e.g. production levels) and the stochastic variables in S_i , whose values are set according to their associated probability distributions, encode the uncertainty in the environment that affects the results of those decisions (e.g. demand for the products). Decision and stochastic variables are clearly analogous to the existential and randomized variables in an SSAT problem, and the partition and ordering of the subsets of V and S are analogous to a $2m$ -block SSAT problem prefix of $V_1 S_1 V_2 S_2 \dots V_m S_m$, and the solution of the m -stage SCSP is similar to the solution of the $2m$ -block SSAT problem. Informally, a solution specifies settings for the decision variables in V_i for each setting of the stochastic variables in $\cup_{j=1}^{i-1} (V_j \cup S_j)$ such that the hard constraints

$C - H$ are satisfied and each chance constraints $h \in H$ is satisfied with probability at least θ_h .

SAT and CSP, the deterministic versions of SSAT and SCP, are both NP-complete and the correspondences between SSAT and SCP problems and their respective complexities are close and immediate. A 1-stage SCSP in which all the variables are stochastic is the SCP version of MAJSAT, and both are PP-complete. A 1-stage SCSP in which a set of decision variables is followed by a set of stochastic variables is the SCP version of E-MAJSAT, and both are NP^{PP}-complete. Finally, an m -stage SCSP is the SCP version of SSAT, and both are PSPACE-complete.

SCSPs are expressed in the *stochastic optimization programming language* (stochastic OPL) [TMW06], an extension of OPL, the constraint modeling language of [VMR99]. Stochastic OPL supports stochastic variables and constraints as well as their deterministic counterparts. Stochastic OPL supports both deterministic and stochastic optimization (e.g. optimize the expectation of an objective function) and risk modeling (e.g. maximize the absolute deviation function, minimize the difference between the best- and worst- case objective function values, maximize the minimum value of the objective function).

The semantics for a stochastic constraint program can be either *policy-based* [Wal02] or *scenario-based* [TMW06]. The policy view is based on a *policy tree*, a tree representing a policy that specifies values for the decision variables (similar to an SSAT solution tree). Each decision variable node has one child (the value chosen by the policy) and each stochastic variable node has a child for each possible value in that variable's domain. The probability of satisfaction of the policy is defined as the sum of the leaf values weighted by their probabilities. A leaf is assigned the value 1 (0) if the partial assignment specified by the path from the root to that leaf satisfies (does not satisfy) all the constraints. The probability of a leaf is the probability that the stochastic variables on that path have the values specified by the partial assignment. Note that the probability of satisfaction of an SSAT solution tree could be defined in the same way. Satisfying policies—in particular, the policy that has the maximum probability of satisfaction—can be found using backtracking and forward checking algorithms. The algorithm described in [Wal02] that is associated with this policy-based view is essentially the *evalssat* algorithm described in Section 34.6.2.1 with forward checking.

Each path in a policy tree can also be thought of as a scenario. The scenario view makes this explicit by constructing a *scenario tree* whose paths correspond exactly to all possible assignments of the discrete stochastic variables in the SCSP. For each path, instantiating those variables to the values specified by that path yields a standard, deterministic CSP. When this is done for each path in the scenario tree, a collection of deterministic CSPs is produced, each of which has V as its set of variables. The values for some of these variables must have the same value in any solution to the SCSP, e.g. the decision variables in V_1 must have the same value in any scenario. With the addition of appropriate constraints ensuring the necessary agreement among shared variables, however, the collection of CSPs can be solved using standard CSP solution techniques, yielding a solution to the underlying SCSP. In spite of the fact that the number of scenarios and, thus, the

collection of CSPs that need to be solved, grows exponentially with the number of stages in the SCSP, [TMW06] report better performance using the scenario-based approach on a production problem from [Wal02] than a policy-based approach using either backtracking or forward checking.

34.8. Future Directions

SSAT research is still in its early stages; there are numerous opportunities for further work, some of which we describe here.

34.8.1. Data Structures

More sophisticated data structures in which to store the matrix of the SSAT instance would almost certainly improve the efficiency of an SSAT engine. *Lazy data structures*, in particular *watched literals*, have been used to great advantage in SAT engines [MMZ⁺01]. Three different types of watched data structures for QBF were investigated in [GGN⁺03]: literals, quantifiers, and clauses. In tests on structured and randomly generated problems, watched literals provided modest performance speed-up (less than an order of magnitude) that was positively correlated with clause size, watched quantifiers provided no improvement, and watched clauses provided the most performance speed-up (as much as two orders of magnitude).

The *trie* data structure has been used to represent SAT problems, and several advantages have been claimed for this approach [ZS00], including automatic elimination of duplicate clauses when the trie is constructed, reduced memory requirements, more efficient unit propagation. These advantages would be obtained in the SSAT setting as well.

34.8.2. Branching Heuristics

As noted in Section 34.6.2.1, branching heuristics for SSAT problems are limited by the requirement that, except for instances of unit propagation and pure variable elimination, variables in the left-most block of the prefix must be assigned values before variables that appear later in the prefix. Branching heuristics come into play, however, in deciding which variable in the left-most block will be branched on next. The DPLL-XSSAT algorithm described in Section 34.6.2.1 merely selects the first variable that appears in the SSAT problem's current prefix; in a randomly generated problem, this is equivalent to following a static, random ordering. SSAT algorithms that solve encodings of probabilistic planning problems, such as MAXPLAN, ZANDER (described in Section 34.6.3.1), and DC-SSAT (described in Section 34.6.3.2), use a branching heuristic that gives priority to variables with lower time indices, but do not specify an ordering for variables within blocks of similarly quantified variables that have the same time index, again using a static, random ordering. Using a random ordering is likely to be insignificant in small problems, but in problems with large blocks, such as planning problem encodings of large real-world planning problems, a branching heuristic that uses a more sophisticated branching heuristic could provide a significant performance gain.

Experiments reported in [LMP01] and briefly described in Section 34.6.2.1 provide evidence that performance gains can be obtained using straightforward adaptations of several common branching heuristics for SAT problems. These heuristics exploit characteristics such as how many clauses a variable appears in, how small these clauses are, and the ratio of positive to negative instances of the variable. It might be possible, however, to develop more effective branching heuristics that take into account other features of SSAT problems, such as the ordering of variables in the prefix or the probabilities associated with the randomized variables.

34.8.3. Graph Representations

It might be useful to study SSAT problems by looking at their hypergraph representations. In one possible hypergraph representation, the vertices represent clauses and a hyperedge represents a variable shared by the subset of clauses the hyperedge connects. There are a number of well-studied characteristics of hypergraphs that appear to have a relationship to the difficulty of SSAT problems [New03]. This approach could yield insights into the nature of SSAT problems and provide the basis for new, more efficient SSAT solvers. For example, DC-SSAT, the solver described in Section 34.6.3.2, is able to solve COPP-SSAT problems so efficiently because, when viewed as a hypergraph, these problems exhibit a high degree of *community structure*, i.e. the existence of groups of nodes that have a high density of connections within the groups but relatively few connections between groups [New03]. In fact, a decomposition of a hypergraph representation of an SSAT encoding of a COPP-SSAT problem that minimizes connections between the components of the decomposition yields exactly the problem decomposition used by the DC-SSAT algorithm. Is it possible to characterize when the DC-SSAT approach will be beneficial in the case of general SSAT problems? Variables that are far apart in the prefix, but share a clause, may induce the solver to explore a long, unproductive path. Assignment compatibility issues that were local in a COPP-SSAT problem become global in the general case. [Wal01] investigated the impact of the connection topologies of graphs associated with real-world search problems and related this to the notion of a *backbone* (variables that have the same value in all solutions). What role do these notions play in SSAT problems? What kinds of structure exist in SSAT encodings of real-world problems and how can that structure be exploited?

34.8.4. Nonchronological Backtracking

Results in [Maj04] indicate that the benefits of nonchronological backtracking (NCB) are not as easy to realize in SSAT as QBF. One response to that problem—monitor the solution process and turn off NCB when it appears that the overhead of NCB will outweigh its benefit—is described in [Maj04]. A more efficient way of creating and manipulating reasons, e.g. using bit vectors, would reduce the overhead of NCB. Since a SAT reason can be any subset of the randomized literals necessary for the satisfaction of some clause, choosing that subset with the aim of minimizing its size may not be the best strategy. [Maj04] suggests

that, where there are choices, a criterion that favors randomized literals that appear in clauses with fewer existential literals may improve the efficiency of NCB, since such literals will have less of a tendency to pull existential literals into the reason during backtracking. The poor performance of NCB on SSAT encodings of planning problems, in which most clauses have at most one randomized literal, lends support to this notion. It may also be possible to develop branching heuristics that reduce the average size of the reasons created, thereby improving the effectiveness of NCB.

34.8.5. Component Caching

Work in [BDP03b, SBB⁺04], briefly described in Section 34.6.2.1, suggests that component caching would be much more effective than the formula caching currently used in DPLL-XSSAT. The superior performance of DC-SSAT, which uses an approach similar to component caching to solve SSAT encodings of completely observable probabilistic planning problems, tends to confirm this and suggests that it would be useful to develop more refined component caching approaches.

34.8.6. Learning

Learning contributes significantly to the speed of state-of-the-art SAT solvers (see Part 1, Chapter 4 for more on this) and it seems likely that learning could improve the performance of SSAT solvers as well. For example, clause learning is an important component of nonchronological backtracking (NCB) in SAT problems. Recording reasons as they are created in order to prevent the solver from rediscovering them in other branches of the computation has been used to significantly enhance the performance benefits obtained from reason creation in both SAT [BS97] and QBF [GNT02] solvers. This technique has the potential to improve the effectiveness of NCB in an SSAT solver (Section 34.6.2.1). UNSAT reasons can be recorded as additional clauses that prevent partial assignments leading to unsatisfiability; recording SAT reasons is not as straightforward [Maj04].

[SM07] use machine learning techniques in a search-based QBF solver to predict and select the best variable selection heuristic to use from a portfolio of heuristics, given the current subproblem. This approach produced positive results both in terms of run times and percentage of problems solved on a suite of benchmarks, and it is likely that this approach would be effective for SSAT problems as well and could be adapted for SSAT without significant alterations.

34.8.7. Stochastic Local Search

[Maj00] describes several ways that stochastic local search could be incorporated into an SSAT solver other than the approach described in Section 34.6.6. The *randevalssat* algorithm could be used as a subroutine in an algorithm that periodically restarts with a new set of samples. Stochastic local search could be used repeatedly to find many satisfying assignments that are used to create a solution tree; this is the approach taken by WALKSSAT, an algorithm described in [ZM05]. WALKSSAT generates an initial path in a potential solution tree by

treating all the variables in the SSAT problem as existential variables and using WALKSAT to search for a solution. WALKSSAT then uses WALKSAT as a subroutine to expand nodes on this path and on subsequently created paths. Node expansion continues until all nodes are expanded, a specified minimum probability of satisfaction is met, or a specified maximum number of expansions is reached. Tests of WALKSSAT were inconclusive. The algorithm could almost certainly be improved by using a better heuristic to direct the order of node expansions; currently WALKSSAT expands the most recently generated node first, like a depth-first search. This also weakens the idea of WALKSSAT as a local search algorithm.

A more promising approach, currently being developed by the author, combines local search and systematic search, using WALKSAT to identify possible paths in a solution tree and depth-limited DPLL-style systematic search to expand the tree. Stochastic local search has also been used as a component in solvers for 2-QBF [HR05] and QBF [GHR03]. In both cases, local search is used to quickly find satisfying assignments to SAT problems that result either from instantiating the universal variables or from treating the universal variables as existential variables, and these approaches could possibly be adapted for SSAT.

34.8.8. Approximation Techniques

A possible approximation technique for SSAT would convert the SSAT instance into a SAT instance by treating the randomized variables as existential variables with values determined by the rounded probabilities associated with those variables, solving the resulting SAT problem efficiently, and then gradually reintroducing uncertainty to improve the quality of the solution. It is not clear, however, how to reintroduce the uncertainty without sacrificing the efficiency gained by removing it.

34.8.9. Algebraic Approaches

Algebraic approaches have been applied to SAT. [CEI96] showed that the Gröbner basis algorithm could be used as the basis for a heuristic for unsatisfiability testing in SAT problems. More recently, [CK07] described a method that uses Gröbner bases to preprocess the SAT CNF formula, adding new constraint information. Preliminary results indicated that, while the preprocessing time often outweighs the reduction in solution time, there appears to be some potential in using the approach on structured problems. It might be useful to investigate this type of approach in the SSAT setting.

34.8.10. Message Passing Algorithms

Survey propagation is an algorithm for solving SAT instances that has shown promise for solving the hardest random k -SAT instances, which, empirically, are concentrated in a sharply defined region corresponding to a clause/variable ratio that varies with the value of k . Like the belief propagation algorithm for belief network inference [Pea88], survey propagation is a message-passing algorithm, but, unlike belief propagation, in which the messages between cliques of variable

nodes in the belief network contain conditional probability information, messages in survey propagation are passed between nodes representing variables and clauses in a *factor graph* representation of the SAT instance, and contain information about the expected values of variables in a solution [BMZ05]. These messages are *surveys*, or aggregations, of simpler *warning messages* that, very roughly speaking, “warn” a clause c containing literal l when there are a number of other clauses containing \bar{l} and, as a result, would like the value of $|l|$ to be set such that l would be **false**, making it more likely that c would become empty. This probabilistic information about the solution is used to fix the values of one or more variables, thus simplifying the problem. This process is iterated until the problem is sufficiently simplified so that it can be solved using a standard SAT solver.

Survey propagation and DC-SSAT (see Section 34.6.3.2) are related. (There are also similarities between survey propagation and bucket elimination, since bucket elimination is similar to a directional version of belief propagation [Dec99]. In fact, all of these algorithms—survey propagation, belief propagation, bucket elimination, and DC-SSAT—operate by distributing locally calculated information throughout the problem and using that information to guide the search for a solution.) Like the messages in survey propagation, the VPAs (viable partial assignments) that are calculated by DC-SSAT and passed between the COPP-SSAT subproblems contain information about how these smaller pieces of the problem restrict the values of variables in any possible solution. A direct generalization of DC-SSAT to problems without the strict linear structure of a COPP-SSAT problem, is unlikely to be as effective as DC-SSAT on SSAT encodings of COPP-SSAT problems. It is possible that the survey propagation technique could provide the basis for a DC-SSAT-like algorithm that could solve general SSAT problems as effectively as DC-SSAT solves SSAT encodings of COPP-SSAT problems.

34.8.11. Adapting Other QBF Techniques

The close relationship between stochastic satisfiability and quantified Boolean formulas (see Section 34.2.1) suggests that some of the techniques that have been developed to solve QBF problems in addition to those mentioned in Sections 34.8.4, 34.8.6, and 34.8.7 could profitably be adapted to solve SSAT problems.

A number of researchers have shown that inference can be an effective tool to solve QBF problems. [KBKF95] introduced *Q-resolution*, a procedure that can eliminate multiple universal variables. sKizzo [Ben04] is a QBF solver that combines variable elimination and search. [CH05] developed Q-PREZ, a QBF solver that uses resolution, mitigating the potential exponential clause growth by partitioning the clauses and storing them in zero-suppressed binary decision diagrams. The QBF solver quantor [Bie05] applies Q-resolution and universal variable expansion until all universal variables are eliminated and the resulting equisatisfiable formula can be solved by a SAT solver. [GNT06] introduced Q-resolution on terms for formulas in disjunctive normal form and related this type of resolution and the original Q-resolution on clauses [KBKF95] to DPLL-based approaches. [SB06] showed how extended binary clause reasoning (hyper-binary

resolution) can be adapted for QBF problems in the solver 2clsQ. (See Part 2, Chapter 30 for a discussion of resolution and variable elimination in QBF.)

Aside from unit propagation and pure variable elimination, inference techniques are absent from current SSAT solvers. The similarity of SSAT and QBF suggests that the inference techniques employed by various QBF solvers could be adapted for use in SSAT solvers. Adapting these techniques, however, is complicated by the fact that the randomized variables in an SSAT problem impose less stringent demands than do universal variables and, consequently, weaken, or prohibit the use of some of the inference techniques employed in QBF solvers. For example, [Bie05] uses Q-resolution and *universal variable expansion* to eliminate variables. Q-resolution is standard resolution followed by *forall reduction*, in which, roughly speaking, universal variables can be removed from a clause if the clause contains no existential variables that come after any of the universal variables in the prefix. The clause must be satisfied by one of its existential literals, since, if all of them are **false**, a contradictory clause of universal literals remains. In an SSAT problem, the standard resolution would be possible, but randomized variables cannot be eliminated in the same way that forall reduction eliminates universal variables. The elimination of randomized variables in a clause, even if there are no existential variables in the clause that appear after any of the randomized variables in the prefix, could erroneously reduce the overall probability of satisfaction, since, even if all its existential literals are **false**, the clause may still be satisfiable with some probability greater than zero. This is a significant problem since this kind of reduction is an important way to control the exponential growth in formula size that variable elimination can produce.

Universal variable expansion is also not possible. In [Bie05], universal variable expansion is applied to a formula in which the last two blocks in the prefix are a universal block followed by an existential block. Roughly speaking, the elimination of a universal variable through expansion is accomplished by duplicating the clauses containing the universal and existential variables, replacing the existential variables in the second set with new variables, and then, in one set of clauses, setting the universal variable to be eliminated to **false** and propagating the effect, and, in the other set, setting the universal variable to **true** and propagating the effect. This can reduce the number of clauses in the matrix as well as eliminating the universal variable. Unfortunately, due to the probabilistic nature of randomized variables, eliminating them in this way can lead to an incorrect reduction in the probability of satisfaction.

Essentially, randomized variables are harder to eliminate than universal variables. In order to eliminate randomized variables, it might be possible to tag the clause groups from which random literals have been removed with information that a SAT solver could use when solving the eventual SAT problem, to produce the correct solution to the SSAT problem. If each group of clauses were tagged with 1) the values of the randomized variables that eliminated the randomized literals in that group of clauses, and 2) the product of the probabilities of those randomized variable settings, the SAT solver could use this information to calculate the probability of satisfaction (the probability of satisfaction would need to be reduced when one of the clauses in a group becomes **false**) and to construct the solution tree. Adapting variable elimination techniques for belief networks

[Pea88, Jor99] might be possible here.

QBF and SSAT share the restriction imposed by the variable ordering in the prefix. Although the variable ordering within blocks of similarly quantified variables can be ignored, the necessity to respect the ordering of the blocks in the prefix is a major factor contributing to the difficulty of solving SSAT problems. [AS04] describe a way, however, to remove this restriction in QBF: as satisfying assignments are found using a DPLL-based SAT solver (treating all variables as existential variables), these assignments are combined in a reduced ordered binary decision diagram (ROBDD) in which the ordering of variables is the same as the variable ordering in the prefix of the QBF instance. If the set of assignments stored in the ROBDD is a solution, then the ROBDD reduces to the 1-terminal node. Such an approach could possibly be adapted to SSAT instances by using some form of algebraic decision diagrams, instead of ROBDDs, to allow probabilities of satisfaction to be represented and manipulated. The optimization nature of an SSAT problem, however, makes the stopping criterion unclear.

34.8.12. Combining Logic-Based Methods and Optimization Methods

Researchers from both the artificial intelligence and operations research communities have begun to develop hybrid representations and solution techniques that integrate logic-based modeling and techniques with mathematical modeling. [HOTK00] has proposed a framework for unifying constraint satisfaction and optimization methods based on the similarity of the search/inference duality in constraint satisfaction and the strengthening/relaxation duality in optimization. Using branching algorithms as an example, [HOTK00] points out that branching on a variable can be viewed as search, from a CSP perspective, or as a strengthening of the original problem by restricting the value of a variable, from the optimization perspective. Furthermore, the reduction of variable domains in constraint satisfaction obtained through constraint propagation (inference) after a variable has been assigned a value is analogous to a relaxation of the problem at that node in the tree in an optimization approach. The use of logic-based methods for optimization and optimization methods for logical inference has been elaborated in [Hoo00] and [CH99], respectively.

As described in Section 34.7, [TMW06, Wal02] have integrated ideas from constraint programming and stochastic satisfiability with ideas from stochastic integer programming to produce stochastic constraint programming (SCP). No work has been done to compare the relative strengths and weaknesses of the SCP-based approach and the SSAT-based approach to decision making under uncertainty. Unlike the SSAT approach, the SCP approach can express global and arithmetic constraints; it can also express variables with non-binary domains more easily. On the other hand, it is likely that the SSAT-based approach can take advantage of some of the same techniques that have produced extremely fast SAT solvers in recent years. In the deterministic setting, a study of mappings between CSPs and SAT problems [Wal00] found that the efficiency of the standard DPLL algorithm for SAT instances and the forward-checking (FC) and maintaining-arc-consistency (MAC) algorithms for CSPs, as measured by the size of the search tree generated, was highly dependent on the encoding used. On

some encodings, DPLL dominated the other two algorithms, while on others, FC and/or MAC dominated. A similar study comparing SCSPs and SSAT problems would help delineate the advantages and disadvantages of these two approaches.

[DGP04, DGLP04, DGH⁺05] have investigated the benefits of pseudo-Boolean representations of SAT problems extensively. (See Part 2, Chapter 28 for a discussion of pseudo-Boolean constraints and satisfiability.) [ZKC01] have developed LPSAT, an efficient linear-programming-based SAT solver that uses mixed integer linear programming (MILP) to solve a circuit design problem involving both Boolean and arithmetic components. In order to combine these different components into the MILP framework, they represent the Boolean components as an integer linear program, rather than a SAT problem, and the arithmetic components as linear arithmetic constraints. [Wal97] has developed a stochastic local search algorithm for pseudo-Boolean representations of SAT problems. And [WW00, KW99] have developed techniques that incorporate linear programming into SAT-based planning. It would be worthwhile to investigate the possibility of using these and other representations and solution techniques borrowed from operations research in the SSAT setting.
