Press

Propositional logic has been recognized throughout the centuries as one of the cornerstones of reasoning in philosophy and mathematics. Over time, its formalization into Boolean algebra was accompanied by the recognition that a wide range of combinatorial problems can be expressed as propositional satisfiability (SAT) problems. Because of this dual role, SAT developed into a mature, multi-faceted scientific discipline, and from the earliest days of computing a search was underway to discover how to solve SAT problems in an automated fashion.

This book, the Handbook of Satisfiability, is the second, updated and revised edition of the book first published in 2009 under the same name. The handbook aims to capture the full breadth and depth of SAT and to bring together significant progress and advances in automated solving. Topics covered span practical and theoretical research on SAT and its applications and include search algorithms, heuristics, analysis of algorithms, hard instances, randomized formulae, problem encodings, industrial applications, solvers, simplifiers, tools, case studies and empirical results. SAT is interpreted in a broad sense, so as well as propositional satisfiability, there are chapters covering the domain of quantified Boolean formulae (QBF), constraints programming techniques (CSP) for word-level problems and their propositional encoding, and satisfiability modulo theories (SMT). An extensive bibliography completes each chapter.

This second edition of the handbook will be of interest to researchers, graduate students, final-year undergraduates, and practitioners using or contributing to SAT, and will provide both an inspiration and a rich resource for their work.

Edmund Clarke, 2007 ACM Turing Award Recipient

“SAT solving is a key technology for 21st century computer science.”

Donald Knuth, 1974 ACM Turing Award Recipient

“SAT is evidently a killer app, because it is key to the solution of so many other problems.”

Stephen Cook, 1982 ACM Turing Award Recipient

“The SAT problem is at the core of arguably the most fundamental question in computer science: What makes a problem hard?”

HANDBOOK OF SATISFIABILITY

Frontiers in Artificial Intelligence and Applications

The book series Frontiers in Artificial Intelligence and Applications (FAIA) covers all aspects of theoretical and applied Artificial Intelligence research in the form of monographs, selected doctoral dissertations, handbooks and proceedings volumes. The FAIA series contains several sub-series, including ‘Information Modelling and Knowledge Bases’ and ‘Knowledge-Based Intelligent Engineering Systems’. It also includes the biennial European Conference on Artificial Intelligence (ECAI) proceedings volumes, and other EurAI (European Association for Artificial Intelligence, formerly ECCAI) sponsored publications. The series has become a highly visible platform for the publication and dissemination of original research in this field. Volumes are selected for inclusion by an international editorial board of well-known scholars in the field of AI. All contributions to the volumes in the series have been peer reviewed.

The FAIA series is indexed in ACM Digital Library; DBLP; EI Compendex; Google Scholar; Scopus; Web of Science: Conference Proceedings Citation Index – Science (CPCI-S) and Book Citation Index – Science (BKCI-S); Zentralblatt MATH.

Preface First Edition

Propositional logic has been recognized throughout the centuries as one of the corner stones of reasoning in philosophy and mathematics. During history, its formalization into Boolean algebra was gradually accompanied by the recognition that a wide range of combinatorial problems can be expressed as propositional satisfiability (SAT) problems. Because of these two roles, SAT has become a mature multi-faceted scientific discipline. Initiated by the work of Cook, who established its \mathcal{NP} -complete status in 1971, SAT has become a reference problem for an enormous variety of complexity statements.

Simultaneously, many real-world problems were formalized as SAT decision problems using different encoding techniques. This includes verification problems in hardware and software, planning, scheduling and combinatorial design.

Due to the potential practical implications, an intensive search from the early days of computing has been underway of how one could solve SAT problems in an automated fashion. In 1957, Allen Newell and Herb Simon introduced one of the first AI programs, the Logic Theory Machine, to prove propositional theorems from Whitehead and Russell's "Principia mathematica". Shortly after in 1960, Martin Davis and Hillary Putnam introduced their now famous decision procedure for propositional satisfiability problems (a more space efficient version due to Martin Davis, George Logemann and Donald Loveland followed in 1962).

Asked by the editors of this handbook as a witness of his role in this development Martin Davis wrote

I felt delighted and honored when I was asked to write a foreword to this Handbook. But when I examined the table of contents and especially, when I read the initial historical article, I concluded that it is an honor that I hardly deserve. When Hilary Putnam and I began our work on automated theorem proving half a century ago, we mainly thought of it as a way to get funding for work on our real passion, Hilbert's tenth problem. We hardly imagined that SAT might have an independent importance aside from its role in automated deduction. It is wonderful to see what a flourishing area of research satisfiability has become.

Of course what is regarded as the most important problem in theoretical computer science, $\mathcal{P} \stackrel{?}{=} \mathcal{NP}$ lives right here. It is remarkable that we still don't know whether or not there is a poly-time algorithm for SAT. I am in a tiny minority in being unconvinced that the answer must be "No". I surely don't expect anyone to find a really efficient uniform algorithm for SAT. But I find the heuristic arguments against the existence of a very inefficient algorithm for SAT that happens to run in poly-time quite unconvincing.

The topics of the handbook span practical and theoretical research on SAT and its applications and include search algorithms, heuristics, analysis of algorithms, hard instances, randomized formulae, problem encodings, industrial applications, solvers, simplifiers, tools, case studies and empirical results. SAT is

interpreted in a rather broad sense. Besides propositional satisfiability it includes the domain of quantified Boolean formulae (QBF), constraints programming techniques (CSP) for word-level problems and their propositional encoding and particularly satisfiability modulo theories (SMT).

The handbook aims to capture the full breadth and depth of SAT and to bundle significant progress and advances in automated solving. It covers the main notions and techniques and introduces various formal extensions. Each area is dealt with in a survey-like style, where some details may be neglected in favor of coverage. The extensive bibliography concluding each chapter will help the interested reader to find his way to master necessary details.

The intended audience of the handbook consists of researchers, graduate students, upper-year undergraduates, and practitioners who wish to learn about the state of the art in actual solving. Limited prior knowledge about the field is assumed. The handbook also aims to assist researchers from other fields in applying ideas and methods to their own work. We thus hope the handbook will provide a means for cross fertilization.

The start and completion of the underlying project would not have been possible without the support and encouragement of many people. As such, this handbook is a community effort and we take this opportunity to express our gratitude to this community as a whole, without addressing to all individual contributions. We are grateful to IOS Press Publishing Company because of their interest in materializing all these efforts into the book you are holding now.

We are indebted to Martin Davis for his contribution to this preface and to Edmund Clarke for his support and recommendations which you may find at the back cover of this copy.

Along with the completion of this handbook another similar project was started by Teofilo Gonzalez. The handbook on \mathcal{NP} -Completeness, Theory and Applications, will be finished shortly and could be considered as a very welcome addition to those concepts which touch propositional proof complexity. These typically proof-system related issues are certainly not fully covered by us. And also there, various practical contributions on SAT solving will find updates which continue to be relevant as the discipline moves forward.

Finally we take the opportunity to spend a few words on a particularly inspiring event who took place during the last SAT conferences: The SAT Competition. Started at the Cincinnati conference in 2002, Daniel Le Berre and Laurent Simon put an incredible amount of work in establishing the format of rules, benchmarks and solver-performance evaluations which made SAT a competitive area where especially young researchers feel triggered to contribute. As a consequence, one of the most frequently used references in this handbook undoubtedly is their competition web page.

Arjen van Lith designed the cover of our Handbook. It is a challenge to recognize various SAT research related patterns hidden there.

Preface Second Edition

When the first edition of this handbook was published in 2009 advances in SAT were mostly only known to experts, and SAT was seen as a key technology only in certain applications. Since then the number of practical applications has exploded, along with greater awareness of the usefulness of SAT in general: In the last century showing that a certain problem is as hard as SAT was the end of the story and trying to solve it directly seemed to be hopeless. Relying on the continuing improvements made in practical SAT solving, it is now widely accepted that being able to encode a problem into SAT also is highly likely to lead to a practical solution. This “SAT Revolution” started at the end of the last century and continues to produce amazing new practical and theoretical results.

Accordingly, this second edition contains several updates, including a completely revamped Chapter 4 on conflict-driven clause learning. Half the chapters were updated or extended or both. Comments by Donald Knuth were also taken into account, collected while he was preparing the Section on Satisfiability in volume 4 of the “The Art of Computer Programming”. This section appeared as fascicle 6a with more than 300 pages in 2015 and is a major milestone in the SAT literature that has appeared since the first edition of this Handbook.

Three important topics, which were already in the first edition of the handbook and deserve their own chapter, are now given enough space and discussed in detail: there is the new Chapter 7 on proof complexity, Chapter 9 on preprocessing, as well as the new Chapter 12 on automated configuration and solver selection. Additionally, the new Chapter 15 covers proofs of unsatisfiability, one of the main recent developments in practical SAT solving. These proofs are essential in solving long-standing mathematical problems.

Beside these four completely new chapters, there are three new chapters which cover topics already discussed in the first edition. These three chapters focus on new aspects and new technology and are written by authors who made fundamental contributions to change the state of the art. First, recent developments regarding quantified Boolean formulas including the discussion of proof systems are covered in the new Chapter 31. Second, the focus of the new Chapter 24 is on core-based methods for maximum satisfiability which have improved scalability considerably. Finally, the last new Chapter 26 covers a novel research direction on practical and approximate model counting with strong statistical guarantees.

Research in SAT has established itself as a vibrant cross community effort. Beside the main SAT conference, other major conferences and journals in diverse fields from automated reasoning, verification, hardware to software engineering, complexity theory, even algorithms and of course artificial intelligence cover SAT

and its extensions areas of interest. It is also worth mentioning that competitions continue to serve as a show case as well as motivation of the field.

One could argue that SAT is now very widespread across these fields. As one example, and maybe most striking, is the adoption of SAT in other reasoning disciplines, starting of course with SMT solving, the use of lazy clause generation in constraint programming, as well as SAT based splitting in first-order theorem proving, and finally in the use of hammers in interactive theorem proving for higher-order logic relying directly or indirectly on SAT.

As the first edition appears to have done, we hope that also this second edition of the Handbook will serve researchers and practitioners using or contributing to SAT, and provide both an inspiration and a rich resource for their own work.

Contents

Part I. Theory and Algorithms

Chapter 1. A History of Satisfiability	3
<i>John Franco and John Martin</i>	
1.1 Preface: the concept of satisfiability	3
1.2 The ancients	6
1.3 The medieval period	8
1.4 The renaissance	9
1.5 The first logic machine	10
1.6 Boolean algebra	10
1.7 Frege, logicism, and quantification logic	12
1.8 Russell and Whitehead	13
1.9 Gödel's incompleteness theorem	14
1.10 Effective process and recursive functions	14
1.11 Herbrand's theorem	15
1.12 Model theory and Satisfiability	15
1.13 Completeness of first-order logic	17
1.14 Application of logic to circuits	18
1.15 Resolution	19
1.16 The complexity of resolution	21
<i>Alasdair Urquhart</i>	
1.17 Refinement of Resolution-Based SAT Solvers	23
1.18 Upper bounds	25
<i>Ewald Speckenmeyer</i>	
1.19 Classes of easy expressions	27
1.20 Binary Decision Diagrams	31
1.21 Probabilistic analysis: SAT algorithms	32
1.22 Probabilistic analysis: thresholds	39
1.23 Stochastic Local Search	42
<i>Holger Hoos</i>	
1.24 Maximum Satisfiability	43
<i>Hantao Zhang</i>	
1.25 Nonlinear formulations	45
<i>Miguel Anjos</i>	
1.26 Pseudo-Boolean Forms	49
1.27 Quantified Boolean formulas	51
<i>Hans Kleine Büning</i>

Chapter 2. CNF Encodings	75
<i>Steven Prestwich</i>	
2.1 Introduction	75
2.2 Transformation to CNF	75
2.3 Case studies	83
2.4 Desirable properties of CNF encodings	91
2.5 Conclusion	94
References	94
Chapter 3. Complete Algorithms	101
<i>Adnan Darwiche and Knot Pipatsrisawat</i>	
3.1 Introduction	101
3.2 Technical Preliminaries	101
3.3 Satisfiability by Existential Quantification	104
3.4 Satisfiability by Inference Rules	109
3.5 Satisfiability by Search: The DPLL Algorithm	112
3.6 Satisfiability by Combining Search and Inference	116
3.7 Conclusions	128
References	128
Chapter 4. CDCL SAT Solving	133
<i>Joao Marques-Silva, Ines Lynce and Sharad Malik</i>	
4.1 Introduction	133
4.2 Preliminaries	135
4.3 Implementing CDCL SAT Solvers	140
4.4 Using CDCL SAT Solvers	152
4.5 Impact of CDCL SAT Solvers	160
4.6 Historical Perspective	161
4.7 To Probe Further	163
4.8 Conclusions & Research Directions	164
References	164
Chapter 5. Look-Ahead Based SAT Solvers	183
<i>Marijn J.H. Heule and Hans van Maaren</i>	
5.1 Introduction	183
5.2 General and Historical Overview	185
5.3 Heuristics	192
5.4 Additional Reasoning	201
5.5 Eager Data-Structures	207
References	210
Chapter 6. Incomplete Algorithms	213
<i>Henry Kautz, Ashish Sabharwal and Bart Selman</i>	
6.1 Greedy Search and Focused Random Walk	215
6.2 Extensions of the Basic Local Search Method	218
6.3 Discrete Lagrangian Methods	219
6.4 The Phase Transition Phenomenon in Random k -SAT	222
6.5 A New Technique for Random k -SAT: Survey Propagation	224

6.6	Conclusion	225
	References	226
Chapter 7. Proof Complexity and SAT Solving		233
	<i>Sam Buss and Jakob Nordström</i>	
7.1	Introduction	233
7.2	Preliminaries	236
7.3	Resolution and CDCL SAT solvers	238
7.4	Resolution and Proof Complexity	255
7.5	Algebraic Proof Systems	270
7.6	Cutting Planes and Pseudo-Boolean Solving	282
7.7	Cutting Planes and Proof Complexity	300
7.8	Extended Resolution and DRAT Proof Systems	312
7.9	Frege and Extended Frege Proof Systems	316

Chapter 1

A History of Satisfiability

John Franco and John Martin

with sections contributed by Miguel Anjos, Holger Hoos, Hans Kleine Büning,
Ewald Speckenmeyer, Alasdair Urquhart, and Hantao Zhang

1.1. Preface: the concept of satisfiability

Interest in Satisfiability is expanding for a variety of reasons, not in the least because nowadays more problems are being solved faster by SAT solvers than other means. This is probably because Satisfiability stands at the crossroads of logic, graph theory, computer science, computer engineering, and operations research. Thus, many problems originating in one of these fields typically have multiple translations to Satisfiability and there exist many mathematical tools available to the SAT solver to assist in solving them with improved performance. Because of the strong links to so many fields, especially logic, the history of Satisfiability can best be understood as it unfolds with respect to its logic roots. Thus, in addition to time-lining events specific to Satisfiability, the chapter follows the presence of Satisfiability in logic as it was developed to model human thought and scientific reasoning through its use in computer design and now as modeling tool for solving a variety of practical problems. In order to succeed in this, we must introduce many ideas that have arisen during numerous attempts to reason with logic and this requires some terminology and perspective that has developed over the past two millennia. It is the purpose of this preface to prepare the reader with this information so as to make the remainder of the chapter more understandable and enlightening.

Logic is about *validity* and *consistency*. The two ideas are interdefinable if we make use of negation (\neg): the argument from p_1, \dots, p_n to q is valid if and only if the set $\{p_1, \dots, p_n, \neg q\}$ is inconsistent. Thus, validity and consistency are really two ways of looking at the same thing and each may be described in terms of syntax or semantics.

The syntactic approach gives rise to *proof theory*. Syntax is restricted to definitions that refer to the syntactic form (that is, grammatical structure) of the sentences in question. In proof theory the term used for the syntactic version of validity is *derivability*. Proofs are derived with respect to an *axiom system* which is defined syntactically as consisting of a set of axioms with a specified

grammatical form and a set of inference rules that sanction proof steps with specified grammatical forms. Given an axiom system, derivability is defined as follows: q is derivable from p_1, \dots, p_n (in symbols, $p_1, \dots, p_n \vdash q$) if and only if there is a proof in the axiom system of q (derivable) from p_1, \dots, p_n . Because the axioms and rules are defined syntactically, so is the notion of derivability. The syntactic version of consistency is simply called *consistency*, and is defined as follows: $\{p_1, \dots, p_n\}$ is *consistent* if and only if it is not possible to derive a contradiction from $\{p_1, \dots, p_n\}$. It follows that $\{p_1, \dots, p_n\}$ is *inconsistent* if and only if there is some contradiction $q \wedge \neg q$ such that $\{p_1, \dots, p_n\} \vdash q \wedge \neg q$. Since derivability has a definition that only makes reference to the syntactic shapes, and since consistency is defined in terms of derivability, it follows that consistency too is a syntactic concept, and is defined ultimately in terms of grammatical form alone. The inference rules of axiom systems, moreover, are always chosen so that derivability and consistency are interdefinable: that is, $p_1, \dots, p_n \vdash q$ if and only if $\{p_1, \dots, p_n, \neg q\}$ is inconsistent.

The semantic approach gives rise to *model theory*. Semantics studies the way sentences relate to “the world.” Truth is the central concept in semantics because a sentence is said to be true if it “corresponds to the world.” The concept of algebraic structure is used to make precise the meaning of “corresponds to the world.”

An *algebraic structure*, or simply *structure*, consists of a non-empty set of objects existing in the world w , called the domain and denoted below by D , and a function, called an *interpretation* and denoted below by R , that assigns to each constant an entity in D , to each predicate a relation among entities in D , and to each functor a function among entities in D . A sentence p is said to be true in w if the entities chosen as the interpretations of the sentence’s terms and functors *stand* to the relations chosen as the interpretation of the sentence’s predicates. We denote a structure by $\langle D, R \rangle$. Below we sometimes use \mathcal{A} to stand for $\langle D, R \rangle$ by writing $\mathcal{A} = \langle D, R \rangle$. A more traditional, algebraic notation for structure is used in Section 1.6. We will speak of *formulas* instead of sentences to allow for the possibility that a sentence contains free variables. The customary notation is to use $\mathcal{A} \models p$ to say p is true in the structure \mathcal{A} .

The semantic versions of validity and consistency are defined in terms of the concept of structure. In model theory validity is just called *validity*. Intuitively, an argument is valid if whenever the premises are true, so is the conclusion. More precisely, the argument from p_1, \dots, p_n to q is *valid* (in symbols, $p_1, \dots, p_n \models q$) if and only if, for all structures \mathcal{A} , if $\mathcal{A} \models p_1, \dots, \mathcal{A} \models p_n$, then $\mathcal{A} \models q$.

We are now ready to encounter, for the first time, *satisfiability*, the central concept of this handbook. Satisfiability is the semantic version of consistency. A set of formulas is said to be satisfiable if there is some structure in which all its component formulas are true: that is, $\{p_1, \dots, p_n\}$ is *satisfiable* if and only if, for some \mathcal{A} , $\mathcal{A} \models p_1$ and \dots and $\mathcal{A} \models p_n$. It follows from the definitions that validity and satisfiability are mutually definable: $p_1, \dots, p_n \models q$ if and only if $\{p_1, \dots, p_n, \neg q\}$ is unsatisfiable.

Although the syntactic and semantic versions of validity and consistency - namely derivability and consistency, on the one hand, and validity and satisfiability, on the other - have different kinds of definitions, the concepts from the two

branches of logic are systematically related. As will be seen later, for the languages studied in logic it is possible to devise axiom systems in such a way that the syntactic and semantic concepts match up so as to coincide exactly. Derivability coincides with validity (*i.e.* $p_1, \dots, p_n \vdash q$ if and only if $p_1, \dots, p_n \models q$), and consistency coincides with satisfiability (*i.e.* $\{p_1, \dots, p_n\}$ is consistent if and only if $\{p_1, \dots, p_n\}$ is satisfiable). Such an axiom system is said to be complete.

We have now located satisfiability, the subject of this handbook, in the broader geography made up of logic's basic ideas. Logic is about both validity and consistency, which are interdefinable in two different ways, one syntactic and one semantic. Among these another name for the semantic version of consistency is satisfiability. Moreover, when the language possesses a complete axiom system, as it normally does in logic, satisfiability also coincides exactly with syntactic consistency. Because of these correspondences, satisfiability may then be used to "characterize" validity (because $p_1, \dots, p_n \models q$ if and only if $\{p_1, \dots, p_n, \neg q\}$ is unsatisfiable) and derivability (because $p_1, \dots, p_n \vdash q$ if and only if $\{p_1, \dots, p_n, \neg q\}$ is unsatisfiable).

There is a further pair of basic logical ideas closely related to satisfiability: *necessity* and *possibility*. Traditionally, a sentence is said to be necessary (or necessarily true) if it is true in all possible worlds, and possible (or possibly true) if it is true in at least one possible world. If we understand a possible world to be a structure, possibility turns out to be just another name for satisfiability. A possible truth is just one that is satisfiable. In logic, the technical name for a necessary formula is logical truth: p is defined to be a *logical truth* (in symbols, $\models p$) if and only if, for all \mathcal{A} , $\mathcal{A} \models p$. (In sentential logic a logical truth is called a *tautology*.) Moreover, *necessary* and *possible* are predicates of the metalanguage (the language of logical theory) because they are used to describe sentences in the "object" language (the language that refers to entities in the world that is the object of investigation in logical theory).

There is one further twist. In the concept of consistency we have already the syntactic version of satisfiability. There is also a syntactic version of a logical truth, namely a theorem-in-an-axiom-system. We say p is a theorem of the system (in symbols $\vdash p$) if and only if p is derivable from the axioms alone. In a complete system, theorem-hood and logical truth coincide: $\vdash p$ if and only if $\models p$. Thus, in logical truth and theorem-hood we encounter yet another pair of syntactic and semantic concepts that, although they have quite different sorts of definitions, nevertheless coincide exactly. Moreover, a formula is necessary if it is not possibly not true. In other words, $\models p$ if and only if it is not the case that p is unsatisfiable. Therefore, satisfiability, theorem-hood, logical truths and necessities are mutually "characterizable."

This review shows how closely related satisfiability is to the central concepts of logic. Indeed, relative to a complete axiom system, satisfiability may be used to define, and may be defined by, the other basic concepts of the field - validity, derivability, consistency, necessity, possibility, logical truth, tautology, and theorem-hood.

However, although we have taken the trouble to clearly delineate the distinction between syntax and semantics in this section, it took over 2000 years before this was clearly enunciated by Tarski in the 1930s. Therefore, the formal notion

of satisfiability was absent until then, even though it was informally understood since Aristotle.

The early history of satisfiability, which will be sketched in the next sections, is the story of the gradual enrichment of languages from very simple languages that talk about crude physical objects and their properties, to quite sophisticated languages that can describe the properties of complex structures and computer programs. For all of these languages, the core concepts of logic apply. They all have a syntax with constants that stand for entities and with predicates that stand for relations. They all have sentences that are true or false relative to possible worlds. They all have arguments that are valid or invalid. They all have logical truths that hold in every structure. They all have sets that are satisfiable and others that are unsatisfiable. For all of them, logicians have attempted to devise complete axiom systems to provide syntactic equivalents that capture, in the set of theorems, exactly the set of logical truths, that replicate in syntactic derivations exactly the valid arguments, and provide derivations of contradictions from every unsatisfiable set. We shall even find examples in these early systems of attempts to define decision procedures for logical concepts. As we shall see, in all these efforts the concept of satisfiability is central.

1.2. The ancients

It was in Athens that logic as a science was invented by Aristotle (384-322 B.C.). In a series of books called the *Organon*, he laid the foundation that was to guide the field for the next 2000 years. The logical system he invented, which is called the syllogistic or *categorical* logic, uses a simple syntax limited to subject-predicate sentences.

Aristotle and his followers viewed language as expressing ideas that signify entities and the properties they instantiate in the “world” outside the mind. They believed that concepts are combined to “form” subject-predicate propositions in the mind. A mental thought of a proposition was something like being conscious of two concepts at once, the subject S and the predicate P . Aristotle proposed four different ways to capture this notion of thought, with respect to a given “world” w , depending on whether we link the subject and predicate universally, particularly, positively, or negatively: that is, every S is P , no S is P , some S is P , and some S is not P . These *categorical propositions* were called, respectively, A (universal affirmative), E (universal negative), I (particular affirmative), and O (particular negative) propositions. Their truth-conditions are defined as follows:

A :	Every S is P is true in w	iff	Everything in w signified by S is something signified in w by S and P
E :	No S is P is true in w	iff	Some S is P is false in w
I :	Some S is P is true in w	iff	There is some T such that everything signified in w by S and P is something that is signified in w by P and T

O : Some S is not P iff Every S is P is false in w
 is true in w

These propositions have the following counterparts in set theory:

$S \subseteq P$	iff	$S = S \cap P$
$S \cap P = \emptyset$	iff	$\neg(S \cap P \neq \emptyset)$
$S \cap P \neq \emptyset$	iff	$\exists T : S \cap P = P \cap T$
$S \cap \bar{P} \neq \emptyset$	iff	$\neg(S = S \cap P)$

The resulting logic is two-valued: every proposition is true or false. It is true that Aristotle doubted the universality of this bivalence. In a famous discussion of so-called future contingent sentences, such as “there will be a sea battle tomorrow,” he pointed out that a sentence like this, which is in the future tense, is not now determined to be either true or false. In modern terms such a sentence “lacks a truth-value” or receives a third truth-value. In classical logic, however, the law of excluded middle (commonly known as *tertium non datur*), that is, p or not p is always true, was always assumed.

Unlike modern logicians who accept the empty set, classical logicians assumed, as a condition for truth, that a proposition’s concepts must signify at least one existing thing. Thus, the definitions above work only if T is a non-empty set. It follows that A and E propositions cannot both be true (they are called contraries), and that I and O propositions cannot both be false. The definitions are formulated in terms of identity because doing so allowed logicians to think of mental proposition formulation as a process of one-to-one concept comparison, a task that consciousness seemed perfectly capable of doing.

In this theory of mental language we have encountered the first theory of satisfiability. A proposition is satisfiable (or possible, as traditional logicians would say) if there is some world in which it is true. A consistent proposition is one that is satisfiable. Some propositions were recognized as necessary, or always true, for example: every S is S .

Satisfiability can be used to show that propositions p_1, \dots, p_n do not logically imply q : one only needs to show that there is some assignment of concepts to the terms so that all the propositions in $\{p_1, \dots, p_n, \neg q\}$ come out true. For example, consider the statement:

$$(\text{some } M \text{ is } A \wedge \text{some } C \text{ is } A) \rightarrow \text{every } M \text{ is } C.$$

Aristotle would show this statement is false by replacing the letters with familiar terms to obtain the requisite truth values: some man is an animal and some cow is an animal are both true, but every man is a cow is false. In modern terms, we say the set

$$\{ \text{some } M \text{ is } A, \text{some } C \text{ is } A, \neg(\text{every } M \text{ is } C) \}$$

is satisfiable.

The means to deduce (that is, provide a valid argument) was built upon syllogisms, using what is essentially a complete axiom system for any conditional $(p_1, \dots, p_n) \rightarrow q$ in which p_1, \dots, p_n , and q are categorical propositions [Mar97].

A syllogism is defined as a conditional $(p \wedge q) \rightarrow r$ in which p, q , and r are A, E, I , or O propositions. To show that propositions are valid, that is $(p_1 \wedge \dots \wedge p_n) \rightarrow q$, Aristotle would create syllogisms $(p_1 \wedge p_2) \rightarrow r_1, (r_1 \wedge p_3) \rightarrow r_2, \dots, (r_{n-2} \wedge p_n) \rightarrow q$, then repeatedly reduce valid syllogisms to one of

- A1: $(\text{every } X \text{ is } Y \wedge \text{every } Y \text{ is } Z) \rightarrow \text{every } X \text{ is } Z$
 A2: $(\text{every } X \text{ is } Y \wedge \text{no } Y \text{ is } Z) \rightarrow \text{no } X \text{ is } Z$

The reduction, when viewed in reverse, is an axiom system where A1 and A2 are axiom schemata, from which are deduced the valid syllogisms, and from the valid syllogisms are deduced all valid conditionals. The system used four inference rules:

- R1: From $(p \wedge q) \rightarrow r$ infer $(\neg r \wedge q) \rightarrow \neg p$
 R2: From $(p \wedge q) \rightarrow r$ infer $(q \wedge p) \rightarrow r$
 R3: From no X is Y infer no Y is X
 R4: From $(p \wedge q) \rightarrow \text{no } X \text{ is } Y$ infer $(p \wedge q) \rightarrow \text{some } X \text{ is not } Y$

For example, to prove

$$(\text{every } P \text{ is } M \wedge \text{no } S \text{ is } M) \rightarrow \text{some } S \text{ is not } P$$

one would deduce

1. $(\text{every } P \text{ is } M \wedge \text{no } M \text{ is } S) \rightarrow \text{no } P \text{ is } S$ Axiom A2
2. $(\text{every } P \text{ is } M \wedge \text{no } S \text{ is } M) \rightarrow \text{no } S \text{ is } P$ Rule R3
3. $(\text{every } P \text{ is } M \wedge \text{no } S \text{ is } M) \rightarrow \text{some } S \text{ is not } P$ Rule R4

The logic of the Stoics (c. 300s-200s BC) developed into a sophisticated sentential logic, using operators $\rightarrow, \wedge, \neg$, and \vee , where a proposition is the *meaning* of a sentence that expresses it and the truth of a proposition may change over time. They combined this with the standard definition of validity to discover a series of propositional inferences that have remained part of logical lore ever since:

$$\begin{array}{ll} p, p \rightarrow q \models q & (\text{modus ponens}) \\ \neg q, p \rightarrow q \models \neg p & (\text{modus tollens}) \\ \neg q, p \vee q \models p & (\text{disjunctive syllogism}) \\ p \rightarrow q, q \rightarrow r \models p \rightarrow r & (\text{hypothetical syllogism}) \end{array}$$

1.3. The medieval period

Logicians of the medieval period knew all of the logic of Aristotle and the Stoics, and much more. The syntax of the languages they used was rich, incorporating combined categorical propositions (with and without modal and epistemic operators), other quantifiers, restrictive and non-restrictive relative clauses, and the propositional connectives into complex sentences. Moreover, although they did

not have set theory, they described interpretations of predicates using set-like notions such as “group” or “collection.”

The development of concepts open to decision by an effective process (such as a *mechanical process*) was actually an important goal of early modern logic, although it was not formulated in those terms. A goal of symbolic logic is to make epistemically transparent judgments that a formula is a theorem of an axiom system or is deducible within an axiom system. An effective process ensures this transparency because it is possible to know with relative certainty that each stage in the process is properly carried out.

The work of Ramon Lull (1232-1315) was influential beyond the medieval period. He devised the first system of logic based on diagrams expressing truth and rotating wheels to achieve some form of deduction. It had similarities to important later work, for example Venn circles, and greatly influenced Leibniz in his quest for a system of deduction that would be universal.

1.4. The renaissance

In the 17th century Descartes and Leibniz began to understand the power of applying algebra to scientific reasoning. To this end, Leibniz devised a language that could be used to talk about either ideas or the world. He thought, like we do, that sets stand to one another in the subset relation \subseteq , and that a new set can be formed by intersection \cap . He also thought that concepts can be combined by definitions: for example the concepts *animal* and *rational* can be combined to form the concept *rational+animal*, which is the definition of the concept *man*, and the concept animal would then be a “part” of the concept *man*. The operator \preceq , called concept inclusion, was introduced to express this notion: thus, animal \preceq man.

Leibniz worked out dual Boolean interpretations of syllogistic propositions joined with the propositional connectives. The first (*intensional*) interpretation assigns terms to “concepts” within a structure of concepts ordered by \preceq and organized by operations that we would call *meet* and *join*. The dual (*extensional*) interpretation is over a Boolean algebra of sets.

The logical operations of multiplication, addition, negation, identity, class inclusion, and the null class were known at this time, well before Boole, but Leibniz published nothing on his ideas related to formal logic. In addition to \preceq his logic is rooted in the operators of identity ($=$), and a conjunction-like operator (\oplus) called *real addition*, which obeys the following:

$$\begin{array}{ll} t \oplus t = t & \text{(idempotency)} \\ t \oplus t' = t' \oplus t & \text{(commutativity)} \\ t \oplus (t' \oplus t'') = (t \oplus t') \oplus t'' & \text{(associativity)} \end{array}$$

where t , t' , and t'' are terms representing substance or ideas. The following, Leibniz’s equivalence, shows the tie between set inclusion and real addition that is the basis of his logics.

$$t \preceq t' \text{ if and only if } t \oplus t' = t'$$

Although Leibniz's system is simplistic and ultimately implausible as an account of science, he came very close to defining with modern rigor complete axiom systems for well-defined formal languages that also possessed decision procedures for identifying the sentences satisfied in every interpretation. It would be 250 years before modern logic accomplished the same for its more complex languages. His vision is relevant to modern times in other ways too. As examples, he invented binary arithmetic, and his *calculus ratiocinator* is regarded by some as a formal inference engine, its use not unlike that of a computer programming language, and by others as referring to a "calculating machine" that was a forerunner to the modern digital computer. In fact, Leibniz constructed a machine, called a Stepped Reckoner, for mathematical calculations. Yet, at this point in history, the notion of satisfiability still had not been enunciated.

1.5. The first logic machine

According to Gardner [Gar58] the first *logic machine*, that is the first machine able to solve problems in formal logic (in this case syllogisms), was invented by Charles Stanhope, 3rd Earl Stanhope (1753-1816). It employed methods similar to Venn circles (Section 1.6) and therefore can in some sense be regarded as Boolean. However, it was also able to go beyond traditional syllogisms to solve numerical syllogisms such as the following: 8 of 10 pigeons are in holes, and 4 of the 10 pigeons are white (conclude at least 2 holes have white pigeons). See [Gar58] for details.

1.6. Boolean algebra

George Boole (1815-1864) advanced the state of logic considerably with the introduction of the algebraic structure that bears his name¹: a structure $\langle B, \vee, \wedge, \neg, 0, 1 \rangle$ is a Boolean algebra if and only if \vee and \wedge are binary operations and \neg is a unary operation on B under which B is closed, $1, 0 \in B$, and

$$\begin{array}{ll} x \wedge y = y \wedge x; & x \vee \neg x = 1; \\ x \vee y = y \vee x; & 1 \wedge x = x; \\ x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z); & 0 \vee x = x; \\ x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z); & x \wedge \neg x = 0; \end{array}$$

Boole's main innovation was to develop an algebra-like notation for the elementary properties of sets. His own objective, at which he succeeded, was to provide a more general theory of the logic of terms which has the traditional syllogistic logic as a special case. He was one of the first to employ a symbolic language. His notation consisted of term variables s, t, u, v, w, x, y, z etc., which he interpreted as standing for sets, the standard "Boolean" operators on sets (complementation indicated by \neg , union indicated by \vee , intersection indicated by \wedge), constants for the universal and empty set (1 and 0), and the identity sign ($=$) used to form equations. He formulated many of the standard "laws" of Boolean algebra, including association, commutation, and distributions, and noted many of

¹The structures we call 'Boolean algebras' were not defined by Boole but by Jevons (see below) who advocated the use of the inclusive or.

the properties of complementation and the universal and empty sets. He symbolized Aristotle's four categorical propositions, relative to subject y and predicate x , by giving names of convenience V ($V \neq 0$) to sets that intersect appropriately with y and x forming subsets:

	Boole	Sets
Every x is y :	$x = x \cdot y$	$x \subseteq y$
No x is y :	$0 = x \cdot y$	$x \subseteq \bar{y}$
Some x is y :	$V = V \cdot x \cdot y$	$x \cap y \neq \emptyset$
Some x is not y :	$V = V \cdot x \cdot (1 - y)$	$x \cap \bar{y} \neq \emptyset$

Boole was not interested in axiom systems, but in the theory of inference. In his system it could be shown that the argument from p_1, \dots, p_n to q is valid (*i.e.* $p_1, \dots, p_n \models q$) by deriving the equation q from equations p_1, \dots, p_n by applying rules of inference, which were essentially cases of algebraic substitution.

However, Boole's algebras needed a boost to advance their acceptance. Gardner [Gar58] cites John Venn (1834-1923) and William Stanley Jevons (1835-1882) as two significant contributors to this task. Jevons regarded Boole's work as the greatest advance since Aristotle but saw some flaws that he believed kept it from significantly influencing logicians of the day, particularly that it was too mathematical. To fix this he introduced, in the 1860's, the "method of indirect inference" which is an application of *reductio ad absurdum* to Boolean logic. For example, to handle 'All x is y ' and 'No y is z ' Jevons would write all possible "class explanations" as triples

$$xyz, xy\bar{z}, x\bar{y}z, x\bar{y}\bar{z}, \bar{x}yz, \bar{x}y\bar{z}, \bar{x}\bar{y}z, \bar{x}\bar{y}\bar{z},$$

where the first represents objects in classes x , y , and z , the second represents objects in classes x and y but not in z , and so on². Then some of these triples would be eliminated by the premises which imply they are empty. Thus, $x\bar{y}z$ and $x\bar{y}\bar{z}$ are eliminated by 'All x is y ' and xyz and $\bar{x}yz$ are eliminated by 'No y is z '. Since no remaining triples contain both x and z , one can conclude 'No x is z ' and 'No z is x '.

Although Jevons' system is powerful it has problems with some statements: for example, 'Some x is y ' cannot eliminate any of the triples xyz and $xy\bar{z}$ since at least one but maybe both represent valid explanations. Another problem is the exponential growth of terms, although this did not seem to be a problem at the time³. Although the reader can see x , y and z taking truth values 0 or 1, Jevons did not appreciate the fact that truth-value logic would eventually replace class logic and his attention was given only to the latter. He did build a logic machine (called a "logic piano" due to its use of keys) that can solve five term problems [Jev70] (1870). The reader is referred to [Gar58] for details.

What really brought clarity to Boolean logic, though, was the contribution of Venn [Ven80] (1880) of which the reader is almost certainly acquainted since it touches several fields beyond logic. We quote the elegantly stated passage of [Gar58] explaining the importance of this work:

²Jevons did not use $\bar{}$ but lower and upper case letters to distinguish inclusion and exclusion.

³Nevertheless, Jevons came up with some labor saving devices such as inked rubber stamps to avoid having to list all possibilities at the outset of a problem.

It was of course the development of an adequate symbolic notation that reduced the syllogism to triviality and rendered obsolete all the quasi-syllogisms that had been so painfully and exhaustively analyzed by the 19th century logicians. At the same time many a controversy that once seemed so important no longer seemed so. ... Perhaps one reason why these old issues faded so quickly was that, shortly after Boole laid the foundations for an algebraic notation, John Venn came forth with an ingenious improvement to Euler's circles⁴. The result was a diagrammatic method so perfectly isomorphic with the Boolean class algebra, and picturing the structure of class logic with such visual clarity, that even a nonmathematically minded philosopher could "see" what the new logic was all about.

As an example, draw a circle each for x , y , and z and overlap them so all possible intersections are visible. A point inside circle x corresponds to x and a point outside circle x corresponds to $\neg x$ and so on. Thus a point inside circles x and y but outside circle z corresponds to Jevons' $xy\neg z$ triple. Reasoning about syllogisms follows Jevons as above except that the case 'Some x is y ' is handled by placing a mark on the z circle in the region representing xy which means it is not known whether the region xyz or $xy\neg z$ contains the x that is y . Then, if the next premise is, say, 'All y is z ', the $xy\neg z$ region is eliminated so the mark moves to the xyz region it borders allowing the conclusion 'Some z is x '. Since the connection between 0-1 logic and Venn circles is obvious, syllogisms can be seen as just a special case of 0-1 logic.

The results of Boole, Jevons, and Venn rang down the curtain on Aristotelian syllogisms, ending a reign of over 2000 years. In the remainder of this chapter syllogisms will appear only once, and that is to show cases where they are unable to represent common inferences.

1.7. Frege, logicism, and quantification logic

In the nineteenth century mathematicians like Cauchy and Weierstrass put analysis on a clear mathematical footing by precisely defining its central terms. George Cantor (1845-1918) extended their work by formulating a more global theory of sets that allowed for the precise specification of such important details as when sets exist, when they are identical, and what their cardinality is. Cantor's set theory was still largely intuitive and imprecise, though mathematicians like Dedekind and Peano had axiomatized parts of number theory. Motivated as much by philosophy as logic, the mathematician Gottlob Frege (1848-1925) conceived a project called logicism to deduce from the laws of logic alone "all of mathematics," by which he meant set theory, number theory, and analysis [Lav94]. Logicism as an attempt to deduce arithmetic from the axioms of logic was ultimately a failure. As a research paradigm, however, it made the great contribution of making clear the boundaries of "formal reasoning," and has allowed deep questions to be posed, but which are still unanswered, about the nature of mathematical truth.

Frege employed a formal language of his own invention, called "concept notation" (Begriffsschrift). In it he invented a syntax which is essential to the formal

⁴The difference between Euler circles and Venn circles is that Venn circles show all possible overlaps of classes while there is no such requirement for Euler circles. Therefore, Euler circles cannot readily be used as a means to visualize reasoning in Boolean logic. Leibniz and Ramon Lull also used Euler-like circles [Bar69].

language we know today for sentential and quantificational logic, and for functions in mathematics. In his *Grundgesetze der Arithmetik* (1890) he used a limited number of “logical axioms,” which consisted of five basic laws of sentential logic, several laws of quantifiers, and several axioms for functions. When he published this work, he believed that he had succeeded in defining within his syntax the basic concepts of number theory and in deducing their fundamental laws from his axioms of logic alone.

1.8. Russell and Whitehead

Bertrand Russell (1882-1970), however, discovered that he could prove in Frege’s system his notorious paradox: if the set of all sets that are not members of themselves is a member of itself, then, by definition, it must not be a member of itself; and if it is not a member of itself then, by definition, it must be a member of itself.

In *Principia Mathematica* (1910-13), perhaps the most important work of early modern logic, Russell and Whitehead simplified Frege’s logical axioms of functions by substituting for a more abstract set describing sets and relations. One of the great weaknesses of traditional logic had been its inability to represent inferences that depend on relations. For example, in the proof of Proposition 1 of his *Elements* Euclid argues, regarding lines, that if $AC=AB$ and $BC=AB$, it follows by commutativity that $CA=AB$, and hence that $AC=BC$ (by either the substitutivity or transitivity or identity). But, the requirement of Aristotelian logic that all propositions take subject-predicate form ‘ S is P ’ makes it impossible to represent important grammatical facts: for example, that in a proposition $AC = AB$, the subject AC and direct object AB are phrases made up of component terms A , B , and C , and the fact that the verb $=$ is transitive and takes the direct object AB . The typical move was to read “ $=AC$ ” as a unified predicate and to recast equations in subject-predicate form:

$AC = AB$:	the individual AC has the property being-identical-to- AB
$BC = AB$:	the individual BC has the property being-identical-to- AB
$AC = BC$:	the individual AC has the property being-identical-to- BC

But the third line does not follow by syllogistic logic from the first two.

One of the strange outcomes of early logic is that syllogistic logic was so unsuccessful at representing mathematical reasoning that in the 2000 years in which it reigned there was only one attempt to reproduce geometrical proofs using syllogisms; it did not occur until the 16th century, and it was unsuccessful [HD66]. Boole’s logic shared with Aristotle’s an inability to represent relations. Russell, however, was well aware both of the utility of relations in mathematics and the need to reform syntax to allow for their expression [Rus02].

Accordingly, the basic notation of *Principia* allows for variables, one-place predicates standing for sets, and n -place predicates standing for relations. Formulas were composed using the sentential connectives and quantifiers. With just this notation it was possible to define all the constants and functions necessary for arithmetic, and to prove with simplified axioms a substantial part of number

theory. It appeared at first that *Principia* had vindicated logicism: arithmetic seemed to follow from logic.

1.9. Gödel's incompleteness theorem

In 1931, Kurt Gödel astounded the mathematical world by proving that the axiom system of *Principia*, and indeed any axiom system capable of formulating the laws of arithmetic, is and must be incomplete in the sense that there will always be some truth of arithmetic that is not a theorem of the system. Gödel proved, in short, that logicism is false - that mathematics in its entirety cannot be deduced from logic. Gödel's result is sweeping in its generality. It remains true, however, that limited parts of mathematics are axiomatizable, for example first-order logic. It is also true that, although incomplete, mathematicians as a rule still stick to axiomatic formulations as their fundamental methodology even for subjects that they know must be incomplete. Axiomatic set theory, for example, contains arithmetic as a part and is therefore provably incomplete. But axiomatics is still the way set theory is studied even within its provable limitations.

Although logicism proved to be false, the project placed logic on its modern foundations: *Principia* standardized the modern notation for sentential and quantificational logic. In the 1930s Hilbert and Bernays christened "first-order" logic as that part of the syntax in which quantifiers bind only variables over individuals, and "higher-order" logic as the syntax in which variables bind predicates, and predicates of predicates, etc.

1.10. Effective process and recursive functions

As logic developed in the 20th century, the importance of effective decidability (see Section 1.3) increased and defining effective decidability itself became a research goal. However, since defining any concept that incorporates as a defining term "epistemic transparency" would require a background theory that explained "knowledge," any direct definition of effective process remained elusive. This difficulty motivated the inductive definitions of recursive function theory, Turing machines, lambda calculus, and more, which, by Church's thesis, succeeds in providing an indirect definition of effective process.

One outcome of logicism was the clarification of some of the basic concepts of computer science: for example, the notion of recursive functions which are supposed to be what a mathematician would intuitively recognize as a "calculation" on the natural numbers. Gödel, in his incompleteness paper of 1931, gave a precise formal definition of the class of primitive recursive functions, which he called "recursive functions." Gödel first singled out three types of functions that all mathematicians agree are calculations and called these recursive functions. He then distinguished three methods of defining new functions from old. These methods moreover were such that everyone agreed they produced a calculation as an output if given calculations as inputs. He then defined the set of recursive functions as the closure of the three basic function types under the three construction methods.

Given the definition of recursive function, Gödel continued his incompleteness proof by showing that for each calculable function, there is a predicate in the language of *Principia* that has that function as its extension. Using this fact, he then showed, in particular, that *Principia* had a predicate T that had as its extension the theorems of *Principia*. In an additional step he showed that *Principia* also possesses a constant c that stands for the so-called liar sentence $\neg Tc$, which says in effect “This sentence is not a theorem.” Finally, he demonstrated both that $\neg Tc$ is a truth of arithmetic and that it is not a theorem of *Principia*. He proved, therefore, that the axiom system failed to capture one of the truths of arithmetic and was therefore incomplete.

Crucial to the proof was its initial definition of recursive function. Indeed, by successfully analyzing “effective process,” Gödel made a major contribution to theoretical computer science: the computable function. However, in his Princeton lectures of 1934, Gödel, attributing the idea of general recursive functions to a suggestion of Herbrand, did not commit himself to whether all effective functions are characterized by his definition. In 1936, Church [Chu36] and Turing [Tur36] independently proposed a definition of the effectively computable functions. Its equivalence with Gödel’s definition was proved in 1943 by Kleene [Kle43]. Emil Post (1897-1954), Andrei Markov (1903-1979), and others confirmed Gödel’s work by providing alternative analyses of computable function that are also provably coextensive with his.

1.11. Herbrand’s theorem

Herbrand’s theorem relates issues of validity and logical truth into ones of satisfiability, and issues of satisfiability into ones concerning the definition of computable functions on syntactic domains. The proof employs techniques important to computer science. A *Herbrand model* for a formula of first-order logic has as its domain literally those terms generated from terms that occur in the formula p . Moreover, the predicates of the model are true of a term if and only if the formula asserting that the predicate holds of the term occurs in p . The first part of Herbrand’s theorem says that p is satisfiable if and only if it is satisfied in its Herbrand model.

Using techniques devised by Skolem, Herbrand showed that the quantified formula p is satisfiable if and only if a specific set of its truth-functional instantiations, each essentially a formula in sentential logic, is satisfiable. Thus, satisfiability of p reduces to an issue of testing by truth-tables the satisfiability of a potentially infinite set S of sentential formulas. Herbrand showed that, for any first-order formula p , there is a decision function f such that $f(p) = 1$ if p is unsatisfiable because, eventually, one of the truth-functions in S will come out false in a truth-table test, but $f(p)$ may be undefined when p is satisfiable because the truth-table testing of the infinite set S may never terminate.

1.12. Model theory and Satisfiability

Although ideas in semantics were central to logic in this period, the primary framework in which logic was studied was the axiom system. But the seemingly

obvious need to define the grammar rules for a formal language was skipped over until Gödel gave a completely formal definition of the formulas of his version of simple type theory in his 1931 paper [Mel92].

In the late nineteenth and early twentieth centuries Charles Sanders Peirce, see [Lew60], and Ludwig Wittgenstein [Wit33] had employed the two-valued truth-tables for sentential logic. In 1936 Marshall Stone proved that the more general class of Boolean algebras is of fundamental importance for the interpretation of classical logic. His “representation theorem” showed that any interpretation of sentential logic that assigns to the connectives the corresponding Boolean operators and defines validity as preserving a “designated value” defined as a maximal upwardly closed subset of elements of the algebra (called a “filter”) has as its logical truths and valid arguments exactly those of classical logic [Sto36]. The early decades of the twentieth century also saw the development of many-valued logic, in an early form by Peirce [TTT66] and then in more developed versions by Polish logicians lead by Jan Łukasiewicz (1878-1956). Thus, in sentential logic the idea of satisfiability was well understood as “truth relative to an assignment of truth-values” in a so-called “logical matrix” of truth-functions.

A precise notion of satisfiability for first-order logic, however, was not developed until the 1930s in the work of Alfred Tarski (1902-1983) [Tar56, Tar44, Tar54]. Tarski’s task was to define a set of necessary and sufficient conditions for “ p is true,” for any formula p of first-order syntax. His solution was not to define the idea in a single phrase applicable to all formulas, but, like Gödel, to give an inductive definition, first defining *truth* for basic formulas and then extending the definition to more complex formulas. The problem was made complex, however, by the fact that, unlike sentential logic in which the truth-value of the parts immediately determine that of the whole (by reference to truth-tables), when the whole expression is universally quantified, it is unclear how its truth is determined by the interpretation of its part. How does the “truth” of the open formula Fx determine that of $\forall x : Fx$?

Tarski solved the problem in two stages. In the first stage he assigned fixed interpretations to the variables. Having done so, it is possible to say when $\forall x : Fx$ is true if we know whether Fx is true under its various interpretations. If Fx is true under all interpretation of x , then $\forall x : Fx$ is also true under each of these interpretations. If Fx is false under even one interpretation of x , however, $\forall x : Fx$ is false under any interpretation of the variables. Tarski coined the technical term *satisfaction* to refer to truth relative to an interpretation of variables.

Let $\mathcal{A} = \langle D, R \rangle$ be a structure and define a variable assignment as any function s that assigns to each variable an entity in D . Given R and s , all the basic expressions of the syntax have a referent relative to D . We can now inductively define “ p is satisfied relative to \mathcal{A} and s .” The atomic formula Ft_1, \dots, t_n is satisfied relative to \mathcal{A} and s if and only if the interpretations of t_1, \dots, t_n in R and s stand in the relation assigned by R to F . The “satisfaction” of molecular formulas made up by the sentential connectives are determined by the two-valued truth-tables depending on whether or not their parts are satisfied. Finally, $\forall x : Fx$ is satisfied relative to \mathcal{A} and s if and only if Fx is satisfied relative to R and every variable assignment s . The notation for “ p is satisfied relative to \mathcal{A} and s ” is $\mathcal{A} \models_s p$.

The second stage of Tarski's definition is to abstract away from a variable assignment and define the simpler notion "p is true relative to \mathcal{A} ." His idea at this stage is to interpret an open formula Fx as true in this general sense if it is "always true" in the sense of being satisfied under every interpretation of its variables. That is, he adopts the simple formula: p is true relative to \mathcal{A} if and only if, for all variable assignments s , p is satisfied relative to \mathcal{A} and s . In formal notation, $\mathcal{A} \models p$ if and only if, for all s , $\mathcal{A} \models_s p$.

Logicians have adopted the common practice of using the term "satisfied in a structure" to mean what Tarski called "true in a structure." Thus, it is common to say that p is satisfiable if there is some structure \mathcal{A} such that p is true in \mathcal{A} , and that a set of formulas X is satisfiable if and only if there is some structure \mathcal{A} such that for all formulas p in X , p is true (satisfied) in \mathcal{A} .

1.13. Completeness of first-order logic

First-order logic has sufficient expressive power for the formalization of virtually all of mathematics. To use it requires a sufficiently powerful axiom system such as the Zermelo-Fraenkel set theory with the axiom of choice (ZFC). It is generally accepted that all of classical mathematics can be formalized in ZFC.

Proofs of completeness of first-order logic under suitable axiom systems date back at least to Gödel in 1929. In this context, completeness means that all logically valid formulas of first-order logic can be derived from axioms and rules of the underlying axiom system. This is not to be confused with Gödel's incompleteness theorem which states that there is no consistent axiom system for the larger set of truths of number theory (which includes the valid formulas of first-order logic as a proper subset) because it will fail to include at least one truth of arithmetic.

Tarski's notion of truth in a structure introduced greater precision. It was then possible to give an elegant proof that first-order logic is complete under its usual axiom systems and sets of inference rules. Of particular interest is the proof due to Leon Henkin (1921-2006) that makes use of two ideas relevant to this book: satisfiability and a structure composed of syntactic elements [Hen49] (1949). Due to the relationship of validity to satisfiability, Henkin reformulated the difficult part of the theorem as: if a set of formulas is consistent, then it is satisfiable. He proved this by first extending a consistent set to what he calls a maximally consistent saturated set, and then showing that this set is satisfiable in a structure made up from the syntactic elements of the set. Although differing in detail, the construction of the structure is similar to that of Herbrand.

Herbrand models and Henkin's maximally consistent saturated sets are relevant prototypes of the technique of constructing syntactic proxies for conventional models. In complexity theory, the truth of predicates is typically determined relative to a structure with a domain of entities that are *programs* or *languages* which themselves have semantic content that allow one to determine a corresponding, more conventional, model theoretic structure. In that sense, the program or language entities can be said to be a proxy for the conventional model and the predicates are second-order, standing for a property of sets.

1.14. Application of logic to circuits

Claude Shannon provided one of the bridges connecting the path of logic over the centuries to its practical applications in the information and digital age. Another bridge is considered in the next section. Whereas the study of logic for thousands of years was motivated by a desire to explain how humans use information and knowledge to deduce facts, particularly to assist in decision making, Shannon, as a student at MIT, saw propositional logic as an opportunity to make rigorous the design and simplification of switching circuits. Boolean algebra, appreciated by a relatively small group of people for decades, was ready to be applied to the fledgling field of digital computers.

In his master's thesis [Sha40] (1940), said by Howard Gardner of Harvard University to be "possibly the most important, and also the most famous, master's thesis of the century," Shannon applied Boolean logic to the design of minimal circuits involving relays. Relays are simple switches that are either "closed," in which case current is flowing through the switch or "open," in which case current is stopped. Shannon represented the state of a relay with a variable taking value 1 if open and the value 0 if closed. His algebra used the operator '+' for "or" (addition - to express the state of relays in series), '.' for "and" (multiplication - to express the state of relays in parallel), and his notation for the negation of variable x was x' .

The rigorous synthesis of relay circuits entails expressing and simplifying complex Boolean functions of many variables. To support both goals Shannon developed two series expansions for a function, analogous, in his words, to Taylor's expansion on differentiable functions. He started with

$$f(x_1, x_2, \dots, x_n) = x_1 \cdot f(1, x_2, \dots, x_n) + x_1' \cdot f(0, x_2, \dots, x_n)$$

which we recognize as the basic splitting operation of DPLL algorithms and the *Shannon expansion* which is the foundation for Binary Decision Diagrams (Section 1.20), and its dual

$$f(x_1, x_2, \dots, x_n) = (f(0, x_2, \dots, x_n) + x_1) \cdot (f(1, x_2, \dots, x_n) + x_1').$$

Using the above repeatedly he arrived at the familiar DNF canonical form

$$\begin{aligned} f(x_1, x_2, \dots, x_n) = & f(0, 0, \dots, 0) \cdot x_1' \cdot x_2' \cdot \dots \cdot x_n' + \\ & f(1, 0, \dots, 0) \cdot x_1 \cdot x_2' \cdot \dots \cdot x_n' + \\ & f(0, 1, \dots, 0) \cdot x_1' \cdot x_2 \cdot \dots \cdot x_n' + \\ & \dots \\ & f(1, 1, \dots, 1) \cdot x_1 \cdot x_2 \cdot \dots \cdot x_n \end{aligned}$$

and its familiar CNF dual. These support the expression of any relay circuit and, more generally, any combinational circuit. To simplify, he introduced the following operations:

$$\begin{aligned} x &= x + x = x + x + x = \dots \\ x + x \cdot y &= x \end{aligned}$$

$$\begin{aligned}
 x \cdot f(x) &= x \cdot f(1) \\
 x' \cdot f(x) &= x' \cdot f(0) \\
 x \cdot y + x' \cdot z &= x \cdot y + x' \cdot z + y \cdot z
 \end{aligned}$$

and their duals. In the last operation the term $y \cdot z$ is the *consensus* of terms $x \cdot y$ and $x' \cdot z$. The dual of the last operation amounts to adding a propositional *resolvent* to a CNF clause set. The first two operations are *subsumption* rules.

In his master's thesis Shannon stated that one can use the above rules to achieve minimal circuit representations but did not offer a systematic way to do so. Independently, according to Brown [Bro03], Archie Blake, an all but forgotten yet influential figure in Boolean reasoning, developed the notion of consensus in his Ph.D. thesis [Bla37] of 1937. Blake used consensus to express Boolean functions in a minimal DNF form with respect to their *prime implicants* (product g is an implicant of function h if $g \cdot h' = 0$ and is prime if it is minimal in literals) and subsumption. An important contribution of Blake was to show that DNFs are not minimized unless consensus is not possible. The notion of consensus was rediscovered by Samson and Mills [SM54] (1954) and Quine [Qui55] (1955). Later, Quine [Qui59] (1959) and McCluskey [McC59] (1959) provided a systematic method for the minimization of DNF expressions through the notion of *essential prime implicants* (necessary prime implicants) by turning the 2-level minimization problem into a covering problem. This was perhaps the first confrontation with complexity issues: although they did not know it at the time, the problem they were trying to solve is \mathcal{NP} -complete and the complexity of their algorithm was $O(3^n/\sqrt{n})$, where n is the number of variables.

1.15. Resolution

Meanwhile, the advent of computers stimulated the emergence of the field of automated deduction. Martin Davis has written a history of this period in [Dav01] on which we base this section. Early attempts at automated deduction were aimed at proving theorems from first-order logic because, as stated in Section 1.13, it is accepted that given appropriate axioms as premises, all reasoning of classical mathematics can be expressed in first-order logic. Propositional satisfiability testing was used to support that effort.

However, since the complexity of the problem and the space requirements of a solver were not appreciated at the time, there were several notable failures. At least some of these determined satisfiability either by simple truth table calculations or expansion into DNF and none could prove anything but the simplest theorems. But, each contributed something to the overall effort. According to Davis [Dav01], Gilmore's [Gil60] (1960) system served as a stimulus for others and Prawitz [Pra60] (1960) adopted a modified form of the method of semantic tableaux. Also notable were the "Logic Theory Machine" of [NSS57] (1957), which used the idea of a search heuristic, and the Geometry machine of [Gel59] (1959), which exploited symmetry to reduce proof size.

Things improved when Davis and Putnam proposed using CNF for satisfiability testing as early as 1958 in an unpublished manuscript for the NSA [DP58].

According to Davis [Dav01], that manuscript cited all the essentials of modern DPLL variants. These include:

1. The one literal rule also known as the unit-clause-rule: for each clause (l), called a *unit clause*, remove all clauses containing l and all literals $\neg l$.
2. The affirmative-negative rule also known as the pure-literal-rule: if literal l is in some clause but $\neg l$ is not, remove all clauses containing l . Literal l is called a *pure literal*.
3. The rule for eliminating atomic formulas: that is, replace

$$(v \vee l_{1,1} \vee \dots \vee l_{1,k_1}) \wedge (\neg v \vee l_{2,1} \vee \dots \vee l_{2,k_2}) \wedge C$$

with

$$(l_{1,1} \vee \dots \vee l_{1,k_1} \vee l_{2,1} \vee \dots \vee l_{2,k_2}) \wedge C$$

if literals $l_{1,i}$ and $l_{2,j}$ are not complementary for any i, j .

4. The splitting rule, called in the manuscript ‘the rule of case analysis.’

Observe that rule 3. is ground resolution: the CNF expression it is applied to having come from a prenex form with its clauses grounded. The published version of this manuscript is the often cited [DP60] (1960). The Davis-Putnam procedure, or DPP, reduced the size of the search space considerably by eliminating variables from a given expression. This was done by repeatedly choosing a target variable v still appearing in the expression, applying all possible ground resolutions on v , then eliminating all remaining clauses still containing v or $\neg v$.

Loveland and Logemann attempted to implement DPP but they found that ground resolution used too much RAM, which was quite limited in those days. So they changed the way variables are eliminated by employing the splitting rule: recursively assigning values 0 and 1 to a variable and solving both resulting subproblems [DLL62] (1962). Their algorithm is, of course, the familiar DPLL.

Robinson also experimented with DPP and, taking ideas from both DPP and Prawitz, he generalized ground resolution so that instead of clauses having to be grounded to use resolution, resolution was lifted directly to the Skolem form [Rob63, Rob65] (1963,1965). This is, of course, a landmark result in mechanically proving first-order logic sentences.

Resolution was extended by Tseitin in [Tse68] (1968) who showed that, for any pair of variables a, b in a given CNF expression ϕ , the following expression may be appended to ϕ :

$$(z \vee a) \wedge (z \vee b) \wedge (\neg z \vee \neg a \vee \neg b)$$

where z is a variable not in ϕ . The meaning of this expression is: either a and b both have value 1 or at least one of a or b has value 0. It may be written $z \Leftrightarrow \neg a \vee \neg b$. It is safe to append such an expression because its three clauses can always be forced to value 1 by setting free variable z to the value of $\neg a \vee \neg b$. More generally, any expression of the form

$$z \Leftrightarrow f(a, b, \dots)$$

may be appended, where f is some arbitrary Boolean function and z is a new, free variable. Judicious use of such extensions can result in polynomial size refutations for problems that have no polynomial size refutations without extension. A

notable example is the pigeon hole formulas. Tseitin also showed that by adding variables not in ϕ , one can obtain, in linear time, a satisfiability-preserving translation from any propositional expression to CNF with at most a constant factor blowup in expression size.

After this point the term satisfiability was used primarily to describe the problem of finding a model for a Boolean expression. The complexity of Satisfiability became the major issue due to potential practical applications for Satisfiability. Consequently, work branched in many directions. The following sections describe most of the important branches.

1.16. The complexity of resolution

by Alasdair Urquhart

Perhaps the theoretically deepest branch is the study of the complexity of resolution. As seen in previous sections, the question of decidability dominated research in logic until it became important to implement proof systems on a computer. Then it became clear empirically and theoretically through the amazing result of Cook [Coo71] (1971) that decidable problems could still be effectively unsolvable due to space and time limitations of available machinery. Thus, many researchers turned their attention to the complexity issues associated with implementing various logic systems. The most important of these, the most relevant to the readers of this chapter, and the subject of this section is the study of resolution refutations of contradictory sets of CNF clauses (in this section clause will mean CNF clause).

Rephrasing the “rule for eliminating atomic formulas” from the previous section: if $A \vee l$ and $B \vee \neg l$ are clauses, then the clause $A \vee B$ may be inferred by the resolution rule, *resolving on* the literal l . A *resolution refutation* of a set of clauses Σ is a proof of the empty clause from Σ by repeated applications of the resolution rule.

Refutations can be represented as trees or as sequences of clauses; the worst case complexity differs considerably depending on the representation. We shall distinguish between the two by describing the first system as “tree resolution,” the second simply as “resolution.”

Lower bounds on the size of resolution refutations provide lower bounds on the running time of algorithms for the Satisfiability problem. For example, consider the familiar DPLL algorithm that is the basis of many of the most successful algorithms for Satisfiability. If a program based on the splitting rule terminates with the output “The set of clauses Σ is unsatisfiable,” then a trace of the program’s execution can be given in the form of a binary tree, where each of the nodes in the tree is labeled with an assignment to the variables in Σ . The root of the tree is labeled with the empty assignment, and if a node other than a leaf is labeled with an assignment ϕ , then its children are labeled with the assignments $\phi[v := 0]$ and $\phi[v := 1]$ that extend ϕ to a new variable v ; the assignments labeling the leaves all falsify a clause in Σ . Let us call such a structure a “semantic tree,” an idea introduced by Robinson [Rob68] and Kowalski and Hayes [KH69].

A semantic tree for a set of clauses Σ can be converted into a tree resolution refutation of Σ by labeling the leaves with clauses falsified by the assignment at

the leaves, and then performing resolution steps corresponding to the splitting moves (some pruning may be necessary in the case that a literal is missing from one of the premisses). It follows that a lower bound on the size of tree resolution refutations for a set of clauses provides a lower bound on the time required for a DPLL-style algorithm to certify unsatisfiability. This lower bound applies no matter what strategies are employed for the order of variable elimination.

The first results on the complexity of resolution were proved by Grigori Tseitin in 1968 [Tse68]. In a remarkable pioneering paper, Tseitin showed that for all $n > 0$, there are contradictory sets of clauses Σ_n , containing $O(n^2)$ clauses with at most four literals in each clause, so that the smallest tree resolution refutation of Σ_n has $2^{\Omega(n)}$ leaves. Tseitin's examples are based on graphs. If we assign the values 0 and 1 to the edges of a finite graph G , we can define a vertex v in the graph to be *odd* if there are an odd number of vertices attached to v with the value 1. Then Tseitin's clauses $\Sigma(G)$ can be interpreted as asserting that there is a way of assigning values to the edges so that there are an odd number of odd vertices. The set of clauses Σ_n mentioned above is $\Sigma(G_n)$, where G_n is the $n \times n$ square grid.

Tseitin also proved some lower bounds for resolution but only under the restriction that the refutation is *regular*. A resolution proof contains an *irregularity* if there is a sequence of clauses C_1, \dots, C_k in it, so that C_{i+1} is the conclusion of a resolution inference of which C_i is one of the premisses, and there is a variable v so that C_1 and C_k both contain v , but v does not occur in some intermediate clause C_j , $1 < j < k$. In other words, an irregularity occurs if a variable is removed by resolution, but is later introduced again in a clause depending on the conclusion of the earlier step. A proof is *regular* if it contains no irregularity. Tseitin showed that the lower bound for Σ_n also applies to regular resolution. In addition, he showed that there is a sequence of clauses Π_n so that there is a superpolynomial speedup of regular resolution over tree resolution (that is to say, the size of the smallest tree resolution refutation of Π_n is not bounded by any fixed power of the size of the smallest regular refutation of Π_n).

Tseitin's lower bounds for the graph-based formulas were improved by Zvi Galil [Gal77], who proved a truly exponential lower bound for regular resolution refutations of sets of clauses based on expander graphs E_n of bounded degree. The set of clauses $\Sigma(E_n)$ has size $O(n)$, but the smallest regular resolution refutation of $\Sigma(E_n)$ contains $2^{\Omega(n)}$ clauses.

The most important breakthrough in the complexity of resolution was made by Armin Haken [Hak85], who proved exponential lower bounds for the pigeonhole clauses PHC_n . These clauses assert that there is an injective mapping from the set $\{1, \dots, n+1\}$ into the set $\{1, \dots, n\}$. They contain $n+1$ clauses containing n literals asserting that every element in the first set is mapped to some element of the second, and $O(n^3)$ two-literal clauses asserting that no two elements are mapped to the same element of $\{1, \dots, n\}$. Haken showed that any resolution refutation of PHC_n contains $2^{\Omega(n)}$ clauses.

Subsequently, Urquhart [Urq87] adapted Haken's argument to prove a truly exponential lower bound for clauses based on expander graphs very similar to those used earlier by Galil. The technique used in Urquhart's lower bounds were employed by Chvátal and Szemerédi [CS88] to prove an exponential lower bound

on random sets of clauses. The model of random clause sets is that of the constant width distribution discussed below in Section 1.18. Their main result is as follows: if c, k are positive integers with $k \geq 3$ and $c2^{-k} \geq 0.7$, then there is an $\epsilon > 0$, so that with probability tending to one as n tends to infinity, the random family of cn clauses of size k over n variables is unsatisfiable and its resolution complexity is at least $(1 + \epsilon)^n$.

The lower bound arguments used by Tseitin, Galil, Haken and Urquhart have a notable common feature. They all prove lower bounds on size by proving lower bounds on width – the *width* of a clause is the number of literals it contains, while the *width* of a set of clauses is the width of the widest clause in it. If Σ is a contradictory set of clauses, let us write $w(\Sigma)$ for the width of Σ , and $w(\Sigma \vdash 0)$ for the minimum width of a refutation of Σ .

The lower bound techniques used in earlier work on the complexity of resolution were generalized and unified in a striking result due to Ben-Sasson and Wigderson [BSW01]. If Σ is a contradictory set of clauses, containing the variables V , let us write $S(\Sigma)$ for the minimum size of a resolution refutation of Σ . Then the main result of [BSW01] is the following lower bound:

$$S(\Sigma) = \exp \left(\Omega \left(\frac{(w(\Sigma \vdash 0) - w(\Sigma))^2}{|V|} \right) \right).$$

This lower bound easily yields the lower bounds of Urquhart [Urq87], as well as that of Chvátal and Szemerédi [CS88] via a width lower bound on resolution refutations.

Tseitin was the first to show a separation between tree resolution and general resolution, as mentioned above. The separation he proved is fairly weak, though superpolynomial. Ben-Sasson, Impagliazzo and Wigderson [BSIW04] improved this to a truly exponential separation between the two proof systems, using contradictory formulas based on pebbling problems in directed acyclic graphs.

These results emphasize the inefficiency of tree resolution, as opposed to general resolution. A tree resolution may contain a lot of redundancy, in the sense that the same clause may have to be proved multiple times. The same kind of inefficiency is also reflected in SAT solvers based on the DPLL framework, since information accumulated along certain branches is immediately discarded. This observation has led some researchers to propose improved versions of the DPLL algorithm, in which such information is stored in the form of clauses. These algorithms, which go under the name “clause learning,” lead to dramatic speedups in some cases – the reader is referred to the paper of Beame, Kautz and Sabharwal [BKS03] for the basic references and some theoretical results on the method.

1.17. Refinement of Resolution-Based SAT Solvers

Most of the current interest in Satisfiability formulations and methods is due to refinements to the basic DPLL framework that have resulted in speed-ups of many orders of magnitude that have turned many problems that were considered intractable in the 1980s into trivially solved problems now. These refinements

include improvements to variable choice heuristics, early pruning of the search space, and replacement of a tree-like search space with a DAG-like search space.

DPLL (1962) was originally designed with two important choice heuristics: the pure-literal rule and the unit-clause rule (Both described on Page 20). But, variable choices in case no unit clauses or pure literals exist were undefined. Thus, extensions of both heuristics were proposed and analyzed in the 1980s through the early 2000s. For example, the unit-clause rule was generalized to the *shortest-clause rule*: choose a variable from an existing clause containing the fewest unset literals [CF90, CR92] (1990, described on Page 36) and the pure-literal rule was extended to *linear autarkies* [vM00] (2000, described on Page 29). Other notable analyzed heuristics include the *majority rule*: choose a variable with the maximum difference between the number of its positive and negative literals [CF86] (1986, see also Page 37), probe-order backtracking [PH97] (1997, see also Page 36), and a greedy heuristic [HS03, KKL04] (2003, described on Page 38). The above heuristics represent parts of many heuristics that have actually been implemented in SAT solvers; they were studied primarily because their performance could be analyzed probabilistically.

Early heuristics designed to empirically speed up SAT solvers were based on the idea that eliminating small clauses first tends to reveal inferences sooner. Possibly the earliest well-known heuristic built on this approach is due to Jeroslow and Wang [JW90] (1990): they choose a value for a variable that comes close to maximizing the chance of satisfying the remaining clauses, assuming the remaining clauses are statistically independent in the sense described on Page 37. They assign weights $w(\mathcal{S}_{i,j})$ for each variable v_j and each value $i \in \{0, 1\}$ where, for a subset of clauses \mathcal{S} , $\mathcal{S}_{i,j}$ is the clauses of \mathcal{S} less those clauses satisfied and those literals falsified by assigning value i to v_j and $w(\mathcal{S}_{i,j}) = \sum_{C \in \mathcal{S}_{i,j}} 2^{-|C|}$ ($|C|$ is the width of clause C). The Jeroslow-Wang heuristic was intended to work better on satisfiable formulas but Böhm [BKB92] (1992) and Freeman [Fre95] (1995) came up with heuristics that work better on unsatisfiable formulas: they choose to eliminate a variable that in some sense maximally causes an estimate of both sides of the resulting search space to be roughly of equal size. This can be done, for example, by assigning variable weights that are the product of positive and negative literal weights as above and choosing the variable of maximum weight. Later, it was observed that the activity of variable assignment was an important factor in search space size. This led to the DLIS heuristic of GRASP [MSS96] and eventually to the VSIDS heuristic of Chaff [MMZ⁺01]. Most recent DPLL based SAT solvers use variations of the VSIDS branching heuristic.

Another important refinement to SAT solvers is the early generation of inferences during search. This has largely taken the appearance of lookahead techniques. It was Stålmärck [SS98] who demonstrated the effectiveness of lookahead in Prover (1992): the particular type of lookahead used there is best described as breadth-first. This scheme is limited by the fact that search space width can be quite large so the lookahead must be restricted to a small number of levels, usually 2. Nevertheless, Prover was regarded to be a major advance at the time. Later, Chaff used depth-first lookahead (this form is generally called restarts) to greater effectiveness [MMZ⁺01]. Depth-first lookahead also solves a problem that comes up when saving non-unit inferences (see below): such inferences may

be saved in a cache which may possibly overflow at some point. In the case of depth-first lookahead, the inferences may be applied and search restarted with a cleared cache.

Extremely important to SAT solver efficiency are mechanisms that reduce the size of the search space: that is, discover early that branch of the search space does not have to be explored. A *conflict analysis* at a falsified node of the search space will reveal the subset V_s of variables involved in that node becoming false. Thus, the search path from root to that falsified node can be collapsed to include only the variables in V_s , effectively pruning many branch points from the search space. This has been called non-chronological backtracking [MSS96] (1996) and is seen in all of the most efficient DPLL based SAT solvers. The result of conflict analysis can also be saved as a non-unit inference in the form of a clause. If later in the search a subset of variables are set to match a saved inference, backtracking can immediately be applied to avoid repeating a search that previously ended with no solution. This idea, known as *clause learning*, is an essential part of all modern DPLL based SAT solvers: its power comes from turning what would be a tree-like search space into a DAG-like search space. This has gone a long way toward mitigating the early advantage of BDDs (see Section 1.20) over search: BDD structures are non-repetitive. In practice, clause learning is often implemented jointly with the opportunistic deletion of the less used learnt clauses, thus reducing the over-usage of physical memory by SAT solvers. Nevertheless, several of the most efficient DPLL based SAT solvers opt for not deleting any of the learnt clauses, and so the need for deleting less used learnt clauses is still not a completely solved issue.

Finally, the development of clever data structures have been crucial to SAT solver success. The most important of these is the structure that supports the notion of the watched literal [MMZ⁺01].

1.18. Upper bounds

by Ewald Speckenmeyer

Deciding satisfiability of a CNF formula ϕ with n Boolean variables can be performed in time $O(2^n |\phi|)$ by enumerating all assignments of the variables. The number m of clauses as well as the number l of literals of ϕ are further parameters for bounding the runtime of decision algorithms for SAT. Note that l is equal to $\text{length}(\phi)$ and this is the usual parameter for the analysis of algorithms. Most effort in designing and analyzing algorithms for SAT solving, however, are based on the number n of variables of ϕ .

A first non-trivial upper bound of $O(\alpha_k^n \cdot |\phi|)$, where α_k^n is bounding the Fibonacci-like recursion

$$\begin{aligned} T(1) &= T(2) = \dots = T(k-1) = 1 \quad \text{and} \\ T(n) &= T(n-1) + T(n-2) + \dots + T(n-k+1), \quad \text{for } n \geq k, \end{aligned}$$

for solving k -SAT, $k \geq 3$, was shown in [MS79, MS85]. For example, $\alpha_3 \geq 1.681$, $\alpha_4 \geq 1.8393$, and $\alpha_5 \geq 1.9276$.

The algorithm supplying the bound looks for a shortest clause c from the current formula. If c has $k - 1$ or less literals, e.g. $c = (x_1 \vee \dots \vee x_{k-1})$ then ϕ is split into $k - 1$ subformulas according to the $k - 1$ subassignments

- 1) $x_1 = 1$;
- 2) $x_1 = 0, x_2 = 1$;
- ...
- $k-1$) $x_1 = x_2 = \dots = x_{k-2} = 0, x_{k-1} = 1$.

If all clauses c of ϕ have length k , then ϕ is split into k subformulas as described, and each subformula either contains a clause of length at most $k - 1$ or one of the resulting subformulas only contains clauses of length k . In the former case, the above mentioned bound holds. In the latter case, the corresponding subassignment is *autark*, that is, all clauses containing these variables are satisfied by this subassignment, so ϕ can be evaluated according to this autark subassignment thereby yielding the indicated upper bound.

For the case $k = 3$, the bound was later improved to $\alpha_3 = 1.497$ by a sophisticated case analysis (see [Sch96]). Currently, from [DGH⁺02], the best deterministic algorithms for solving k -SAT have a run time of

$$O\left(\left(2 - \frac{2}{k+1}\right)^n\right).$$

For example, the bounds are $O(1.5^n)$, $O(1.6^n)$, $O(1.666\dots^n)$ for 3, 4, and 5 literal clause formulas. These bounds were obtained by the derandomization of a multistart-random-walk algorithm based on covering codes. In the case of $k = 3$ the bound has been further improved to $O(1.473^n)$ in [BK04]. This is currently the best bound for deterministic 3-SAT solvers.

Two different probabilistic approaches to solving k -SAT formulas have resulted in better bounds and paved the way for improved deterministic bounds. The first one is the algorithm of Paturi-Pudlak-Zane [PPZ97] which is based on the following procedure:

Determine a truth assignment of the variables of the input formula ϕ by iterating over all variables v of ϕ in a randomly chosen order: If ϕ contains a unit clause $c = (x)$, where $x = v$ or $\neg v$, set $t(v)$ such that $t(x) = 1$. If neither v nor $\neg v$ occur in a unit clause of ϕ , then randomly choose $t(v)$ from $\{0, 1\}$. Evaluate $\phi := t(\phi)$. Iterate this assignment procedure at most r times or until a satisfying truth assignment t of ϕ is found, starting each time with a randomly chosen order of variables for the assignment procedure.

After $r = 2^{n(1-\frac{1}{k})}$ rounds a solution for a satisfiable formula is found with high probability [PPZ97]. By adding to ϕ clauses originating from resolving input clauses up to a certain length this bound can be improved. In case of $k = 3, 4, \text{ and } 5$, the basis of the exponential growth function is 1.36406, 1,49579, and 1,56943 [PPZ98]. For $k \geq 4$ this is currently the best probabilistic algorithm for solving k -SAT.

The second approach is due to Schöning [Sch99, Sch02] and extends an idea

of Papadimitriou [Pap91]. That procedure is outlined as follows:

Repeat the following for r rounds: randomly choose an initial truth assignment t of ϕ ; if t does not satisfy ϕ , then repeat the following for three times the number of variables of ϕ or until a satisfying assignment t is encountered: select a falsified clause c from ϕ and randomly choose and flip a literal x of c .

If the algorithm continues, round after round, without finding a satisfying assignment nothing definite can be said about the satisfiability of ϕ . However, in this case the higher the number of rounds r , the lower the probability that ϕ is satisfiable. To guarantee an error probability of $e^{-\lambda}$, the number of rounds should be at least $O(\lambda(2^{\frac{k-1}{k}})^n)$. For $k = 3, 4,$ and 5 the basis of the exponential growth is 1.3334, 1.5, and 1.6.

The case of $k = 3$ has since been improved to $O(1.324^n)$ by Iwama and Tamaki [IT03]. For CNF formulas of unrestricted clause length the best time bound for a deterministic solution algorithm is $O(2^{n(1-\frac{1}{\log(2m)})})$, where n is the number of variables and m the number of clauses. This result, by Dantsin and Wolpert [DW04], is obtained from a derandomization of a randomized algorithm by Schuler [Sch05], of the same time complexity. Dantsin and Wolpert recently improved this bound for randomized algorithms to $O\left(2^{n(1-\frac{1}{\ln(\frac{m}{n})+O(\frac{1}{\ln(\ln(m))})})}\right)$ [DW05].

1.19. Classes of easy expressions

An entire book could be written about the multitude of classes of the Satisfiability problem that can be solved in polynomial time, so only some of the classical results will be mentioned here. It is often not enough that a class of problems is solved in polynomial time - an instance may have to be recognized as a member of that class before applying an efficient algorithm. Perhaps surprisingly, for some classes the recognition step is unnecessary and for some it is necessary but not known to be tractable.

The reader may have the impression that the number of polynomial time solvable classes is quite small due to the famous dichotomy theorem of Schaefer [Sch73]. But this is not the case. Schaefer proposed a scheme for defining classes of propositional expressions with a generalized notion of “clause.” He proved that every class definable within his scheme was either \mathcal{NP} -complete or polynomial-time solvable, and he gave criteria to determine which. But not all classes can be defined within his scheme. The Horn and XOR classes can be but we will describe several others including q-Horn, extended Horn, CC-balanced and SLUR that cannot be so defined. The reason is that Schaefer’s scheme is limited to classes that can be recognized in log space.

All clauses of a 2-SAT expression contain at most two literals. A two literal clause describes two inferences. For example, inferences for the clause $(x \vee y)$ are: 1) if x is 0 then y is 1; and 2) if y is 0 then x is 1. For a given 2-SAT expression an implication graph may be constructed where directed edges between pairs of literals represent all the inferences of the expression. A cycle in the inference

graph that includes a pair of complementary literals is proof that no model exists. Otherwise a model may be determined easily with a depth-first search of the graph, which amounts to applying unit propagation. A full algorithm is given in [EIS76] (1976). A linear time algorithm is given in [APT79] (1979).

All clauses of an expression said to be *Horn* have at most one *positive literal*. This class is important because of its close association with Logic Programming: for example, the clause $(\neg v_1 \vee \neg v_2 \vee v)$ expresses the rule $v_1 \wedge v_2 \rightarrow v$ or $v_1 \rightarrow v_2 \rightarrow v$. However, the notion of causality is generally lost when translating from rules to Horn expressions. An extremely important property of Horn expressions is that every satisfiable one has a unique minimum model with respect to 1 (the unique minimum model is the intersection of all models of the expression). Finding a model is a matter of applying unit propagation on positive literals until all positive literals are eliminated, then assigning all remaining literals the value 0 (if satisfiable, a unique minimum model is the result). It took a few iterations in the literature to get this universally understood and the following are the important citations relating to this: [IM82] (1982), [DG84] (1984), [Scu90] (1990).

A given expression may be *renameable Horn*, meaning a change in the polarity of some variables results in an equivalent Horn expression. Renameable Horn expressions were shown to be recognized and solved in linear time by [Lew78] (1978) and [Asp80] (1980).

A number of polynomially solvable relaxations of Linear Programming problems were shown to be equivalent to classes of Satisfiability; this work, quite naturally, originated from the Operations Research community. Representing CNF expressions as $(0, \pm 1)$ matrices where columns are indexed on variables and rows indexed on clauses, Satisfiability may be cast as an Integer Programming problem. If the matrix has a particular structure the Integer Program can be relaxed to a Linear Program, solved, and the non-integer values of the solution rounded to 0 or 1. Notable classes based on particular matrix structures are the extended Horn expressions and what we call the CC-balanced expressions.

The class of *extended Horn* expressions was introduced by Chandru and Hooker [CH91] (1991). Their algorithm is due to a theorem of Chandrasekaran [Cha84] (1984). Essentially, a model for a satisfiable expression may be found by applying unit propagation, setting values of unassigned variables to $1/2$ when no unit clauses remain, and rounding the result by a matrix multiplication. This algorithm cannot, however, be reliably applied unless it is known that a given expression is extended Horn and, unfortunately, the problem of recognizing an expression as extended Horn is not known to be solved in polynomial time.

The class of *CC-balanced* expressions has been studied by several researchers (see [CCK⁺94] (1994) for a detailed account of balanced matrices and a description of CC-balanced formulas). The motivation for this class is the question, for Satisfiability, when do Linear Programming relaxations have integer solutions? The satisfiability of a CNF expression can be determined in linear time if it is known to be CC-balanced and recognizing that a formula is CC-balanced takes linear time.

Horn, Renameable Horn, Extended Horn, CC-balanced expressions, and other classes including that of [SW95] (1991) turn out to be subsumed by a larger, efficiently solved class called *SLUR* for Single Lookahead Unit Resolution [SAFS95]

(1995). The SLUR class is peculiar in that it is defined based on an algorithm rather than on properties of expressions. The SLUR algorithm recursively selects variables sequentially and arbitrarily, and considers a one-level lookahead, under unit propagation in both directions, choosing only one, if possible. If a model is found, the algorithm is successful, otherwise it “gives up.” An expression is SLUR if, for all possible sequences of variable selections, the SLUR algorithm does not give up. Observe that due to the definition of this class, the question of class recognition is avoided. In fact, SLUR provides a way to avoid preprocessing or recognition testing for several polynomial time solvable classes of SAT when using a reasonable variant of the DPLL algorithm.

The worst case time complexity of the SLUR algorithm would appear to be quadratic. However, a simple modification brings the complexity down to linear: run both calls of unit propagation simultaneously, alternating execution of their repeat blocks. When one terminates without an empty clause in its output formula, abandon the other call.

The *q-Horn* class also originated in the Operations Research community [BCH90, BHS94] (1990) and for several years was thought to be what was described as the largest, succinctly expressed class of polynomial time solvable expressions. This claim was due to a measure on an underlying $(0, \pm 1)$ matrix representation of clauses called the *satisfiability index* [BCHS94] (1994). The q-Horn class was also studied as a special case of the maximum monotone decomposition of matrices [Tru94] (1994). We find it easier to describe the efficient solution of q-Horn expressions by following [Tru98] (1998). Using the $(0, \pm 1)$ matrix representation, an expression is q-Horn if columns can be multiplied by -1 , and permuted, and rows can be permuted with the result that the matrix has four quadrants as follows: northeast - all 0s; northwest - a Horn expression; southeast - a 2-SAT expression; southwest - no $+1$ s. A model may be found in linear time, if one exists, by finding a model for the northwest quadrant Horn expression, cancelling rows in the southern quadrants whose clauses are satisfied by that model, and finding a model for the southeast quadrant 2-SAT expression. It was shown in [BCHS94] (1994) that a CNF expression is q-Horn if and only if its satisfiability index is no greater than 1 and the class of all expressions with a satisfiability index greater than $1 + 1/n^\epsilon$, for any fixed $\epsilon < 1$, is \mathcal{NP} -complete. The SLUR and q-Horn classes are incomparable [FVG03] (2003).

The class of *linear autarkies*, developed by Kullmann [Kul00] (2000), was shown by van Maaren [vM00] (2000) to include the class of q-Horn formulas. It was also shown to be incomparable with the SLUR class. An autarky for a CNF formula ϕ is a partial assignment that satisfies all those clauses of ϕ affected by it: for example, a pure literal is an autarky. Therefore, a subformula obtained by applying an autarky to ϕ is satisfiable if and only if ϕ is. A formula with $(0, \pm 1)$ matrix representation A has a linear autarky $x \in Q^n$, $x \neq 0$, if $Ax \geq 0$. in polynomial time. There exists a simple, efficient decomposition that results in a partial, autark assignment. Applying this decomposition repeatedly results in a unique, linear-autarky-free formula. If the decomposition is repeatedly applied to a renameable Horn formula without unit clauses what is left is empty and if it is applied repeatedly to a 2-SAT formula, the formula is unsatisfiable if what is left is not empty and satisfiable otherwise.

The class of *matched expressions* was analyzed to provide a benchmark for testing the claim made for the q-Horn class. This is a class first described in [Tov84] (1984) but not extensively studied, probably because it seems to be a rather useless and small class of formulas. Establish a bipartite graph $G_\phi = (V_1, V_2, E)$ for an expression ϕ where V_1 vertices represent clauses, V_2 vertices represent variables, and edge $\langle c, v \rangle \in E$ if and only if clause c contains v or its complement. If there is a total matching in G_ϕ , then ϕ is said to be matched. Clearly, matched expressions are always satisfiable and are trivially solved. The matched class is incomparable with the q-Horn and SLUR classes. However, as is shown in Section 1.22, with respect to frequency of occurrence on random expressions, matched expressions are far more common than both those classes together [FVG03] (2003).

The worst case complexity of *nested satisfiability*, a class inspired by Lichtenstein's theorem of planar satisfiability [Lic82] (1982), has been studied in [Knu90] (1990). Index all variables in an expression consecutively from 1 to n and let positive and negative literals take the index of their respective variables. A clause c_i is said to *straddle* another clause c_j if the index of a literal of c_j is strictly between two indices of literals of c_i . Two clauses are said to *overlap* if they straddle each other. A formula is said to be *nested* if no two clauses overlap. For example, the following formula is nested

$$(v_6 \vee \neg v_7 \vee v_8) \wedge (v_2 \vee v_4) \wedge (\neg v_6 \vee \neg v_9) \wedge (v_1 \vee \neg v_5 \vee v_{10}).$$

The class of nested formulas is quite limited in size for at least the reason that a nested expression can contain no more than $2m + n$ literals. Thus, no expression consisting of k -literal clauses is a nested formula unless $m/n < 1/(k-2)$. The class of nested expressions is incomparable with both the SLUR and q-Horn classes. However, by the measure of Section 1.22 (also in [FVG03] (2003)) a random expression is far more likely to be matched, q-Horn, or even SLUR than nested. The algorithm for nested expressions is notable for being quite different than those mentioned above: instead of relying on unit propagation, it uses dynamic programming to find a model in linear time. The question of whether the variable indices of a given formula can, in linear time, be permuted to make the formula nested appears to be open. An extension to nested satisfiability, also solvable in linear time, has been proposed in [HJP93] (1993).

None of the classes above covers a significant proportion of unsatisfiable expressions. Nevertheless, several classes of unsatisfiable expressions have been identified. It is interesting that most known polynomial time solvable classes with clauses containing three or more literals either are strongly biased toward satisfiable expressions or strongly biased toward unsatisfiable expressions.

An expression is said to be *minimally unsatisfiable* if it is unsatisfiable and removing any clause results in a satisfiable expression. A minimally unsatisfiable expression with n variables must have at least $n + 1$ clauses [AL86] (1986). Every variable of a minimally unsatisfiable expression occurs positively *and* negatively in the expression. The class of minimally unsatisfiable formulas is solved in $n^{O(k)}$ if the number of clauses exceeds the number of variables by a fixed positive constant k [KB99] (1999) and [KB00] (2000). Szeider improved this to $O(2^k)n^4$ [Sze03] (2003). Kullmann has generalized this class in [Kul03] (2003) and continues to

find larger versions. Some SAT solvers look for minimally unsatisfiable sets of clauses to reduce search space size.

A CNF expression is said to be k -BRLR if all resolvents derived from it have a number of literals bounded by k or if the null clause is derivable from resolvents having at most k literals. Obviously, this class is solved in time bounded by $2^k \binom{n}{k}$.

Finally, we mention that semidefinite programming which is discussed at length in Section 1.25 is biased toward verifying unsatisfiability and this accounts for the success of this approach.

1.20. Binary Decision Diagrams

Binary Decision Diagrams (BDDs) were considered for a while to be the best way to handle some problems that are rooted in real applications, particularly related to circuit design, testing, and verification. They are still quite useful in various roles [DK03, FKS⁺04, HD04, JS05, MM02, PV05, CGGT97] and in some ways are complementary to search [US94, GZ03].

A BDD may be regarded as a DAG representation of the truth table of a Boolean function. In a BDD non-leaf vertices are labeled as variables, there are two out-directed edges for each non-leaf vertex, each labeled with value 0 or 1, and two leaves, labeled 1 and 0. There is a single root and any path from root to a “1” (“0”) leaf indicates an assignment of values to the variables which causes the represented function to have value 1 (0). A BDD may also be viewed as representing a search space in which paths to the 1 leaf represent models.

The attraction to BDDs is due in part to the fact that no subproblem is represented more than once in a collection of BDDs - this is in contrast to the tree-like search spaces of DPLL implementations of the 1980s. In addition, efficient implementations exist for BDD operations such as existential quantification, “or,” “and,” and others. The down side is: 1) each path from the root of a BDD must obey the same variable ordering, so BDDs are not necessarily a minimal representation for a function; and 2) repeatedly conjoining pairs of BDDs may create outrageously large intermediate BDDs even though the final BDD is small. By the late 1990s, DPLL advances such as conflict resolution, clausal learning, backjumping, restarts, and more gave rise to DAG search spaces with dynamic variable ordering. The result was improved performance for search over BDDs in some cases.

BDDs were introduced in [Lee59] (1959) as a data structure based on the Shannon expansion (see Section 1.14). They were publicized in [Bou76] (1976) and [Ake78] (1978). But BDDs became most useful with the introduction of reduced order BDDs by Bryant [Bry86, Bry92] (1986,1992) and their implementation [BRB90] (1990) which supports subproblem sharing over collections of BDDs and the efficient manipulation of those BDDs.

A number of operations on BDDs have been proposed over the years to assist in the efficiency of combining BDDs. One of the most important and basic operations is **existential quantification** which arises directly from Shannon’s expansion of Section 1.14: namely, replace f with $f|_{v=0} \vee f|_{v=1}$. This operation can be used to eliminate a variable at the expense of first conjoining all BDDs containing it. It is not clear when existential quantification was first used but it

was probably known very early. An important problem in managing BDD size is how to simplify a function f (implemented as a BDD), given a constraint c (implemented as a BDD): that is, replace f with a function f' that is equal to f on the domain defined by c . The operation of **restrict** [CBM90] (1990) does this by pruning paths from the BDD of f that are ‘false’ in the BDD of c . A more complex operation with restrict-like properties but admitting removal of a BDD from a collection of BDDs at the expense of increasing the size of some of the remaining BDDs is the **constrain** or **generalized cofactor** operation [CM90] (1990). Constraining f to c results in a function h with the property that $h(x) = f(\mu(x))$ where $\mu(x)$ is the closest point to x in c where distance between binary vectors $x, y \in \{0, 1\}^n$ is measured by $d(x, y) = \sum_{1 \leq i \leq n} 2^{n-i} \cdot ((x_i + y_i) \bmod 2)$ under a BDD variable ordering which matches the index order. Additional minimization operations, based on **restrict**, that do not increase BDD size are proposed in [HBBM97] (1997).

BDDs were designed primarily for the efficient representation of switching circuits and their manipulation, but a number of variations on BDDs have appeared over the years to target related classes of problems. BDDs of various kinds have been used successfully to represent relations and formulas to support symbolic model checking [BCM⁺92, McM93] (1992), although more recently, it has been found that SAT solvers for Bounded Model Checking [BCCZ99] (1999) can sometimes achieve even better results. The ZDD, for Zero-suppressed BDD, introduced in 1993 [Min93], differs from the BDD in that a vertex is removed if its 1 edge points to the 0 leaf. This helps improve efficiency when handling sparse sets and representing covers. Thus, the ZDD has been used successfully on problems in logic synthesis such as representing an irredundant DNF of an incompletely specified Boolean function [CMFT93] (1993), finding all essential prime implicants in DNF minimization [Cou94] (1994), factorization [Min96] (1996), and decomposition [JM01] (2001). The BMD, for Binary Moment Diagram, is a generalization of the BDD for handling numbers and numeric computations, particularly multiplication [BC95] (1995). The ADD, for Algebraic Decision Diagram (also known as Multi-Terminal Decision Diagram), allows more than two leaves (possibly real-valued) and is useful for mapping Boolean functions to sets [BFG⁺93] (1993) as might be needed to model the delay of MOS circuits, for example [MB01] (2001). The XDD has been used to efficiently represent equations involving the xor operation. The essential idea is that vertex x with 1 edge to vertex a and 0 edge to vertex b represents the equation $(x \wedge a) \oplus b = 1$. Many other varieties of BDD have been proposed but there is not enough space to mention them all.

1.21. Probabilistic analysis: SAT algorithms

Probabilistic and average-case analysis of algorithms can give useful insight into the question of what SAT algorithms might be effective and why. Under certain circumstances, one or more structural properties shared by each of a collection of formulas may be exploited to solve such formulas efficiently; or structural properties might force a class of algorithms to require superpolynomial time. Such properties may be identified and then, using probabilistic analysis, one may argue that these properties are so common that the performance of an algorithm

or class of algorithms can be predicted for most of a family of formulas. The first probabilistic results for SAT had this aim.

Probabilistic results of this sort depend on an underlying input distribution. Although many have been proposed, well-developed histories exist for just two, plus a few variants, which are defined over CNF inputs. All the results of this section are based on these two. In what follows, the *width* of a clause is the number of literals it contains. The distributions we discuss here are:

1. *Variable width distribution:* Given integers n , m , and a function $p : N^+ \times N^+ \rightarrow [0, 1]$. Let $V = \{v_1, \dots, v_n\}$ be a set of n Boolean variables. Construct a random clause (disjunction) c by independently adding literals to c as follows: for each variable v_i , $1 \leq i \leq n$, add literal v_i with probability $p(m, n)$, add literal $\neg v_i$ with probability $p(m, n)$ (therefore add neither v_i nor $\neg v_i$ with probability $1 - 2p(m, n)$). A random input consists of m independently constructed random clauses and is referred to below as a random (n, m, p) -CNF expression. In some cases $p(m, n)$ is independent of m and n and then we use p to represent $p(m, n)$.
2. *Constant width distribution:* Given integers n , m , k . Let $V = \{v_1, \dots, v_n\}$ be a set of n Boolean variables. Construct a random clause (disjunction) c by choosing, uniformly and without replacement, k variables from V and then complementing each, independently, with probability $1/2$. A random input consists of m independently constructed random clauses and is referred to below as a random (n, m, k) -CNF expression. Such an input is widely known as a uniform random k -SAT instance or simply random k -SAT instance.

1.21.1. Variable width distribution

Goldberg was among the first to apply probability to the analysis of SAT algorithms. He investigated the frequency with which simple backtracking returns a model quickly on random CNF formulas by providing an average-case analysis of a variant of DPLL which does not handle pure literals or unit clauses [Gol79] (1979). The result received a lot of attention when it was first presented and even 10 years afterward some people still believed it was the definitive probabilistic result on satisfiability algorithms.

Goldberg showed that, for random (n, m, p) -CNF expressions, the DPLL variant has average complexity bounded from above by $O(m^{-1/\log(p)}n)$ for any fixed $0 < p < 1$. This includes the “unbiased” sample space when $p = 1/3$ and all expressions are equally likely. Later work [GPB82] (1982) showed the same average-case complexity even if pure literals are handled as well. Very many problems confronting the scientific and engineering communities are unsatisfiable, but Goldberg made no mention of the frequency of occurrence of unsatisfiable random (n, m, p) -CNF expressions.

However, Franco and Paull [FP83] (1983) pointed out that large sets of random (n, m, p) -CNF expressions, for fixed $0 < p < 1/2$, are dominated by trivial *satisfiable* expressions: that is, any random assignment of values to the variables of such a random expression is a model for that expression with high probability. This result is refined somewhat in [Fra86b] (1986) where it is shown that a

random assignment is a model for a random (n, m, p) -CNF expression with high probability if $p > \ln(m)/n$ and a random expression is unsatisfiable with high probability if $p < \ln(m)/2n$. In the latter case, a “proof” of unsatisfiability is trivially found with high probability because a random (n, m, k) -CNF expression for this range of p usually contains at least one empty clause, which can easily be located, and implies unsatisfiability. The case $p = c \ln(m)/n$, $1/2 \leq c \leq 1$ was considered in [FH89] (1988) where it was shown that a random (n, m, p) -CNF expression is satisfiable with high probability if $\lim_{n, m \rightarrow \infty} m^{1-c}/n^{1-\epsilon} < \infty$, for any $0 < \epsilon < 1$.

Although these results might be regarded as early threshold results (see Section 1.22) the main impact was to demonstrate that probabilistic analysis can be highly misleading and requires, among other things, some analysis of input distribution to ensure that a significant percentage of non-trivial inputs are generated. They show that random (n, m, p) -CNF expressions, satisfiable or unsatisfiable, are usually trivially solved because either they contain empty clauses (we get the same result even if empty or unit clauses are disallowed) or they can be satisfied by a random assignment. In other words, only a small region of the parameter space is capable of supporting significantly many non-trivial expressions: namely, when the average clause width is $c \ln(m)/n$, $1/2 \leq c \leq 1$. These results demonstrate shortcomings in choosing random (n, m, p) -CNF expressions for analysis and, because of this, such generators are no longer considered interesting by many.

Nevertheless, some interesting insights were developed by further analysis and we mention the most significant ones here. The results are shown graphically in Figure 1.1 which partitions the entire parameter space of the variable width distribution according to polynomial-average-time solvability. The vertical axis ($p \cdot n$) measures average clause width and the horizontal axis (m/n) measures density. Each result is presented as a line through the chart with a perpendicular arrow. Each line is a boundary for the algorithm labeling the line and the arrow indicates that the algorithm has polynomial average time performance in that region of the parameter space that is on the arrow side of the line (constant and even log factors are ignored for simplicity).

Goldberg’s result is shown as the diagonal line in the upper right corner of the figure and is labeled **Goldberg**: it is not even showable as a region of the parameter space, so there is no arrow there. Iwama analyzed an algorithm which counts models using inclusion-exclusion [Iwa89] (1989) and has polytime-average-time complexity in the region above and to the right of the line labeled **Counting**. A random expression generated at a point in that region satisfies conditions, with high probability, under which the number of terms in the inclusion-exclusion expansion is polynomial in m and n . However, every clause of the same random expression is a tautology (contains a literal and its complement) with high probability. Therefore, this seems to be another example of a misleading result and, judging from the relation between the **Counting** and **Goldberg** regions in the figure, lessens the significance of Goldberg’s result even more.

There have been a number of schemes proposed for limiting resolution steps to obtain polynomial complexity. A simple example is to perform resolution only if the pivot variable appears once as a positive literal and once as a negative literal - then, if an empty clause does not exist when no more resolutions are possible,

Figure 1.1. The parameter space of the variable width distribution partitioned by polynomial-average-time solvability. Pick a point in the parameter space. Locate the lines with names of algorithms on the side of the line facing the chosen point. Random formulas generated with parameters set at that point are solved in polynomial average time by the named algorithms.

do a full search for a solution. The conditions under which this algorithm runs in polynomial average time under random variable width expressions are too complex to be given here but they are represented by the regions in Figure 1.1 below the lines labeled **Limited Resolution** [Fra86a] (1991).

If pure literal reductions are added to the algorithm analyzed by Goldberg then polynomial average time is achieved in the **Pure Literals** region, considerably improving the result of Goldberg [PB85] (1985). But a better result, shown as the region bounded from above by the lines labeled **Unit Clauses**, is obtained by performing unit propagation [Fra93] (1993) and is consistent with the empirically and theoretically demonstrated importance of unit propagation in DPLL algorithms. Results for Search Rearrangement Backtracking [Pur83] (1983) are disappointing (shown bounded by the two lines labeled **Backtracking**) but a slightly different variant in which only variables from positive clauses (a *positive clause* contains only positive literals) are chosen for elimination (if there is no positive clause, satisfiability is determined by assigning all unassigned variables the value 0), has spectacular performance as is shown by the line labeled **Probe Order Backtracking** [PH97] (1997). The combination of probe order backtracking and unit clauses yield polynomial average time for random (n, m, p) -CNF expressions at every point of the parameter space except for some points along the thin horizontal region $p \cdot n = c \cdot \log(n)$.

By 1997, what Goldberg had set out to do in 1979, namely show DPLL has polynomial average time complexity for variable width distributions, had been accomplished. The research in this area had some notable successes such as the analysis of probe order backtracking which demonstrated that a slight algorithmic change can have a major effect on performance. But, the fact that nearly every point in the parameter space is covered by an algorithm that has polynomial average time complexity is rather disturbing, though, since there are many practical applications where SAT is considered extremely difficult. Largely for this reason attention shifted to the constant width distribution and, by the middle of the 1990s, research on the variable width distribution all but disappeared.

Constant width distribution

Franco and Paull (1983) in [FP83] (see [PRF87], 1987, for corrections) set out to test Goldberg's result on other distributions. They formulated the constant width distribution and showed that for all $k \geq 3$ and every fixed $m/n > 0$, with probability $1 - o(1)$, the algorithm analyzed by Goldberg takes an *exponential* number of steps to report a result: that is, either to report all ("cylinders" of) models, or that no model exists. They also showed that a random (n, m, k) -CNF expression is unsatisfiable with probability tending to 1 when $m/n > -\ln(2)/\ln(1 - 2^{-k})$. For $k = 3$ this is $m/n > 5.19$.

Perhaps the first positive result using the constant width distribution was presented in [CF86] (1986) where a non-backtracking, incremental assignment algorithm employing unit propagation, called UC, was shown to find a model with bounded probability when $m/n < O(1) \cdot 2^k/k$. This work introduced an analysis tool called "clause-flows" analysis which was refined by Achlioptas [Ach01] (2001) using a theorem of Wormald [Wor95]. Analysis of clause flows via differential equations was to be the basic analytic tool for most of the following results in this area. In [CF90] (1990) it was shown that a generalization of unit propagation,

called GUC, in which a variable from a “smallest” clause is chosen for assignment finds a model with probability $1 - o(1)$ when $m/n < O(1) \cdot 2^k/k$, $k \geq 4$. This was improved by Chvátal and Reed [CR92] (1992) who showed that GUC, with assignment rules relaxed if no unit or two literal clauses are present (called SC for shortest clause), finds a model with probability $1 - o(1)$ when $m/n < O(1) \cdot 2^k/k$ for $k \geq 3$.

Observe that the results of the previous two paragraphs show a gap between the range $m/n > \ln(2)/\ln(1 - 2^{-k}) \approx 2^k \ln(2)$, where random expressions are unsatisfiable with high probability, and $m/n < O(1) \cdot 2^k/k$, where analyzed non-backtracking incremental assignment algorithms find models for random expressions with high probability. According to results of Friedgut (1999 - see Section 1.22) there is a sharp satisfiability threshold r_k for every $k \geq 2$ (it is still not known whether the threshold depends on n) and the results above show $2^k/k < r_k < 2^k \ln(2)$. The question of the location of r_k was pondered for quite some time. Most people intuitively believed that r_k was located near $2^k \ln(2)$ so the question became known as the ‘*Why 2 k?*’ problem (Pittel, 1999). This was verified by Achlioptas, Moore, and Perez in [AM02, AP04] (2002,2004) who showed that $r_k = 2^k \ln(2) - O(k)$ by applying the second moment method to a symmetric variant of satisfiability, known as not-all-equal k -SAT (NAE- k -SAT). In NAE- k -SAT the question is whether, for a given CNF expression, there is a satisfying assignment whose complement is also a satisfying assignment. Obviously, the class of k -CNF expressions satisfiable in NAE- k -SAT is a subset of the class satisfiable in the traditional sense. Hence, for the purposes of finding the threshold, NAE- k -SAT may be analyzed instead of k -SAT. The symmetric nature of NAE- k -SAT results in a low variance in the number of satisfying assignments and this makes the second moment method work.

Most interest, though, has centered on the case $k = 3$. It is believed, from experiment, that $r_3 \approx 4.25$. In [CF86] (1986) it is shown that UC finds a model with bounded probability when $m/n < 8/3 = 2.66..$ and, when combined with a “majority” rule (that is, choose a variable with the maximum difference between the number of its positive and negative literals if unit propagation cannot be applied), this improves to $m/n < 2.9$. Frieze and Suen [FS96] (1996) considered SC and GUC and showed that for $m/n < 3.003..$, both heuristics succeed with positive probability. Moreover, they proved that a modified version of GUC, called GUCB, which uses a limited form of backtracking, succeeds almost surely for the same range of m/n . Later, Achlioptas [Ach00] (2000) analyzed SC, modified slightly to choose two variables at a time from a clause with two unfalsified literals, for an improvement to $m/n \leq 3.145$ with probability $1 - o(1)$.

Nearly all the results above apply to *myopic* algorithms. A non-backtracking, variable assignment algorithm is called *myopic* [AS00] if, under the spectral coalescence of states, the distribution of expressions corresponding to a particular coalesced state can be expressed by its spectral components alone: that is, by the *number* of clauses of width i , for all $1 \leq i \leq k$, and the *number* of assigned variables. Being myopic considerably assists an analysis by preserving statistical independence from one algorithmic step to the next. Unfortunately, in [AS00] (2000) it is shown that no myopic algorithm can have good probabilistic performance when $m/n > 3.26$. In the same paper it is shown that at least one myopic

algorithm almost surely finds a model if $m/n < 3.26$.

However, Kaporis et al. [KKL06] (2002) found a workaround to this “barrier” and analyzed a simple non-myopic greedy algorithm for Satisfiability. They control the statistical dependence problem by considering a different generator of expressions such that probabilistic results also hold for random $(n, m, 3)$ -CNF expressions. Their result is that a greedy algorithm for satisfiability almost always finds a model when $m/n < 3.42$. Similar algorithms have been shown to find a model, almost always, when $m/n < 3.52$ [HS03, KKL04] (2003). With this analysis machinery in place, better results are expected.

Although most of the results of the previous paragraph were motivated by threshold research (see Section 1.22), their analyses can influence algorithm development. It is hoped future probabilistic results will reveal new generally useful search heuristics, or at least explain the mechanics of existing search heuristics.

Another analysis should be noted for the following non-myopic incremental assignment algorithm: repeatedly assign values to pure literals to eliminate the clauses containing them. Broder, Frieze and Upfal [BFU93] (1993) proved that this algorithm almost always finds a model when $m/n \leq 1.63$ and $k = 3$. They used Martingales to offset distribution dependency problems as pure literals are uncovered. Mitzenmacher [Mit97] (1997) showed that this bound is tight.

This section concludes with a history of results on algorithms which are intended to return certificates of unsatisfiability. Most of these results, all pessimistic, are obtained for resolution. The best result, though, is obtained for an algorithm which finds lower bounds on the number of variable assignments that must be positive and the number that must be negative (via translation to two hitting set problems) and returns “unsatisfiable” if the sum is greater than the number of variables. This result is notable also because it makes use of a highly underused analysis tool in this area: eigenvalues. Recall that nearly all random constant width expressions are unsatisfiable if $m/n > 2^k \ln(2)$.

Chvátal and Szemerédi obtained the earliest result on constant width distributions, inspired by the work reported in Section 1.16, is that, with high probability, every resolution proof for a random unsatisfiable expression is exponentially long if $\lim_{n,m \rightarrow \infty} m/n = f(k) > 2^k \ln(2)$ [CS88] (1988). The analysis shows the root cause to be a property known as sparseness; which roughly indicates the number of times pairs of clauses have a common literal or complementary pair of literals. When an expression is sparse any “moderately large” subset of its clauses must contain a “large” number of variables that occur exactly once in that subset. Sparsity forces the proof to have a large resolvent. But, almost all “short” resolution refutations contain no long clauses after eliminating all clauses satisfied by a particular small random partial assignment ρ . Moreover, resolution refutations for almost all unsatisfiable random (n, m, k) -CNF expressions with clauses satisfied by ρ removed are sparse and, therefore, must have at least one high width resolvent. Consequently, almost all unsatisfiable random expressions have long resolution refutations. Beame, Karp, Pitassi, Saks, Ben-Sasson, and Wigderson, among others, contributed ideas leading up to a concise understanding of this phenomenon in [BP96] (1996), [BKPS98] (1998), [BSW01] (2001).

Despite considerable tweaking, the best we can say right now is that, with probability tending to 0, the width of a shortest resolution proof is bounded

by a polynomial in n when $m/n > 2^k \ln(2)$ and $\lim_{m,n \rightarrow \infty} m/n^{(k+2)/(4-\epsilon)} < 1$, where ϵ is some small constant; and with probability tending to 1, the width is polynomially bounded when $\lim_{m,n \rightarrow \infty} m/n > (n/\log(n))^{k-2}$.

The failure of resolution has led to the development of a new technique by Goerdts for certifying unsatisfiability, mentioned above, that uses eigenvalues. In [GK01] this spectral technique is used to obtain bounds sufficient to show that certifying unsatisfiability in polynomial time can be accomplished with high probability when $\lim_{m,n \rightarrow \infty} m/n > n^{k/2-1+o(1)}$ which is considerably better than resolution.

1.22. Probabilistic analysis: thresholds

Results of the 1980s (see Section 1.21) showed that, for random width k expressions density, that is the ratio m/n , is correlated with certain interesting expression properties. For example, it was shown that if $m/n > 2^k \ln(2)$ then a random instance is unsatisfiable with high probability and if $m/n < O(1) \cdot 2^k/k$ a random expression is satisfiable with high probability. So, it was clear that a crossover from probably unsatisfiable to probably satisfiable occurs as density is changed. Early on it was speculated that “hardness” is directly related to the nature of crossover and this motivated the study of Satisfiability thresholds.

Actually, thresholds can apply to a multitude of properties, not just the property of a formula being satisfiable, so we give a general definition of threshold here. Let $X = \{x_1, \dots, x_e\}$ be a set of e elements. Let A_X , a subset of the power set of X (denoted 2^X), be called a *property*. Call A_X a *monotone property* if for any $s \in A_X$, if $s \subset s'$, then $s' \in A_X$. Typically, a monotone property follows from a high-level description which applies to an infinite family of sets X . For example, let $X = \mathcal{C}_{k,n}$ be the set of all non-tautological, width k clauses that can be constructed from n variables. Thus $e = 2^k \binom{n}{k}$ and any $s \in 2^{\mathcal{C}_{k,n}}$ is a k -CNF expression. Let $UNSAT_{\mathcal{C}_{k,n}}$ denote the property that a k -CNF expression constructed from n variables is unsatisfiable. That is, any $s \in UNSAT_{\mathcal{C}_{k,n}}$ has no model and any $s \in 2^{\mathcal{C}_{k,n}} \setminus UNSAT_{\mathcal{C}_{k,n}}$ has a model. If $s \in UNSAT_{\mathcal{C}_{k,n}}$ and $c \in \mathcal{C}_{k,n}$ such that $c \notin s$, then $s \cup \{c\} \in UNSAT_{\mathcal{C}_{k,n}}$ so the property $UNSAT_{\mathcal{C}_{k,n}}$ is monotone for $k < n$.

For any $0 \leq p \leq 1$ and any monotone property $A_X \subset 2^X$ define

$$\mu_p(A_X) = \sum_{s \in A_X} p^{|s|} (1-p)^{e-|s|}$$

to be the probability that a random set has the monotone property. For the property $UNSAT_{\mathcal{C}_{k,n}}$ (among others), s is a set of clauses, hence this probability measure does not match that for what we call random k -CNF expressions but comes very close with $p = m/(2^k \binom{n}{k}) \approx m \cdot k!/(2n)^k$.

Observe that $\mu_p(A_X)$ is an increasing function of p .⁵ Let $p_c(X)$ denote that value of p for which $\mu_p(A_X) = c$. The values of $p_c(X)$ change as the size of X increases. There are two threshold types.

⁵By illustration using $UNSAT_{\mathcal{C}_{k,n}}$ this reflects the fact that, as p increases, the average number of clauses increases, so the probability that an expression has the $UNSAT_{\mathcal{C}_{k,n}}$ property increases.

A_X is said to have a *sharp threshold* if, for any small, positive ϵ ,

$$\lim_{|X| \rightarrow \infty} (p_{1-\epsilon}(X) - p_\epsilon(X))/p_{1/2}(X) = 0.$$

A_X is said to have a *coarse threshold* if, for any small, positive ϵ ,

$$\lim_{|X| \rightarrow \infty} (p_{1-\epsilon}(X) - p_\epsilon(X))/p_{1/2}(X) > 0.$$

From experiments based on the constant width distribution it appeared that $UNSAT_{C_{k,n}}$ has a sharp threshold and that the density at which the crossover occurs is a function of k . The so-called *satisfiability threshold* was therefore denoted by r_k . In addition, as m/n is reduced significantly below (the experimentally determined) r_k , algorithms of various types were observed to perform better and expressions were more likely to be members of a polynomial time solvable class (see Section 1.19 for a description - an analysis of these classes is given later in this section), and as m/n is increased significantly above r_k various algorithms were observed to perform better. But, in the neighborhood of r_k random expressions seemed to reach a point of maximum difficulty, at least for well-known, well-tried algorithms. Hence, the study of satisfiability thresholds was motivated by a possible connection between the nature of hardness and the nature and location of thresholds. The constant width distribution has dominated this study, perhaps because expressions generated when parameters are set near r_k tend to be extremely difficult for known algorithms.

The conjecture of a sharp threshold can be traced to a paper by Mitchell, Selman, and Levesque [MSL92] (1992) where the “easy-hard-easy” phenomenon is pointed out. A possible explanation is given by Cheeseman in [CKT91] (1991) where long “backbones” or chains of inference are stated to be a likely cause as the high density of well-separated “near-solutions” induced by backbones leads to thrashing in search algorithms. Tremendous insight on this phenomenon came from the field of Statistical Mechanics [MZK⁺99b, MZ02] where the connection between backbones and hardness was seen to be analogous to phase transitions in spin glasses. Achlioptas advanced this further with a rigorous analysis as this volume was going to press.

The satisfiability threshold for random $(n, m, 2)$ -CNF expressions was found by Chvátal and Reed to be sharp with $r_2 = 1$ [CR92] (1992) (it is historically correct to note that Fernandez de la Vega [FdlV92] and Goerdt [Goe96] independently achieved the same result in the same year). The fact that $(n, m, 2)$ -CNF expressions can be solved in polynomial time [Coo71] means that there is a *simple* characterization for those instances which are unsatisfiable. Both [CR92] and [Goe96] make use of this characterization by focusing on the emergence of the “most likely” unsatisfiable random $(n, m, 2)$ -CNF expressions.

For $k > 2$ the situation was much more difficult. The results of Section 1.21, some of which were bounded probability results, can be regarded as a history of lower bounds for the satisfiability threshold. Upper bounds were improved at a consistent rate for a while, the most intense investigation focusing on the case $k = 3$. Results due to Frieze and Suen [FS96] (1996), Kamath, Motwani, Palem, Spirakis [KMPS95] (1995), Fernandez de la Vega [EMFdlV97] (1997), Dubois,

Boufkhad [DB97] (1997), Kirousis, Kranakis, Krizanc [KKK96] (1996), Kirousis, Kranakis, Krizanc, Stamatiou [KKKS98] (1998), Dubois [Dub01] (2001), and Dubois, Boufkhad, Mandler [DBM00] (2002), containing many beautiful ideas, have brought the upper bound down to just over 4.5 for $k = 3$. From Section 1.21 the lower bound for $k = 3$ is 3.52. From experiments, we expect $r_3 \approx 4.25$.

Friedgut [Fri99] (1999) proved that sharp satisfiability thresholds exist for random (n, m, k) -CNF expressions, thereby confirming the conjecture of [MSL92]. This result immediately lifted all previously known and future constant probability bounds, to almost surely bounds. Friedgut's result has left open the possibility that the satisfiability threshold is a function of both k and n and it is still not known whether the satisfiability threshold depends on n , as weak as that dependency must be.

Monasson [MZK⁺99b, MZK⁺99a] (1999) and others conjectured that there is a strong connection between the “order” of threshold sharpness, that is whether the transition is smooth or discontinuous, and hardness. Consistent with this, using the characterization of unsatisfiable $(n, m, 2)$ -CNF expressions mentioned above, Bollobas et al. [BBC⁺01] (2001) completely determined the “scaling window” for random $(n, m, 2)$ -CNF expressions, showing that the transition from satisfiability to unsatisfiability occurs for $m = n + \lambda n^{2/3}$ as λ goes from $-\infty$ to $+\infty$. For some time scaling windows for various problems were consistent with Monasson's conjecture (e.g. [CD99, CD03b]). But eventually the conjecture was disproved in [ACIM01] (2001) where it was found that the order of threshold sharpness for the 1-in- k SAT problem, which is \mathcal{NP} -complete, is the same as that of 2-SAT.

On the other hand, the work of Creignou and Daudé [CD03a] (2002), [CD04] (2004) revealed the importance of *minimal monotonic structures* to the existence of sharp transitions. An element $s \in A_X$ is said to be *minimal* if for all $s' \subset s$, $s' \in 2^X \setminus A_X$. Those results have been used, for example, to show the limitations of most succinctly defined polynomial-time solvable classes of expressions, such as those mentioned in Section 1.19. Using density m/n of (n, m, k) -CNF distributions as a measure, thresholds for some classes of Section 1.19 have been determined: for example, a random (n, m, k) -CNF expression, $k \geq 3$, is q-Horn with probability tending to 1 if $m/n < O(1)/(k^2 - k)$ and with probability tending to 0 if $m/n > O(1)/(k^2 - k)$ [FVG03, CDF05]. Except for the matched class, the monotonic structure analysis shows why the classes of Section 1.19, including q-Horn, SLUR, renameable Horn and many others, are weak: they are “vulnerable” to cyclic clause structures, the presence of any of these in an expression prevents it from having the polynomial-time solvable property. A random expression is matched with probability tending to 1 if $m/n < 0.64$ [FVG03]: a result that adds perspective to the scope of most polynomial-time solvable classes.

Also of historical importance are results on $2 + p$ mixed random expressions: random expressions with width 2 and width 3 clauses, the p being the fraction of width 3 clauses. This distribution was introduced in [KS94] (1994) to help understand where random expressions get hard during search: if a search algorithm that embodies unit propagation is presented with a $(n, m, 3)$ -CNF expression, every search node represents such a mixed expression with a particular value of p so hardness for some range of p could translate to hardness for search. Experi-

mental evidence suggested that for some p_c , figured to be around 0.417, if $p < p_c$ the width 3 clauses were effectively irrelevant to the satisfiability of a random expression but if $p > p_c$ the transition behavior was more like that of a random width 3 expression. In [AKKK01] (2001) it was shown that $0.4 < p_c < 0.696$ and conjectured that $p_c = 0.4$. In [ABM04] (2004) it was shown that a random $2 + p$ mixed expression has a minimum exponential size resolution refutation (that includes any DPLL algorithm) with probability $1 - o(1)$ when the number of width 2 clauses is less than ρn , $\rho < 1$, and p is any constant. Actually, the results of this paper are quite far-ranging and provide new insights into the behavior of DPLL algorithms as they visit search nodes that represent $2 + p$ expressions.

1.23. Stochastic Local Search

by Holger Hoos

Stochastic local search (SLS) is one of the most successfully and widely used general strategies for solving hard combinatorial problems. Early applications to optimization problems date back to the 1950s (for example, see [Cro58, Flo56, Lin65]), and the Lin-Kernighan algorithm for the Traveling Salesman problem [LK73] (1973) is still among the most widely known problem-specific SLS algorithms. Two of the most prominent general SLS methods are Simulated Annealing [KGV83] (1983) and Evolutionary Algorithms [FOW66, Hol75, Sch81] (1966–1981).

SLS algorithms for SAT were first presented in 1992 by Gu [Gu92] and Selman et al. [SLM92] (following earlier applications to Constraint Satisfaction [MJPL90] and MAX-SAT [HJ90]). Interestingly, both Gu and Selman et al. were apparently unaware of the MAX-SAT work, and Hansen and Jaumard and Minton et al. appear to have been unaware of each other's work. The success of Selman et al.'s GSAT algorithm in solving various types of SAT instances more effectively than DPLL variants of the day sparked considerable interest in the AI community, giving rise to a fruitful and active branch of SAT research. GSAT is based on a simple iterative best improvement method with static restarts; in each local search step, it flips the truth value of one propositional variable such that the number of unsatisfied clauses in the given CNF formula is maximally reduced.

Within a year, the original GSAT algorithm was succeeded by a number of variants. These include HSAT [GW93], which uses a very limited form of search memory to avoid unproductive cycling of the search process; GSAT with Clause Weighting [SK93], which achieves a similar goal using dynamically changing weights associated with the clauses of the given CNF formula; and GSAT with Random Walk (GWSAT) [SK93], which hybridizes the “greedy” search method underlying GSAT with a simple random walk procedure (which had previously been shown by Papadimitriou [Pap91] to solve satisfiable 2-CNF formulae almost certainly in $O(n^2)$ steps).

Two relatively subtle modifications of GWSAT lead to the prominent (basic) WalkSAT algorithm [SKC94], which is based on the idea of selecting a currently unsatisfied clause in each step and satisfying that clause by flipping the value assigned to one of its variables. Basic WalkSAT (also known as WalkSAT/SKC) was shown empirically to outperform GWSAT and most other GSAT variants

for a broad range of CNF formulae; it is also somewhat easier to implement. Variants of WalkSAT that additionally use search memory, in particular WalkSAT/Tabu [MSK97] (1997) and Novelty⁺ [Hoo98, Hoo99] (1998) – an extension of the earlier Novelty algorithm of McAllester et al. [MSK97] – typically achieve even better performance. Novelty+, which has been proven to solve satisfiable CNF formulae with arbitrarily high probability given sufficient time, was later extended with an adaptive noise mechanism [Hoo02] (2002), and the resulting Adaptive Novelty+ algorithm is still one of the most effective SLS algorithms for SAT currently known.

Based on the same fundamental idea of dynamically changing clause weights as GSAT with Clause Weighting, Wah et al. developed an approach known as Discrete Lagrangian Method [SW98] (1998), whose later variants were shown to be highly effective, particularly for solving structured SAT instances [WW99, WW00]. A conceptually related approach, which uses multiplicatively modified clause weights has been developed by Schuurmans et al. [SSH01] (2001) and later improved by Hutter et al. [HTH02] (2002), whose SAPS algorithm was, until recently, one of the state-of-the-art SLS algorithms for SAT.

A detailed survey of SLS algorithms for SAT up to 2004 can be found in Chapter 6 of the book by Hoos and Stützle [HS05]. Since then, a number of new algorithms have been developed, including Li and Huang's G²WSAT [LH05] (2005), which combines ideas from the GSAT and WalkSAT family of algorithms, and Ishtaiwi et al.'s DDFW algorithm [ITA⁺06] (2006), which uses a dynamic clause weight redistribution. In another line of work, Anbulagan et al. have reported results suggesting that by using a resolution-based preprocessing method, the performance of several state-of-the-art SLS algorithms for SAT can be further improved [APSS05](2005).

SLS algorithms for SAT have also played an important role in theoretical work on upper bounds on worst-case time complexity for solving SAT on k -CNF formulae; this includes the previously mentioned random walk algorithm by Papadimitriou [Pap91] (1991) and later extensions by Schöning [Sch99] (1999) and Schuler et al. [SSW01] (2001).

1.24. Maximum Satisfiability

by Hantao Zhang

The problem of finding a truth assignment to the variables of a CNF expression that satisfies the maximum number of clauses possible is known as Maximum Satisfiability or MAX-SAT. If clauses have at most two literals each, the problem is known as MAX-2-SAT. The decision version of MAX-SAT and even MAX-2-SAT is \mathcal{NP} -complete. Unfortunately, there is no polynomial time approximation scheme for MAX-SAT unless $\mathcal{P} = \mathcal{NP}$ [AL97]. Because the MAX-SAT problem is fundamental to many practical problems in Computer Science [HJ90] and Electrical Engineering [XRS02], efficient methods that can solve a large set of instances of MAX-SAT are eagerly sought.

1.24.1. MAX-SAT: Decision Algorithms

Many of the proposed methods for MAX-SAT are based on approximation algorithms [DGH⁺02] (2002); some of them are based on branch-and-bound methods [HJ90] (1990), [BF99] (1999), [BR99] (1999), [Hir00] (2000), [NR00] (2000), [dGLMS03] (2003); and some of them are based on transforming MAX-SAT into SAT [XRS02] (2002), [ARMS02a] (2002).

Worst-case upper bounds have been obtained with respect to three parameters: the length L of the input formula (*i.e.*, the number of literals in the input), the number m of the input's clauses, and the number n of distinct variables occurring in the input. The best known bounds for MAX-SAT are $O(L2^{m/2.36})$ and $O(L2^{L/6.89})$ [BR99] (1999). The question of whether there exist exact algorithms with complexity bounds down to $O(L2^n)$ has been open and of great interest (see [Nie98] (1998), [AGN01] (2000), [GHNR03] (2003)) since an algorithm which enumerates all the 2^n assignments and then counts the number of true clauses in each assignment would take time $O(L2^n)$. Recently, it has been shown that a branch-and-bound algorithm can achieve $O(b2^n)$ complexity where b is the maximum number of occurrences of any variable in the input. Typically, $b \simeq L/n$.

The operation of the best branch-and-bound algorithms for MAX-SAT is similar to that of DPLL. Notable implementations are due to Wallace and Freuder (implemented in Lisp) [WF96] (1996), Gramm [Gra99] (1999), Borchers and Furman [BF99] (1999 - implemented in C and publicly available), Zhang, Shen, and Manyà [ZSM03] (2003), and Zhao and Zhang [ZZ04] (2004).

1.24.2. MAX-2-SAT: Decision Algorithms

MAX-2-SAT is important because a number of other \mathcal{NP} -complete problems can be reduced to it in a natural way, for example graph problems such as Maximum Cut and Independent Set [CCTW96] (1996), [MR99a]. For MAX-2-SAT, the best bounds have been improved from $O(m2^{m/3.44})$ [BR99] (1999), to $O(m2^{m/2.88})$ [NR00] (2000), and recently to $O(m2^{m/5})$ [GHNR03] (2003). The recent branch-and-bound algorithm cited above results in a bound of $O(n2^n)$ since $b \leq 2n$. When $m = 4n^2$ the bound is $O(\sqrt{m}1.414^{\sqrt{m}})$, which is substantially better than the result reported in [GHNR03].

For random 2-CNF formulas satisfiability thresholds have been found as follows:

Theorem [CGHS04] :

1. For $c < 1$, $K(n, cn) = \Theta(1/n)$.
2. For c large,

$$(0.25c - 0.343859\sqrt{c} + O(1))n \geq K(n, cn) \geq (0.25c - 0.509833\sqrt{c})n.$$

3. For any fixed $\epsilon > 0$, $\frac{1}{3}\epsilon^3 n \geq K(n, (1 + \epsilon)n)$.

In the above theorem, \geq is a standard asymptotic notation: $f(n) \geq g(n)$ means that f is greater than or equal to g *asymptotically*, that is, $f(n)/g(n) \geq 1$ when n goes to infinity, although it may be that $f(n) < g(n)$ even for arbitrarily large values of n .

1.25. Nonlinear formulations

by Miguel Anjos

The nonlinear formulations for SAT are based on the application of the fundamental concept of lift-and-project for constructing tractable continuous relaxations of hard binary (or equivalently, Boolean) optimization problems. The application of continuous relaxations to binary optimization dates back at least to Lovász's introduction of the so-called theta function as a bound for the stability number of a graph [Lov79]. More generally, the idea of liftings for binary optimization problems has been proposed by several researchers, and has led to different general-purpose frameworks. Hierarchies based on linear programming relaxations include the lift-and-project method of Balas, Ceria and Cornuéjols [BCC93], the reformulation-linearization technique of Sherali and Adams [SA90], and the matrix-cuts approach of Lovász and Schrijver [LS91]. Researchers in the SAT community have studied the complexity of applying some of these techniques, and generalizations thereof, to specific classes of SAT problems (see the recent papers [BOGH⁺03, GHP02a, GHP02b]).

While the aforementioned techniques use linear programming relaxations, the recent Lasserre hierarchy is based on semidefinite programming relaxations [Las00, Las02]. (Semidefinite constraints may also be employed in the Lovász-Schrijver matrix-cuts approach, but in a different manner from that of the Lasserre paradigm.) A detailed analysis of the connections between the Sherali-Adams, Lovász-Schrijver, and Lasserre frameworks was done by Laurent [Lau03]. In particular, Laurent showed that the Lasserre framework is the tightest among the three.

Semidefinite programming (SDP) refers to the class of optimization problems where a linear function of a symmetric matrix variable X is optimized subject to linear constraints on the elements of X and the additional constraint that X must be positive semidefinite. This includes linear programming problems as a special case, namely when all the matrices involved are diagonal. The fact that SDP problems can be solved in polynomial-time to within a given accuracy follows from the complexity analysis of the ellipsoid algorithm (see [GLS93]). A variety of polynomial time interior-point algorithms for solving SDPs have been proposed in the literature, and several excellent solvers for SDP are now available. The SDP webpage [Hel] and the books [dK02, WSVe00] provide a thorough coverage of the theory and algorithms in this area, as well as a discussion of several application areas where semidefinite programming researchers have made significant contributions. In particular, SDP has been very successfully applied in the development of approximation algorithms for several classes of hard combinatorial optimization problems, including maximum-satisfiability (MAX-SAT) problems.

A σ -approximation algorithm for MAX-SAT is a polynomial-time algorithm that computes a truth assignment such that at least a proportion σ of the clauses in the MAX-SAT instance are satisfied. The number σ is the approximation ratio

or guarantee. For instance, the first approximation algorithm for MAX-SAT is a $\frac{1}{2}$ -approximation algorithm due to Johnson [Joh74]: given n values $\pi_i \in [0, 1]$, the algorithm sets the i^{th} Boolean variable to 1 independently and randomly with probability π_i ; the resulting total expected weight of the satisfied clauses is $\frac{1}{2}$. Unless $\mathcal{P} = \mathcal{NP}$, there is a limit to the approximation guarantees that can be obtained. Indeed, Håstad [Hås01] proved that unless $\mathcal{P} = \mathcal{NP}$, for any $\epsilon > 0$, there is no $(\frac{21}{22} + \epsilon)$ -approximation algorithm for MAX-2-SAT, and no $(\frac{7}{8} + \epsilon)$ -approximation algorithm for MAX-SAT.

The most significant breakthrough was by Goemans and Williamson [GW95] who proposed an SDP-based 0.87856-approximation algorithm for MAX-2-SAT. The key to their analysis is the ingenious use of a randomly generated hyperplane to extract a binary solution from the set of n -dimensional vectors defined by the solution of the SDP relaxation. The randomized hyperplane rounding procedure can be formally de-randomized using the techniques in [MR99b].

A further significant improvement was achieved by Feige and Goemans [FG95] who proposed a 0.931-approximation algorithm for MAX-2-SAT. There are two key innovations introduced by Feige and Goemans. The first one is that they tighten the SDP relaxation of Goemans and Williamson by adding the $\binom{n}{3}$ triangle inequalities. From the optimal solution of this strengthened SDP relaxation, they similarly obtain a set of vectors, but instead of applying the random hyperplane rounding technique to these vectors directly, they use them to generate a set of rotated vectors to which they then apply the hyperplane rounding.

Karloff and Zwick [KZ97] proposed a general construction of SDP relaxations for MAX- k -SAT. Halperin and Zwick [HZ01] consider strengthened SDP relaxations for MAX- k -SAT, and specifically for MAX-4-SAT, they studied several rounding schemes, and obtained approximation algorithms that almost attain the theoretical upper bound of $\frac{7}{8}$. Most recently, Asano and Williamson [AW02] have combined ideas from several of the aforementioned approaches and obtained a 0.7846-approximation algorithm for general MAX-SAT.

For the decision version of SAT, the first SDP-based approach is the Gap relaxation of de Klerk, van Maaren, and Warners [dKvMW00, dKvM03]. This SDP relaxation was inspired by the work of Goemans and Williamson as well as by the concept of elliptic approximations for SAT instances. These approximations were first proposed in [vM99] and were applied to obtain effective branching rules as well as to recognize certain polynomially solvable classes of SAT instances. The idea behind the elliptic approximations is to reformulate a SAT formula on n boolean variables as the problem of finding a ± 1 (hence binary) n -vector in an intersection of ellipsoids in \mathcal{R}^n . Although it is difficult to work directly with intersections of ellipsoids, it is possible to relax the formulation to an SDP problem. The resulting SDP relaxation is called the Gap relaxation. This relaxation characterizes unsatisfiability for 2-SAT problems [dKvMW00]. More interestingly, it also characterizes satisfiability for a class of covering problems, such as mutilated chessboard and pigeonhole instances. Rounding schemes and approximation guarantees for the Gap relaxation, as well as its behaviour on $(2 + p)$ -SAT problems, are studied in [dKvM03].

An elliptic approximation uses a quadratic representation of SAT formulas. More powerful relaxations can be obtained by considering higher-degree poly-

mial representations of SAT formulas. The starting point is to define for each clause a polynomial in ± 1 variables that equals 0 if and only if the clause is satisfied by the truth assignment represented by the values of the binary variables. Thus, testing satisfiability of a SAT formula is reduced to testing whether there are values $x_1, \dots, x_n \in \{-1, 1\}$ such that for every clause in the instance, the corresponding polynomial evaluated at these values equals zero.

We present two ways that SDP can be used to attempt to answer this question. One of them applies the Lasserre hierarchy mentioned above as follows. The Gap relaxation has its matrix variable in the space of $(n+1) \times (n+1)$ symmetric matrices, and is thus a first lifting. To generalize this operation, we allow the rows and columns of the SDP relaxations to be indexed by subsets of the discrete variables in the formulation. These larger matrices can be interpreted as higher liftings. Applying directly the Lasserre approach to SAT, we would use the SDP relaxations Q_{K-1} (as defined in [Las00]) for $K = 1, 2, \dots, n$ where the matrix variable of Q_{K-1} has rows and columns indexed by all the subsets I with $\|I\| \leq K$ (hence for $K = 1$, we obtain the matrix variable of the Gap relaxation). The results in [Las02] imply that for $K = n$, the resulting SDP relaxation characterizes satisfiability for every instance of SAT. However, this SDP has dimension exponential in n . Indeed, the SDP problems quickly become far too large for practical computation. This limitation motivated the study of partial higher liftings, where we consider SDP relaxations that have a much smaller matrix variable, as well as fewer linear constraints. The construction of such partial liftings for SAT becomes particularly interesting if we let the structure of the SAT instance specify the structure of the SDP relaxation.

One of these partial liftings was proposed in [Anj05]. This construction considers all the monomials $\prod_i x_i$ that appear in the instance's satisfiability conditions. An appropriate SDP relaxation is then defined where each row and column of the matrix variable corresponds to one of these terms. The resulting matrix is highly structured, and hence the SDP relaxation can be strengthened by adding some constraints that capture this structure. The tradeoff involved in adding such constraints to the SDP problem is that as the number of constraints increases, the SDP problems become increasingly more demanding computationally. Anjos [Anj05] defines the SDP relaxation R_3 by proposing to add a relatively small number of these constraints, judiciously chosen so that it is possible to prove the following result: if R_3 is infeasible, then the SAT instance is unsatisfiable; while if R_3 is feasible, and Y is a feasible matrix such that $\text{rank}(Y) \leq 3$, then the SAT instance is satisfiable, and a model can be extracted from Y . Thus the SDP relaxation can prove either satisfiability or unsatisfiability of the given SAT instance. A more compact relaxation is obtained by defining the columns of the matrix variable using only the sets of odd cardinality. This yields the SDP relaxation R_2 [Anj04a], an intermediate relaxation between the Gap relaxation (call it R_1) and R_3 . The names of the relaxations reflect their increasing strength in the following sense: For $k = 1, 2, 3$, any feasible solution to the relaxation R_k with rank at most k proves satisfiability of the corresponding SAT instance. Furthermore, the increasing values of k also reflect an improving ability to detect unsatisfiability, and an increasing computational time for solving the relaxation.

From the computational point of view, it is only possible to tackle relatively

small SAT instances (regardless of the choice of SDP relaxation) if branching is needed [Anj04b]. However, when it does not require branching, the SDP approach can be competitive. For instance, the SDP approach can successfully prove (without branching) the unsatisfiability of the **hgen8** instances, one of which was the smallest unsatisfiable instance that remained unsolved during the SAT competitions of 2003 and 2004.

A second way to test whether there is a set of ± 1 values for which the clause polynomials all equal zero was proposed by van Maaren and van Norden [vMvN05, vMvN08]. They consider (among others) the aggregate polynomial obtained by summing all the polynomials arising from clauses. This polynomial turns out to be non-negative on $\{-1, 1\}^n$, and for $x \in \{-1, 1\}^n$ it equals the number of unsatisfied clauses. (Hence, MAX-SAT is equivalent to the minimization of this polynomial over $\{-1, 1\}^n$.) An SDP relaxation is obtained as follows. Suppose we are given a column vector β of monomials in the variables x_1, \dots, x_n and a polynomial $p(x)$. Then $p(x)$ can be written as a sum-of-squares (SOS) in terms of the elements of β if and only if there exists a matrix $S \succeq 0$ such that $\beta^T S \beta = p$ [Par03]. If S is symmetric positive semidefinite, then $S = W^T W$ for some matrix W , and hence we have an explicit decomposition of p as an SOS: $\beta^T S \beta = p \Rightarrow \|W\beta\|_2^2 = p$. The resulting SDP problem is

$$\begin{aligned} \max \quad & g \\ \text{s.t.} \quad & F_{\Phi}^{\mathcal{B}}(x) - g \equiv \beta^T S \beta \text{ modulo } I_{\mathcal{B}} \\ & S \succeq 0 \end{aligned}$$

where $I_{\mathcal{B}}$ denotes the ideal generated by the polynomials $x_k^2 - 1, k = 1, \dots, n$. (The fact that each degree k polynomial that is non-negative on $\{-1, 1\}^n$ can be expressed as an SOS modulo $I_{\mathcal{B}}$ follows from the work of Putinar [Put93].) Note that since β is fixed, the equation $F(x) - g = \beta^T S \beta$ is linear in S and g , and hence this is an SDP problem. The SOS approach can thus be applied to obtain proofs of (un)satisfiability. For instance, it is straightforward to prove that if there exists a monomial basis β and an $\epsilon > 0$ such that $F^{\mathcal{B}}(x) - \epsilon$ is a SOS modulo $I_{\mathcal{B}}$, then the underlying SAT formula is unsatisfiable.

For the SOS approach, different choices of the basis β result in different SDP relaxations. Among the choices considered by van Maaren and van Norden are the following: SOS_{GW} is the relaxation obtained using the basis containing $1, x_1, \dots, x_n$; SOS_p is obtained using the basis containing $1, x_1, \dots, x_n$, plus the monomial $x_{k_1} x_{k_2}$ for each pair of variables that appear together in a clause; SOS_{ap} is obtained using the basis containing $1, x_1, \dots, x_n$, plus the monomials $x_{k_1} x_{k_2}$ for all pairs of variables; SOS_t is obtained using the basis containing $1, x_1, \dots, x_n$, plus the monomial $x_{k_1} x_{k_2} x_{k_3}$ for each triple of variables that appear together in a clause; and SOS_{pt} is obtained using the basis containing $1, x_1, \dots, x_n$, plus the monomial $x_{k_1} x_{k_2}$ for each pair of variables that appear together in a clause, plus $x_{k_1} x_{k_2} x_{k_3}$ for each triple of variables that appear together in a clause.

The notation SOS_{GW} is justified by the fact that SOS_{GW} is precisely the dual of the SDP relaxation used by Goemans and Williamson in their seminal paper [GW95]. van Maaren and van Norden prove that SOS_{GW} gives the same upper bound for MAX-2-SAT as the relaxation of Goemans and Williamson. They also show that for each triple $x_{k_1} x_{k_2} x_{k_3}$, adding the monomials $x_{k_1} x_{k_2}$,

$x_{k_1}x_{k_3}$, and $x_{k_2}x_{k_3}$ gives an SDP relaxation at least as tight as that obtained by adding the corresponding triangle inequality to the Goemans-Williamson relaxation. Furthermore, they prove that the SDP relaxation SOS_{ap} is at least as tight as the Feige-Goemans relaxation, and that for every instance of MAX-3-SAT, the SDP relaxation SOS_{pt} provides a bound at least as tight as the Karloff-Zwick relaxation.

From the computational point of view, van Maaren and van Norden provide computational results comparing several of these relaxations on instances of varying sizes and varying ratios of number of clauses to number of variables. They propose rounding schemes for MAX-2-SAT and MAX-3-SAT based on SOS_p and SOS_t respectively, and present preliminary results comparing their performance with the rounding schemes mentioned above. They also compare the performance of the R_3 relaxation with the SOS approach using either SOS_t or SOS_{pt} . Their preliminary results suggest that SOS_{pt} offers the best performance.

The most recent result about the nonlinear approach is that the SDP approach can explicitly characterize unsatisfiability for the well-known Tseitin instances on toroidal grid graphs. Consider a $p \times q$ toroidal grid graph and for each node (i, j) , set the parameter $t(i, j) = 0$ or 1. Introduce a Boolean variable for each edge, and for each node (i, j) , define 8 clauses on the four variables adjacent to it as follows: if $t(i, j) = 0$, add all clauses with an odd number of negations; and if $t(i, j) = 1$, add all clauses with an even number of negations. It is clear that the SAT instance is unsatisfiable if and only if $\sum_{(i,j)} t(i, j)$ is odd. It is shown in [Anj06] how to construct an SDP relaxation with matrix variable of dimension $14pq$ and with $23pq - 1$ linear equality constraints such that the SDP problem is infeasible if and only if the SAT instance is unsatisfiable. Therefore, for these instances, the SDP-based approach provides, in theory, an explicit certificate of (un)satisfiability, and therefore makes it possible to numerically compute such a certificate to within a given precision in polynomial time.

1.26. Pseudo-Boolean Forms

Let \mathcal{B}^n be the set of binary vectors of length n . Mappings $f : \mathcal{B}^n \mapsto \mathfrak{R}$ are called *pseudo-Boolean* functions. Let $V = \{v_1, v_2, \dots, v_n\}$ be a set of n binary variables. Since there is a one-to-one correspondence between subsets of V and \mathcal{B}^n these functions are called set functions. There is a natural connection between pseudo-Boolean functions and binary optimization which has been exploited since the 1960s, especially following the seminal treatment of the topic by Hammer and Rudeanu in 1968 [HR68]. Areas impacted by pseudo-Boolean functions are diverse and include VLSI design (for example, [BGM88]), maximum satisfiability (for example, [Kar72]), clustering in statistics (for example, [Rao71]), economics (for example, [HS71]), graph theory (for example, [PR75]), and scheduling, among many others.

There are at least two important representations of pseudo-Boolean functions. All pseudo-Boolean functions may be uniquely represented as *multi-linear polynomials* of the form

$$f(v_1, v_2, \dots, v_n) = c_f + \sum_{S \subseteq V} c_S \prod_{v \in S} v$$

where c_S is some real number that depends on S and c_f is a constant. The degree of such a polynomial is the largest S for which $c_S \neq 0$. A degree 1 polynomial is called *linear*, a degree 2 polynomial is called *quadratic* and so on.

Polynomials can also be written with non-negative constants using products of literals instead of products of variables as follows:

$$f(v_1, v_2, \dots, v_n) = c_f + \sum_{S \subseteq V \cup \bar{V}} c_S \prod_{l \in S} l$$

where $\bar{V} = \{\neg v_1, \neg v_2, \dots, \neg v_n\}$ is the set of negative literals associated with variables (and positive literals) V and $c_S \geq 0$ with $c_S = 0$ if there is a complementary pair $\{v, \neg v\} \in S$. This is called the *posiform* representation of a pseudo-Boolean function. Although a posiform uniquely determines a pseudo-Boolean function, a pseudo-Boolean function may be represented by more than one posiform. Moreover, it is easy to compute a posiform from a polynomial representation but it may be difficult to compute a *unique* polynomial representation corresponding to a given posiform. Because factors c_S are non-negative, minimizing a posiform is essentially the same as maximizing the number of terms that are 0. Thus, the posiform representation is closely related to instances of maximum satisfiability and the problem of determining satisfiability of a Boolean formula may be viewed as testing whether the minimum of a posiform is equal to its constant term.

The optimization of a pseudo-Boolean function can be reduced in polynomial time to the optimization of a quadratic pseudo-Boolean function [Ros72] (1972) by repeatedly substituting a new variable for a product of two variables and the addition of constraints that force the new variable to take the value of the product. However, a posiform corresponding to a quadratic pseudo-Boolean function may have degree higher than 2.

The *basic algorithm* for finding the optimum value of a pseudo-Boolean function was introduced in [HRR63b, HRR63a] (1963) and refined in [HR68] (1968). Although the algorithm has exponential complexity, special cases have been found, for example where the algorithm is fixed-parameter tractable [CHJ90] (1990). An upper (lower) bound of a pseudo-Boolean function may be obtained by a term-by-term majorization (minorization) procedure which was introduced in [HHS84] (1984). An algorithm for posiforms known as the DDT algorithm was developed in [BHS89] (1989).

In [CEI96] (1996) a variant of the Gröbner basis algorithm was applied to systems of posiforms restricted to modulo 2 arithmetic. The base operations of that algorithms were posiform addition, modulo 2, and variable multiplication. Application of such an operation is called a derivation. It was shown in [CEI96] that the algorithm uses a number of derivations that is guaranteed to be within a polynomial of the minimum number possible and that the minimum number of derivations cannot be much greater than, and may sometimes be far less than, the minimum number needed by resolution.

More recently, conventional resolution-based SAT solvers have been generalized to solve systems of linear polynomials. An early example is OPBDP [Bar95] (1995). Notable advanced examples include PBS [ARMS02b] (2002) which has advanced to PBS4 [AAR] (2005), Galena [CK03] (2003), and Pueblo [SS06] (2006). In [ES06] (2006) it is shown that translating linear polynomials to CNF clauses

and then solving with a conventional SAT solver is a viable alternative to specialized pseudo-Boolean solvers although some expertise is needed to obtain the best translations. The authors point out that translations might be the best approach when problems are modeled with many clauses and a few pseudo-Boolean constraints.

1.27. Quantified Boolean formulas

by Hans Kleine Büning

The concept of quantified Boolean formulas (QBF) is an extension of propositional logic that allows existential (\exists) and universal (\forall) quantifiers. The intended semantics of quantified Boolean formulas, without free variables, is that a universally quantified formula $\psi = \forall x\phi$ is true if and only if for every assignment of the truth values 1 and 0 to the variable x , ψ is true. For existentially quantified formulas $\psi = \exists x\phi$, ψ is true if and only if there is an assignment to x for which ϕ is true. In the case of free variables, ψ is called *satisfiable* if there is a truth assignment to the free variables such that ψ is true. The satisfiability problem for quantified Boolean formulas is often denoted as QSAT.

Most of the research has been done for formulas in prenex form, that is, formulas of the form $Q_1x_1 \dots Q_nx_n\phi$, where $Q_i \in \{\exists, \forall\}$, x_1, \dots, x_n are variables, and ϕ is a propositional formula called the *matrix*. By standard techniques, every quantified Boolean formula can be transformed into a logically equivalent formula in prenex form. In the same way, by the well-known procedure for propositional formulas, logically equivalent formulas with a CNF matrix or 3-CNF matrix can be obtained. These classes are denoted as QCNF and Q3-CNF.

Quantified Boolean formulas with free variables are logically equivalent to Boolean functions. But, clearly, there is no polynomial p such that every n -ary Boolean function can be represented as a quantified Boolean formula of length $p(n)$. However, for various applications, QBFs lead to shorter formulas in comparison to propositional formulas. See, for example, [JB06].

The first papers on QBFs were motivated by questions arising from computational complexity. Like SAT for NP, it has been shown in [MS73] that QSAT is one of the prominent \mathcal{PSPACE} -complete problems. In a more detailed analysis, a strong relationship was shown between the satisfiability problem of formulas with a fixed number of alternations of quantifiers and the polynomial-time hierarchy [MS72] where the polynomial-time hierarchy is defined as follows ($k \geq 0$):

$$\begin{aligned} \Delta_0^P &:= \Sigma_0^P := \Pi_0^P := P \\ \Sigma_{k+1}^P &:= NP^{\Sigma_k^P}, \quad \Pi_{k+1}^P := co\Sigma_{k+1}^P, \quad \Delta_{k+1}^P := P^{\Sigma_k^P} \end{aligned}$$

For quantified Boolean formulas in prenex form, the prefix type is defined as follows:

1. The prefix type of a propositional formula is $\Sigma_0 = \Pi_0$.
2. Let Φ be a formula with prefix type Σ_n (Π_n respectively), then the formula $\forall x_1 \dots \forall x_n \Phi$ ($\exists x_1 \dots \exists x_n \Phi$ respectively) is of prefix type Π_{n+1} (Σ_{n+1} respectively).

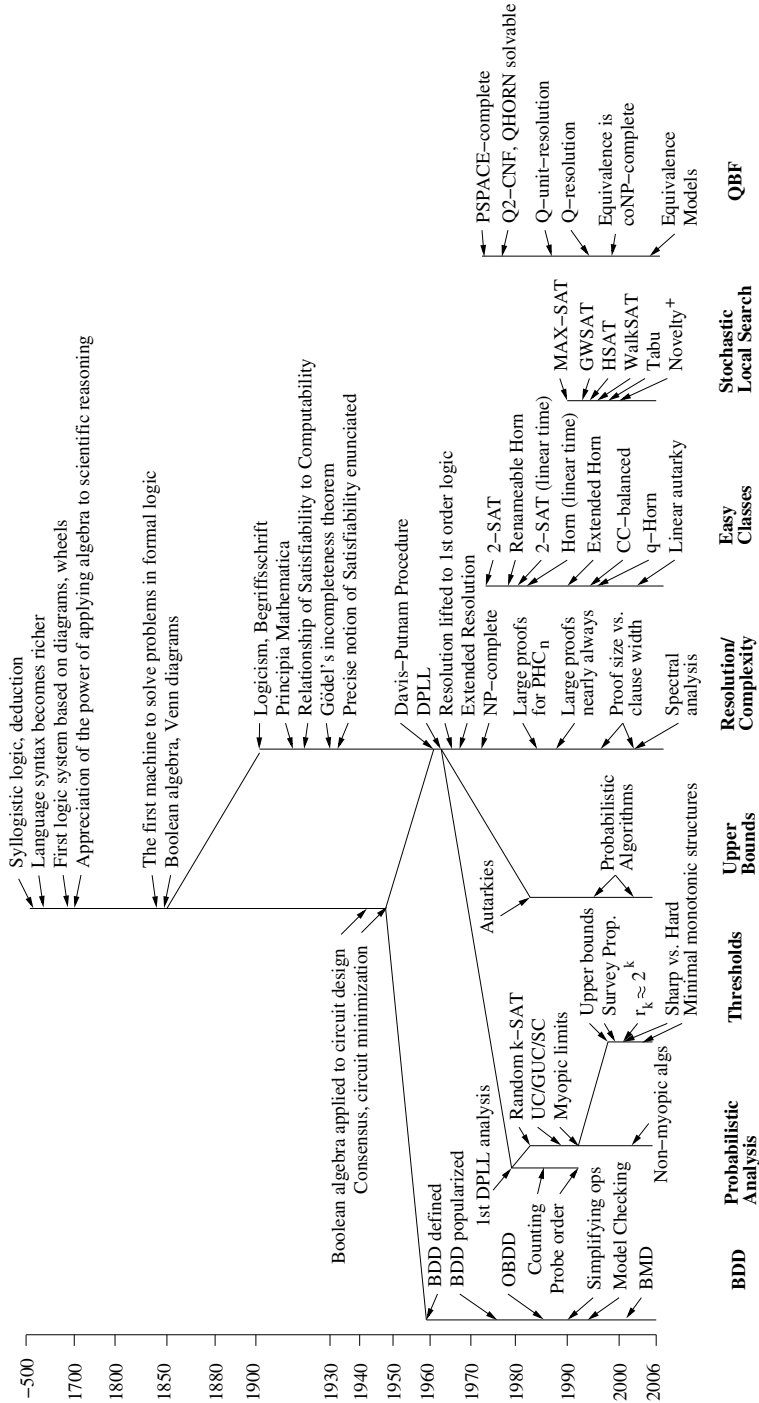

Figure 1.2. Timeline: Some nodes on the history tree (continued on next page). The intention is to provide some perspective on the level of activity in a particular area during a particular period.

Figure 1.2. (continued) Survey propagation is shown on the chart but is not mentioned in the text. A history of algorithms inspired by statistical mechanics may be found in the Survey Propagation chapter of this Handbook.

It has been proved that for $k \geq 1$, the satisfiability problem for formulas with prefix type Σ_k (Π_k respectively) is Σ_k^P -complete (Π_k^P -complete respectively) [Sto77, Wra77]. Since $\mathcal{PSPACE} = \mathcal{NPSPACE}$ [Sav70], almost all quantified Boolean formula problems are solvable in \mathcal{PSPACE} . For example, in propositional logic, the equivalence problem is coNP -complete, whereas for quantified Boolean formulas, the problem remains \mathcal{PSPACE} -complete.

In addition to propositional formulas, a dichotomy theorem for quantified Boolean formulas has been established in [Sch73]. The idea was to classify classes of quantified Boolean formulas by means of a finite set of constraints, where the constraints are Boolean functions. The dichotomy theorem says that if the Boolean functions are equivalent to Horn formulas (anti-Horn formulas, 2-CNF formulas, XOR-CNF formulas respectively), then the satisfiability problems for the quantified classes are in P, otherwise they are \mathcal{PSPACE} -complete. As a consequence, the solvability of the satisfiability problem for Q2-CNF and QHORN follows, where QHORN is the set of formulas, whose matrix is a Horn formula. Detailed proofs and extensions of the dichotomy theorem can be found, for example, in [Dal97, CKS92]. For formulas with fixed prefix type, further results have been shown in [Hem94].

For Q2-CNF, the first linear-time algorithm for solving the satisfiability problem has been presented in [APT79]. For QHORN, the best known algorithm can be found in [KBKF95]. The latter algorithm requires not more than $O(r \cdot n)$ steps, where r is the number of universal variables and n is the length of the formula.

Not all the problems solvable in polynomial time for propositional formulas remain polynomial-time solvable for quantified formulas. For example, in contrast to the polynomial-time solvability of the equivalence problem for Horn formulas, the equivalence problem for quantified Horn formulas is coNP -complete [KBL99].

Instead of restrictions on the form of clauses, classes of quantified formulas satisfying some graph properties have been investigated. Examples are quantified versions of ordered binary decision diagrams (OBDDs) and free binary decision diagrams (FBDDs) (see, for example, [CMLBLM06]). For instance, the satisfiability problem for quantified FBDDs is \mathcal{PSPACE} -complete.

Q-resolution is an extension of the resolution calculus for propositional formulas to quantified formulas. Q-unit-resolution was introduced in [KKBS88] and was then generalized to Q-resolution in [KBKF95]. Here, a Q-unit clause contains at most one free or existentially quantified literal and arbitrarily many universal literals. The idea of Q-resolution is to resolve only over complementary pairs of existential or free variables, combined with a careful handling of the universal literals. Q-resolution is refutation complete and sound for QCNF. Similar to propositional Horn formulas, Q-unit-resolution is refutation complete for QHORN, and also for the class QEHORN. That is the set of formulas for which, after deleting the universal literals in the matrix, the remaining matrix is a Horn formula. The satisfiability problem for that class remains \mathcal{PSPACE} -complete [KKBF91].

A more functional view of the valuation of quantified Boolean formulas is the observation that a formula is true if and only if for every existential variable y there is a Boolean function $f_y(x_1, \dots, x_m)$ depending on the dominating universal variables x_1, \dots, x_m , such that after replacing the existential variables y by the associated functions $f_y(x_1, \dots, x_m)$ the formula is true. The set of such functions

is called a satisfiability model. For some classes of quantified Boolean formulas, the structure of the satisfiability models has been investigated. For example, satisfiable quantified Horn formulas have satisfiability models which consist of the constants *true* and *false* or conjunctions of variables. For Q2-CNF, the models are constants or a literal [KBSZ07]. Instead of satisfiability models, one can ask for Boolean functions, such that after replacing the existentially quantified variables with the functions, the formula is logically equivalent to the initial formula. These functions are called equivalence model. Equivalence models describe in a certain sense the internal dependencies of the formula. For example, quantified Horn formulas have equivalence models consisting of monotone functions. By means of this result, it has been shown that every quantified Horn formula can be transformed into an equivalent existentially quantified Horn formula in time $O(r \cdot n)$, where r is the number of universal variables and n is the length of the formula [BKBZ05].

Chapter 2

CNF Encodings

Steven Prestwich

2.1. Introduction

Before a combinatorial problem can be solved by SAT methods, it must usually be transformed (*encoded*) to *conjunctive normal form* (CNF): a conjunction of clauses $\bigwedge_i c_i$, each clause c_i being a disjunction of literals $\bigvee_j l_j$, and each literal l_j being either a Boolean variable v or its negation \bar{v} . CNF has the advantage of being a very simple form, leading to easy algorithm implementation and a common file format. Unfortunately there are several ways of encoding most problems and few guidelines on how to choose among them, yet the choice of encoding can be as important as the choice of SAT solver.

This chapter reviews theoretical and empirical work on CNF encodings. In Section 2.2 we describe techniques for transforming from a formula in propositional logic to CNF (and 3-CNF), in particular the Tseitin encodings and some variants, the encoding of extensional and intensional constraints, and the DIMACS file format for CNF. In Section 2.3 we present case studies in CNF encoding, illustrating the techniques of this section and other modelling aspects. In Section 2.4 we discuss what makes one encoding better than another. Finally, Section 2.5 concludes the chapter.

Some of the topics mentioned in this chapter are covered in greater depth elsewhere in this book, but we cover them briefly to aid the discussion. For the sake of readability we shall omit some details from examples of SAT encodings. In particular, instead of $\bigwedge_{j=1}^m (\bigvee_{i=1}^n v_{i,j})$ we shall simply write $\bigvee_i v_{i,j}$ and leave it to the reader to quantify the variable i over its range, and to form conjunctions of clauses by quantifying the free variable j over its range. For full details please consult the various papers cited below.

2.2. Transformation to CNF

Propositional logic formulae can be transformed to CNF in several ways, but this may lose a great deal of structural information. Some of this information can be computed from the CNF encoding and can be used to boost the performance of both DPLL [Li00, OGMS02] (the Davis-Putnam-Logemann-Loveland

[DP60, DLL62] family of backtracking-based SAT algorithms) and local search [Seb94], but some of it is intractable to compute [LM98]. To avoid this difficulty, solvers for non-CNF problems have been devised [AG93, VG88, KMS97, MS06, Ott97, PTS07, Sta01, TBW04]. These techniques can yield great improvements on certain structured problems.

However, CNF currently remains the norm. The reason might be that tried and tested heuristics, based on problem features such as clause lengths and the number of occurrences of literals, would need to be adapted to non-CNF formulae. In this section we describe methods for transforming propositional logic formulae and constraints into CNF.

2.2.1. Transformation by Boolean algebra

A propositional logic formula can be transformed to a logically equivalent CNF formula by using the rules of Boolean algebra. For example consider the propositional formula

$$(a \rightarrow (c \wedge d)) \vee (b \rightarrow (c \wedge e))$$

(taken from [TBW04]). The implications can be decomposed:

$$((a \rightarrow c) \wedge (a \rightarrow d)) \vee ((b \rightarrow c) \wedge (b \rightarrow e))$$

The conjunctions and disjunctions can be rearranged:

$$\begin{aligned} & ((a \rightarrow c) \vee (b \rightarrow c)) \wedge ((a \rightarrow c) \vee (b \rightarrow e)) \wedge \\ & ((a \rightarrow d) \vee (b \rightarrow c)) \wedge ((a \rightarrow d) \vee (b \rightarrow e)) \end{aligned}$$

The implications can be rewritten as disjunctions, and duplicated literals removed:

$$(\bar{a} \vee \bar{b} \vee c) \wedge (\bar{a} \vee \bar{b} \vee c \vee e) \wedge (\bar{a} \vee \bar{b} \vee c \vee d) \wedge (\bar{a} \vee \bar{b} \vee d \vee e)$$

Finally, subsumed clauses can be removed, leaving the conjunction

$$(\bar{a} \vee \bar{b} \vee c) \wedge (\bar{a} \vee \bar{b} \vee d \vee e)$$

This example reduces to a compact CNF formula, but in general this method yields exponentially large formulae.

2.2.2. Transformation by Tseitin encoding

Conversion to CNF is more usually achieved using the well-known Tseitin encodings [Tse83], which generate a linear number of clauses at the cost of introducing a linear number of new variables, and generate an equisatisfiable formula (satisfiable if and only if the original formula is satisfiable). Tseitin encodings work by adding new variables to the CNF formula, one for every subformula of the original formula, along with clauses to capture the relationships between these new variables and the subformulae. On the above example the Tseitin encoding would introduce a variable f_1 with definition

$$f_1 \leftrightarrow (c \wedge d)$$

to represent subformula $(c \wedge d)$. This definition can be reduced to clausal form:

$$(\overline{f_1} \vee c) \wedge (\overline{f_1} \vee d) \wedge (\overline{c} \vee \overline{d} \vee f_1)$$

Similarly it would introduce a definition

$$f_2 \leftrightarrow (c \wedge e)$$

which reduces to clauses

$$(\overline{f_2} \vee c) \wedge (\overline{f_2} \vee e) \wedge (\overline{c} \vee \overline{e} \vee f_2)$$

Applying these definitions the original formula is reduced to

$$(\overline{a} \vee f_1) \wedge (\overline{b} \vee f_2)$$

Next two more variables would be introduced with definitions

$$f_3 \leftrightarrow (\overline{a} \vee f_1)$$

and

$$f_4 \leftrightarrow (\overline{b} \vee f_2)$$

and clauses

$$(\overline{f_3} \vee \overline{a} \vee f_1) \wedge (a \vee f_3) \wedge (\overline{f_1} \vee f_3) \wedge (\overline{f_4} \vee \overline{b} \vee f_2) \wedge (b \vee f_4) \wedge (\overline{f_2} \vee f_4)$$

The formula is now reduced to

$$(f_3 \vee f_4)$$

Finally, a variable would be introduced with definition

$$f_5 \leftrightarrow (f_3 \vee f_4)$$

and clauses

$$(\overline{f_5} \vee f_3 \vee f_4) \wedge (\overline{f_3} \vee f_5) \wedge (\overline{f_4} \vee f_5)$$

Tseitin CNF encodings are linear in the size of the original formula as long as the Boolean operators that appear in the formula have linear clausal encodings. The operators *and*, *or*, *not*, *nand*, *nor* and *implies* all have linear clausal encodings. In practice we might choose not to define some variables, for example $(f_3 \vee f_4)$ is already in clausal form so we need not define f_5 . We might also choose to expand some non-clausal subformulae.

Alternatives to the Tseitin encodings have been described, mainly in the context of Boolean circuits, but the ideas are relevant to SAT in general. Consider the following example (taken from [TBW04]). Suppose we have a formula $X \vee (p \wedge q)$ where X is a large unsatisfiable formula and p, q are Boolean variables. A Tseitin encoding will include auxiliary variables x, y, z defined by $x \leftrightarrow X$, $y \leftrightarrow (p \wedge q)$ and $z \leftrightarrow (x \vee y)$. Now suppose that DPLL first selects variables y, z and sets them to true. Then unit propagation will set p, q to true. Next suppose that it selects variable x and sets it to false. Then DPLL only needs to find any variable assignment that falsifies X (which should be easy) and the problem is solved. However, if x was instead set to true then DPLL might be forced to perform a lengthy search to refute X , before backtracking to set x to false. Under the assignments $[\overline{x}, y, z]$ the X variables have become *don't care variables*: their values do not affect the satisfiability of the problem and they have become *unobservable*. A survey of transformation techniques for avoiding this source of inefficiency is given in [Vel05].

2.2.3. Transformation from CNF to 3-CNF

3-CNF formulae have exactly three literals in each clause. These problems are interesting in their own right, and random 3-CNF problems have been extensively studied. However, any SAT problem can be transformed into 3-CNF. SAT is known to be NP-complete, so this transformation proves the completeness of 3-CNF, by showing that 3-CNF is as expressive as CNF.

A well-known transformation is as follows. Suppose we have a SAT instance with clauses c_1, \dots, c_m over variables u_1, \dots, u_n , where each clause c_i may contain any positive number of literals. This can be transformed to 3-CNF as follows. For a clause $c_i = (z_1 \vee \dots \vee z_k)$ there are four cases:

- ($k = 1$) Create two new variables $y_{i,1}, y_{i,2}$ and replace c_i by the clauses $(z_1 \vee y_{i,1} \vee y_{i,2})$, $(z_1 \vee \overline{y_{i,1}} \vee y_{i,2})$, $(z_1 \vee y_{i,1} \vee \overline{y_{i,2}})$ and $(z_1 \vee \overline{y_{i,1}} \vee \overline{y_{i,2}})$.
- ($k = 2$) Create one new variable $y_{i,1}$ and replace c_i by the clauses $(z_1 \vee z_2 \vee y_{i,1})$ and $(z_1 \vee z_2 \vee \overline{y_{i,1}})$.
- ($k = 3$) Leave clause c_i unchanged.
- ($k > 3$) Create new variables $y_{i,1}, y_{i,2}, \dots, y_{i,k-3}$ and replace c_i by the clauses $(z_1 \vee z_2 \vee y_{i,1})$, $(\overline{y_{i,1}} \vee z_3 \vee y_{i,2})$, $(\overline{y_{i,2}} \vee z_4 \vee y_{i,3})$, \dots , $(\overline{y_{i,k-3}} \vee z_{k-1} \vee z_k)$.

This transformation does not seem to have many practical applications, but it may be useful for generating 3-CNF benchmarks, or as a preprocessor for a specialised algorithm that only accepts 3-CNF problems.

2.2.4. Extensional constraints in CNF

One way of modelling a problem as SAT is first to model it as a constraint satisfaction problem (CSP), then to apply a standard encoding from CSP to SAT. A finite-domain CSP has variables $v_1 \dots v_n$ each with a finite domain $\text{dom}(v_i)$ of values, and constraints prescribing prohibited combinations of values (alternatively, constraints may prescribe *allowed* combinations of assignments). The problem is to find an assignment of values to all variables such that no constraint is violated. An example of a constraint is $(v_3 = 2, v_4 = 2)$ which prohibits the combination of assignments $v_3 = 2$ and $v_4 = 2$. This is a *binary* constraint because it contains only two variables, and a binary CSP contains only binary constraints.

The most natural and widely-used encoding from CSP to SAT is the *direct encoding* (also called the *sparse encoding*). A SAT variable $x_{v,i}$ is defined as true if and only if the CSP variable v has the domain value i assigned to it. The direct encoding consists of three sets of clauses. Each CSP variable must take at least one domain value, expressed by *at-least-one* clauses:

$$\bigvee_i x_{v,i}$$

No CSP variable can take more than one domain value, expressed by *at-most-one* clauses:

$$\overline{x_{v,i}} \vee \overline{x_{v,j}}$$

Conflicts are enumerated by *conflict* clauses:

$$\overline{x_{v,i}} \vee \overline{x_{w,j}}$$

An alternative to the direct encoding is the *support encoding* (defined only for binary CSPs) [Gen02, Kas90] in which conflict clauses are replaced by *support* clauses. Suppose that $S_{v,j,w}$ are the *supporting values* in $\text{dom}(v)$ for value $j \in \text{dom}(w)$: these are the values in $\text{dom}(w)$ that do not conflict with $w = j$. Then add a support clause

$$\overline{x_{w,j}} \vee \left(\bigvee_{i \in S_{v,j,w}} x_{v,i} \right)$$

A third alternative is the *log encoding*, first defined for Hamiltonian circuit, clique and colouring problems [IM94] and since used for other problems including planning [EMW97] and vertex colouring [VG07]. Its motivation is to exponentially reduce the number of SAT variables with respect to the direct encoding. Each CSP variable/domain value bit has a corresponding SAT variable, and each conflict has a corresponding clause prohibiting that combination of bits in the specified CSP variables. Define variables $x_{b,v}$ where $x_{b,v} = 1$ if and only if bit b of the domain value assigned to v is 1 (here we number the bits from 0 with the 0^{th} bit being least significant). For example to prohibit the combination $[p = 2, q = 1]$ where p, q have domains $\{0, 1, 2\}$ and therefore require two bits each, we must prohibit the combination $[\overline{x_{0,p}}, x_{1,p}, \overline{x_{0,q}}, x_{1,q}]$ by adding a conflict clause $(x_{0,p} \vee \overline{x_{1,p}} \vee x_{0,q} \vee \overline{x_{1,q}})$. No at-least-one or at-most-one clauses are required, but if the domain size of v is not a power of 2 then we must add clauses to prohibit combinations of bits representing non-domain values. For example here we must prevent the bit pattern $[x_{0,p}, x_{1,p}]$ representing $p = 3$ by adding a clause $\overline{x_{0,p}} \vee \overline{x_{1,p}}$, and similarly for q .

To illustrate the three encodings we use a simple graph colouring problem as an example, with two adjacent vertices v and w and three available colours $\{0, 1, 2\}$. Each vertex must take exactly one colour, but because they are adjacent they cannot take the same colour. This problem has six solutions: $[v = 0, w = 1]$, $[v = 0, w = 2]$, $[v = 1, w = 0]$, $[v = 1, w = 2]$, $[v = 2, w = 0]$ and $[v = 2, w = 1]$. The direct encoding of the problem contains at-least-one clauses

$$x_{v,0} \vee x_{v,1} \vee x_{v,2} \quad x_{w,0} \vee x_{w,1} \vee x_{w,2}$$

at-most-one clauses

$$\begin{array}{ccc} \overline{x_{v,0}} \vee \overline{x_{v,1}} & \overline{x_{v,0}} \vee \overline{x_{v,2}} & \overline{x_{v,1}} \vee \overline{x_{v,2}} \\ \overline{x_{w,0}} \vee \overline{x_{w,1}} & \overline{x_{w,0}} \vee \overline{x_{w,2}} & \overline{x_{w,1}} \vee \overline{x_{w,2}} \end{array}$$

and conflict clauses

$$\overline{x_{v,0}} \vee \overline{x_{w,0}} \quad \overline{x_{v,1}} \vee \overline{x_{w,1}} \quad \overline{x_{v,2}} \vee \overline{x_{w,2}}$$

The support encoding contains the same at-least-one and at-most-one clauses, plus support clauses

$$\begin{array}{ccc} x_{v,1} \vee x_{v,2} \vee \overline{x_{w,0}} & x_{v,0} \vee x_{v,2} \vee \overline{x_{w,1}} & x_{v,0} \vee x_{v,1} \vee \overline{x_{w,2}} \\ x_{w,1} \vee x_{w,2} \vee \overline{x_{v,0}} & x_{w,0} \vee x_{w,2} \vee \overline{x_{v,1}} & x_{w,0} \vee x_{w,1} \vee \overline{x_{v,2}} \end{array}$$

The log encoding contains only conflict clauses

$$\begin{array}{c} x_{v,0} \vee x_{v,1} \vee x_{w,0} \vee x_{w,1} \\ \overline{x_{v,0}} \vee \overline{x_{v,1}} \vee \overline{x_{w,0}} \vee \overline{x_{w,1}} \\ x_{w,0} \vee \overline{x_{w,1}} \vee x_{w,0} \vee \overline{x_{w,1}} \end{array}$$

and *prohibited value clauses* to forbid non-domain values

$$\overline{x_{v,0}} \vee \overline{x_{v,1}} \qquad \overline{x_{w,0}} \vee \overline{x_{w,1}}$$

There are also further encodings. *Hierarchical encodings* recursively subdivide domains [Vel07], and *representative-sparse encoding* [BHN14] are based on hierarchical and direct encodings. A hybrid of the log and support encodings called the *log support encoding* was devised by [Gav07]. Variables and prohibited value clauses as in the log encoding, and some of the conflict clauses are replaced by support clauses. A variant based on Gray codes was also proposed. The *binary transform* of [FP01] is a variant of the log encoding that avoids the use of prohibited value clauses. The direct encoding without at-most-one clauses is often used with SAT local search algorithms, and has been called the *multivalued encoding* [Pre04]. SAT solutions under this encoding represent *bundles* of solutions to the CSP, formed by taking the Cartesian product of the CSP domain values allowed in the SAT solution, and to extract a single solution we simply select any allowed value for each CSP variable. For binary CSPs the *maximal encoding* [Pre04] eliminates all but the maximal bundles (in which no additional domain values are allowed) by adding *maximality clauses* to the multivalued encoding:

$$x_{v,i} \vee \bigvee_{w,j} x_{w,j}$$

where w, j range over the assignments to other variables $w = j$ that conflict with $v = i$. The maximal encoding breaks a form of dominance between CSP solutions and can speed up all-solution search. On the above example the maximality clauses are:

$$x_{v,0} \vee x_{w,0} \qquad x_{v,1} \vee x_{w,1} \qquad x_{v,2} \vee x_{w,2}$$

For CSPs with integer linear constraints, a better alternative is the *order encoding* [AM04, CB94, TTKB09]. In this encoding a SAT variable $v_{x,a}$ represents a *primitive comparison* $x \leq a$ for integer variable x and upper bound a . Other comparisons (linear constraints) are transformed into primitive comparisons via a method described in [TTKB09], illustrated here by an example. For integer variables x, y, z each with domain $\{0, 1, 2, 3\}$ the comparison $x + y < z - 1$ becomes

$$\begin{array}{lll} v_{x,-1} \vee v_{y,-1} \vee \overline{v_{z,1}} & v_{x,-1} \vee v_{y,0} \vee \overline{v_{z,2}} & v_{x,-1} \vee v_{y,1} \vee \overline{v_{z,3}} \\ v_{x,0} \vee v_{y,-1} \vee \overline{v_{z,2}} & v_{x,0} \vee v_{y,0} \vee \overline{v_{z,3}} & v_{x,1} \vee v_{y,-1} \vee \overline{v_{z,3}} \end{array}$$

(Variables corresponding to non-existent domain values such as -1 can be eliminated.) The order relation is represented by *axiom clauses* of the form

$$\overline{v_{x,a}} \vee v_{x,a+1}$$

The order encoding was proved to transform a tractable CSP into a tractable SAT problem by [PJ11]. Improved variants were developed by [AS14] to handle problems with large domains, incorporating techniques from the log and support encodings, and Multi and Binary Decision Diagrams. The *compact order encoding* [TTB11] combines ideas from the order and log encodings, and the *representative-order encoding* [Ngu17] uses the order encoding in partitions of the variables, which are represented by selected variables.

2.2.5. Intensional constraints in CNF

Not all constraints are conveniently expressed extensionally by listing conflicts, and we may wish to SAT-encode constraints that are usually expressed intentionally. For example the *at-most-one* constraint states that at most one of a set of variables $x_1 \dots x_n$ can be true. We shall use this example to illustrate alternative encodings of an intensional constraint. The often-used *pairwise encoding* treats the constraint extensionally, and simply enumerates $O(n^2)$ at-most-one clauses:

$$\overline{x_i} \vee \overline{x_j}$$

where $i < j$. The *ladder encoding* described by [GN04] is more compact: define new variables $y_1 \dots y_{n-1}$ and add *ladder validity clauses*

$$\overline{y_{i+1}} \vee y_i$$

and *channelling clauses* expanded from

$$x_i \leftrightarrow (y_{i-1} \wedge \overline{y_i})$$

The ladder adds $O(n)$ new variables but only $O(n)$ clauses. The *binary encoding* was proposed by [FPDN05] and later by [Pre07a] who named it the *bitwise encoding* (we use the former name here). Define new Boolean variables b_k where $k = 1 \dots \lceil \log_2 n \rceil$. Add clauses

$$\overline{x_i} \vee b_k \quad [\text{or } \overline{b_k}]$$

if bit k of $i - 1$ is 1 [or 0]. This encoding has $O(\log n)$ new variables and $O(n \log n)$ binary clauses: more literals but fewer new variables than the ladder encoding. The pairwise encoding is acceptable for fairly small n , while for large n the ladder encoding gives good results with DPLL, and the binary encoding gives good results with local search algorithms. A *relaxed ladder encoding* defined in [Pre07a] also gave improved performance with local search. Further at-most-one encodings are surveyed in [NM15] and we briefly mention them here. In the *commander encoding* [KK07] the SAT variables are partitioned into subsets, each represented by a *commander variable* to reduce the number of clauses. The *product encoding* [Che10] is recursive and based on Cartesian products, and requires few clauses and variables. The *bimander encoding* [NM15] is based on the commander encoding but replaces the commander variables by variables from the binary encoding.

A useful generalisation of the at-most-one constraint is the *cardinality constraint*, which states that at most (or at least) k of a set of variables $x_1 \dots x_n$ can be true. This can be compactly SAT-encoded and a survey of such encodings was given by [MSL07], who also show that SAT solver performance on such encodings can be improved by effectively ignoring the auxiliary variables that they introduce. [BB03a] used a similar arithmetic-based method to that of [War98] for linear inequalities, but with a unary representation of integer variables to improve propagation. [Sin05] described two improved encodings: one smaller and based on a sequential counter, the other with better propagation and based on a parallel counter. [ANORC09, ANORC11b] based their encoding on sorting networks.

[CZI10] based a more compact encoding on a different type of sorting network. [OLH⁺13] used a different type of arithmetic network to obtain another compact encoding, which performed well on MaxSAT problems.

Integer linear inequalities (or *pseudo-Boolean constraints*) further generalise cardinality constraints and are of the form:

$$\sum_i w_i x_i \leq k$$

for some integer weights w_i (interpreting false as 0 and true as 1); the \leq relation may be replaced by $<$, \geq , $>$ or $=$. These constraints can be handled either directly by generalising SAT to linear pseudo-Boolean problems, or indirectly by finding SAT encodings. [War98] SAT-encoded hardware arithmetic circuits to model these constraints. [ES06] described three encoding methods based on Binary Decision Diagrams, arithmetic networks and sorting networks. [ANORC11a] used Binary Decision Diagrams to obtain an encoding with improved propagation.

Another intensional constraint is the *parity* constraint $(\bigoplus_{i=1}^n v_i) \leftrightarrow p$ which states that p is true if and only if there is an even number of true variables in the set $\{v_1, \dots, v_n\}$. This can be encoded simply by enumerating all possible combinations of v_i truth values, together with their parity p , but this creates exponentially many clauses and is only reasonable for small constraints. A more practical linear method due to [Li00] decomposes the constraint by introducing new variables f_j :

$$(v_1 \oplus f_1) \leftrightarrow p \quad (v_2 \oplus f_2) \leftrightarrow f_1 \quad \dots \quad (v_{n-3} \oplus f_{n-3}) \leftrightarrow f_{n-2} \quad v_n \leftrightarrow f_{n-1}$$

These binary and ternary constraints are then put into clausal form by enumerating cases, for example $(v_1 \oplus f_1) \leftrightarrow p$ becomes:

$$(\overline{v_1} \vee \overline{f_1} \vee p) \wedge (v_1 \vee \overline{f_1} \vee \overline{p}) \wedge (\overline{v_1} \vee f_1 \vee \overline{p}) \wedge (v_1 \vee f_1 \vee p)$$

A commander encoding-style hybrid of the enumeration and linear methods was used in [Pre07b] to improve local search performance.

2.2.6. The DIMACS file format for CNF

A file format for SAT problems in CNF (as well as vertex colouring and clique problems) was devised in the DIMACS Challenge of 1993 [JT96], and has been followed ever since. (A format for general SAT was also proposed but does not appear to have been generally adopted.) Having a common file format has facilitated the collection of SAT benchmark problems in the SATLIB web site ¹, the Beijing challenges ² and the regular SAT solver competitions ³, which have stimulated a great deal of research into efficient algorithms and implementations. This is similar to the use of AMPL files for MIP problems, and file formats have also been introduced into Constraint Programming for solver competitions.

The format is as follows. At the start is a *preamble* containing information about the file. These optional comment lines begin with the letter “c”:

¹<http://www.cs.ubc.ca/~hoos/SATLIB/>

²<http://www.cirl.uoregon.edu/crawford/beijing>

³<http://www.satcompetition.org/>

c This is an example of a comment line.

Then a line of the form

p cnf variables clauses

states the number of Boolean variables and clauses in the file, where *variables* and *clauses* are positive integers and variables are numbered $1 \dots variables$. The rest of the file contains the clauses. Each clause is represented by a list of non-zero integers, followed by a zero which represents the end of the clause. The integers must be separated by spaces, tabs or newlines. A positive integer i represents a positive literal with variable number i , while a negative integer $-i$ represents a negative literal with variable number i . For example the line

1 5 -8 0

represents the clause $v_1 \vee v_5 \vee \overline{v_8}$. Clauses may run over more than one line, spaces and tabs may be inserted freely between integers, and both the order of literals in a clause and the order of clauses in the file are irrelevant.

2.3. Case studies

In this section we discuss concrete SAT models. We use simple problems to illustrate CSP-to-SAT encodings, alternative and non-obvious variable definitions, alternative combinations of clauses, the selective application of Tseitin encodings, the exploitation of subformula polarity, the use of implied and symmetry-breaking clauses, special modelling techniques for local search, and some common sources of error.

2.3.1. N-queens

We begin with an example of CSP-to-SAT modelling: the well-known n-queens problem. Consider a generalised chess board, which is a square divided into $n \times n$ smaller squares. The problem is to place n queens on it in such a way that no queen attacks any other. A queen *attacks* another if it is on the same row, column or diagonal (in which case both attack each other). How many ways are there to model this problem as a SAT problem? One or two models might spring to mind, but in a classic paper [Nad90] Nadel presents no fewer than nine constraint models (denoted by Q1–Q9), some representing families of models and one being isomorphic to a SAT problem. There are several ways of SAT-encoding a CSP, so we immediately have a rather large number of ways of modelling n-queens as SAT. We now discuss some of these ways, plus additional variants.

Nadel's model Q1 is perhaps the most obvious one. For each row define a variable with a finite domain of n values, denoting the column in which the queen on that row is placed. Add binary constraints to prevent attacks, by forbidding pairs of variables from taking values that place queens in the same column (the values are identical) or cause queens to attack along a diagonal (their absolute difference matches the absolute difference between the variable numbers). Row attacks are implicitly forbidden because each row variable takes exactly one value.

Model Q2 is very similar to Q1, but variables correspond to columns and values to rows. A direct encoding of Q1 or Q2 gives almost identical results, except for clauses ensuring that each row (Q1) or column (Q2) contains at least one queen. A further option is to use both sets of clauses, because in any n -queens solution there is a queen in each row and column. This is an example of adding implied clauses to a model: an implied clause is one that is implied by other clauses in the model, and therefore logically redundant. Implied clauses have been shown to speed up both backtracking [ABC⁺02] and local search [CI96, KD95].

Model Q6 is already a SAT model. For each board square (i, j) define a Boolean variable $v_{i,j}$, which is true if and only if a queen is placed on it. To prevent partially-filled boards (including the empty board) from being solutions add clauses

$$\bigvee_i v_{i,j}$$

to ensure that each row contains a queen; alternatively we could ensure that each column contains a queen; or both. To prevent attacks add a clause

$$(\overline{v_{i,j}} \vee \overline{v_{i',j'}})$$

for each distinct pair of squares $(i, j), (i', j')$ that are on the same row, column or diagonal and therefore attack each other. It is worth pointing out here that there is no point in adding multiple versions of the same clause, for example:

$$(\overline{v_{2,5}} \vee \overline{v_{3,6}}) \quad (\overline{v_{3,6}} \vee \overline{v_{2,5}})$$

This would occur if we only considered distinct attacking squares: $(i, j) \neq (i', j')$. Instead the attacking squares used in conflict clauses should satisfy $(i, j) \prec (i', j')$ for some total ordering \prec on squares; for example the lexicographical ordering $(i, j) \prec (i', j')$ if and only if (i) $i < i'$ or (ii) $i = i'$ and $j < j'$. This type of needless duplication is easy to commit when SAT-encoding. Model Q6 is almost identical to the direct encoding of Q1 or Q2, modulo details of whether we ensure no more than one queen per row, column or both.

Model Q5 is quite different. It associates a variable with each queen, and each variable has a domain ranging over the set of squares on the board. A direct encoding would define a Boolean variable $v_{q,i,j}$ for each queen q and each square (i, j) , which is true if and only if that queen is placed on that square. Add clauses to prevent two queens from being placed on the same square:

$$(\overline{v_{q,i,j}} \vee \overline{v_{q',i,j}})$$

for all pairs q, q' such that $q < q'$ (to avoid generating two equivalent versions of each clause). Add clauses to prevent attacks:

$$(\overline{v_{q,i,j}} \vee \overline{v_{q',i',j'}})$$

for each pair of queens $q < q'$ and each distinct pair of attacking squares $(i, j) \neq (i', j')$. Alternatively we could enumerate each distinct pair of queens $q \neq q'$ and each pair of attacking squares such that $(i, j) \prec (i', j')$. However, it would be incorrect to enforce both $q < q'$ and $(i, j) \prec (i', j')$ because this would (for

example) prevent the attacking configuration of queen 1 at (1,1) and queen 2 at (2,2), but it would not prevent the attacking configuration of queen 2 at (1,1) and queen 1 at (2,2). Great care must be taken with these issues when SAT-encoding.

A possible drawback with Q5 is that it contains a great deal of symmetry: every solution has $n!$ SAT models because the queens can be permuted. To eliminate this symmetry we can add further clauses, for example by forcing queens to be placed in squares with increasing indices:

$$(\overline{v_{q,i,j}} \vee \overline{v_{q',i',j'}})$$

where $q > q'$ and $(i, j) < (i', j')$. N-queens itself also has 8 symmetries: any solution can be reflected 2 times and rotated 4 times. To break these symmetries and thus reduce the size of the search space we may add further clauses, but we shall not consider these details.

Nor shall we consider Nadel's other constraint models, two of which define a variable for each upward or downward diagonal instead of each row or column: these again lead to SAT-encodings similar to Q6. But there are other ways of encoding the attack constraints. For example, suppose we define the Boolean variables $v_{i,j}$ of Q6. We must ensure that at most one queen is placed on any given row, column or diagonal, which in Q6 was achieved by enumerating all possible pairs of attacking queens. This is the pairwise encoding of the at-most-one constraint, but instead we could use a more compact encoding such as the ladder encoding. Another possibility is to model support instead of conflict in model Q1, replacing several conflict clauses

$$\overline{v_{i,j}} \vee \overline{v_{i',j'}}$$

by a clause

$$\overline{v_{i,j}} \vee \left(\bigvee_{j' \in C_{i,j,i'}} v_{i,j'} \right)$$

where $C_{i,j,i'}$ is the set of columns whose squares on row i' are not attacked by a queen at (i, j) . This clause states that if a queen is placed on square (i, j) then the queen on row j' must be placed on a non-attacking column: note that its correctness depends on clauses ensuring that exactly one queen can be placed in any row. This model corresponds to a support encoding of Q1. We could also exchange the roles of rows and columns to obtain a support encoding of Q2, or use conflict or support clauses from Q1 and Q2 to obtain hybrid models.

The n-queens problem illustrates the approach of first modelling a problem as a CSP, then SAT-encoding the CSP. It shows that, even for a very simple problem, there may be a choice of problem features to encode as variables. Even after making this fundamental choice there may be alternative sets of clauses giving a logically correct model. It provides examples of implied clauses and symmetry breaking clauses. It also illustrates that care must be taken to avoid accidentally excluding solutions by adding too many clauses.

2.3.2. All-interval series

For our next example we take the all-interval series (AIS) problem, an arithmetic problem first used by Hoos [Hoo98] to evaluate local search algorithms, and in-

spired by a problem occurring in serial musical composition. There is a constructive solution to the AIS problem that requires no search so it is inherently easy. However, the easily-found solution is highly regular and other solutions might be more interesting to musicians. The problem is to find a permutation of the numbers $\{0, \dots, n - 1\}$ such that the set of differences between consecutive numbers contains no repeats. For example, a solution for $n = 11$ (taken from [GMS03]) with differences written underneath the numbers is:

$$\begin{array}{cccccccccccc} 0 & 10 & 1 & 9 & 2 & 8 & 3 & 7 & 4 & 6 & 5 \\ & 10 & 9 & 8 & 7 & 6 & 5 & 4 & 3 & 2 & 1 \end{array}$$

First define Boolean variables $s_{i,j}$ each of which is true if and only if the i^{th} number is the integer j . AIS is a sequence of integers so each number takes exactly one value:

$$\left(\bigvee_i s_{i,j} \right) \wedge (\overline{s_{i,j}} \vee \overline{s_{i,j'}})$$

We may model differences as follows: if the formula

$$\bigvee_j (s_{i,j} \wedge s_{i+1,j \pm k})$$

is true then the difference between numbers i and $i + 1$ is k , so we can enforce distinct differences by the formula:

$$\overline{\bigvee_j (s_{i,j} \wedge s_{i+1,j \pm k})} \vee \overline{\bigvee_j (s_{i',j} \wedge s_{i'+1,j \pm k})}$$

for distinct i, i' and relevant k values. (The meaning of $j \pm k$ here is that clauses should be generated using both $j + k$ and $j - k$, wherever the resulting numbers are within the range of the second index of the s variable.) A CNF encoding of this formula may be obtained by expansion, giving a set of quaternary clauses of the form

$$\overline{s_{i_1,j_1}} \vee \overline{s_{i_2,j_2}} \vee \overline{s_{i_3,j_3}} \vee \overline{s_{i_4,j_4}}$$

Alternatively, we may introduce Tseitin variable definitions

$$d_{i,k} \leftrightarrow \left[\bigvee_j (s_{i,j} \wedge s_{i+1,j \pm k}) \right]$$

which means that $d_{i,k}$ is true if and only if the difference between numbers i and $i + 1$ is k . We then replace the difference formulae by clauses

$$\overline{d_{i,k}} \vee \overline{d_{i',k}}$$

and CNF-encode the $d_{i,k}$ definitions. However, we can be more compact than the Tseitin method here. It was noted in [PG86] that only clauses corresponding to positive [negative] implications are logically necessary when transforming a subformula with negative [positive] *polarity*. The polarity of a subformula is

positive [negative] if it only occurs under an even [odd] number of negations. In this case each subformula

$$\bigvee_j (s_{i,j} \wedge s_{i+1,j \pm k})$$

only occurs negatively, so we only need clauses derived from the implication

$$d_{i,k} \leftarrow \left[\bigvee_j (s_{i,j} \wedge s_{i+1,j \pm k}) \right]$$

yielding clauses of the form

$$\overline{s_{i,j}} \vee \overline{s_{i+1,j \pm k}} \vee d_{i,k}$$

This is convenient, as the \rightarrow implication would require either a larger expansion or more auxiliary variables.

To this encoding may be added several families of implied clauses. The $s_{i,j}$ variables encode a permutation of the integers $0 \dots n$ so each integer occurs at most once:

$$\overline{s_{i,j}} \vee \overline{s_{i',j}}$$

The d variables encode a sequence of differences:

$$\bigvee_i d_{i,k}$$

and

$$\overline{d_{i,j}} \vee \overline{d_{i,j'}}$$

These differences form a permutation of the numbers $1 \dots n$:

$$\overline{d_{i,j}} \vee \overline{d_{i',j}}$$

We have now arrived at Hoos's original AIS encoding [Hoo98]. A further study of AIS encodings was presented by [ABC⁺02]. They experimented with omitting the at-most-one clauses

$$\overline{s_{i,j}} \vee \overline{s_{i,j'}}$$

and

$$\overline{d_{i,k}} \vee \overline{d_{i,k'}}$$

which is safe because of the clauses ensuring that the two sets of variables encode permutations. Thus they treated the at-most-one clauses as implied clauses, and also introduced a less-obvious set of implied clauses:

$$\overline{d_{i,k}} \vee s_{i-1,m} \wedge \overline{d_{i,k}} \vee s_{i,m}$$

where $k > n/2$ (n is assumed to be even) and $n - k \leq m \leq k - 1$. In experiments with local search algorithms, different combinations of these implied clauses had either very good or very bad effects on performance, showing the unpredictable computational effects of implied clauses.

As pointed out by Gent et al. [GMS03] the AIS problem contains symmetry, which can be broken by adding further clauses. An AIS sequence may be reversed to give another sequence, so we may add clauses

$$\overline{s_{0,j}} \vee \overline{s_{1,j'}}$$

where $j' < j$ forcing the second number to be greater than the first. We may also subtract each value from $n - 1$ to obtain another sequence so we can add clauses to ensure that the first value is no greater than $n/2$:

$$\overline{s_{0,j}}$$

where $j \leq n/2$. Gent et al. also use a clever technique to boost the performance of a constraint solver by a factor of 50. They point out a *conditional symmetry* of AIS, which is a symmetry that occurs during search when a subset of the variables have been assigned values. Breaking the conditional symmetry is not easy in the original AIS model, but they generalise AIS to a new problem containing additional symmetry (rotation of sequence values) that can easily be broken, which incidentally also breaks the symmetry and conditional symmetry in AIS.

The AIS example illustrates the unpredictable but potentially beneficial effects of adding implied clauses, the selective use of Tseitin variables, the exploitation of subformula polarity to reduce the size of the encoding, the use of non-obvious implied clauses, and the possibility of better models that might be found by ingenuity.

2.3.3. Stable marriages

In the above examples there was nothing very surprising about the variable definitions themselves: they mostly corresponded to assignments of constraint variables to domain values. In our next example, taken from a study by Gent et al. [GIM⁺01], the variable definitions are less obvious. In the stable marriage problem we have n men and n women. Each man ranks the women in order of preference, and women similarly rank men. The problem is to marry men and women in a *stable* way, meaning that there is no incentive for any two individuals to elope and marry each other. In the version of the problem considered, incomplete preference lists are allowed, so that a man [woman] might be unacceptable to some women [men]. A person is willing to leave his/her current partner for a new partner only if he/she is either unmatched or considers the new partner better than the current partner. A pair who mutually prefer each other are a blocking pair, and a matching without blocking pairs is stable. The problem of finding a stable matching is not NP-complete but an extended version allowing preference ties is, and can be modelled in a similar way; here we discuss only the simpler problem.

A direct encoding of Gent et al.'s first constraint model would contain a Boolean variable for each man-woman pair, which is true when they are matched. However, they also present a second model that is more compact and already in SAT form. They define a variable $x_{i,p}$ to be true if and only if man i is either unmatched or matched to the woman in position p or later in his preference

list, where $1 \leq p \leq L_{m,i}$ and $L_{m,i}$ is the length of his list. They also define $x_{i,L_{m,i}+1}$ which is true if and only if man i is unmatched. Similarly they define variables $y_{j,q}$ for each woman j . Note that each SAT variable corresponds to a set of possibilities, unlike those in our previous examples; also that marriages are modelled indirectly via the preference lists.

The clauses are as follows. Each man or woman is either matched with someone in their preference list or is unmatched, which is enforced by the unit clauses

$$x_{i,1} \wedge y_{j,1}$$

If a man gets his p^{th} choice then he certainly gets his $p+1^{\text{th}}$ choice:

$$\overline{x_{i,p}} \vee x_{i,p+1}$$

Similarly for women:

$$\overline{y_{j,q}} \vee y_{j,q+1}$$

The x and y variables must be linked so that if man i is matched to woman j then woman j is also matched to man i . We can express the fact that man i is matched to the woman in position p in his preference list indirectly by the assignments $[x_{i,p}, \overline{x_{i,p+1}}]$ so the clauses are:

$$(\overline{x_{i,p}} \vee x_{i,p+1} \vee y_{j,q}) \wedge (\overline{x_{i,p}} \vee x_{i,p+1} \vee \overline{y_{j,q+1}})$$

where p is the rank of woman j in the preference list of man i , and q is the rank of man i in the preference list of woman j . Similarly:

$$(\overline{y_{j,q}} \vee y_{j,q+1} \vee x_{i,p}) \wedge (\overline{y_{j,q}} \vee y_{j,q+1} \vee \overline{x_{i,p+1}})$$

Stability is enforced by clauses stating that if man i is matched to a woman he ranks below woman j then woman j must be matched to a man she ranks no lower than man i :

$$\overline{x_{i,p}} \vee \overline{y_{j,q+1}}$$

where the man finds the woman acceptable (mentioned in the preference list). Similarly:

$$\overline{y_{j,q}} \vee \overline{x_{i,p+1}}$$

This problem provides a nice illustration of the use of non-obvious variable definitions.

Here it is worth pointing out another common source of error in SAT encoding: omitting common-sense axioms. The meaning of variable $x_{i,p}$ being true is that man i is matched to the woman in position p or later in his list. This must of course be explicitly stated in the SAT encoding via clauses $\overline{x_{i,p}} \vee x_{i,p+1}$. In the same way, if we are trying to construct a tree, a DAG or some other data structure then we must include axioms for those structures. However, in some cases these axioms are implied by other clauses. For example, if we are trying to construct a permutation of n numbers with some property then we would normally use at-least-one and at-most-one clauses, because the permutation is a list of length n with each position containing exactly one number. But if we add clauses stating that no two positions contain the same number then the at-most-one clauses become redundant.

2.3.4. Modelling for local search

So far we have largely ignored an important aspect of SAT modelling: the search algorithm that will be applied to the model. It is not immediately clear that the choice of algorithm should affect the choice of model, but it has been found that local search sometimes requires different models than DPPL if it is to be used effectively. This may partly explain the relatively poor performance of local search algorithms on industrial problems in the regular SAT solver competitions: they were perhaps modelled with DPPL in mind. [Pre02] showed that two particularly hard problems for local search can be solved by remodelling. Here we briefly summarise the SAT modeling techniques that were used.

A problem that makes heavy use of parity constraints is *minimal disagreement parity learning* described in [CKS94]. DPPL (and extended versions) on standard encodings is much more successful than local search on this problem. The explanation seems to be that standard encodings use a similar structure to the linear encoding of the parity constraint described in Section 2.2.5, which is very compact but creates a long chain of variable dependencies. These are known to slow down local search [KMS97], and when they form long chains they may cause local search to take polynomial or even exponential time to propagate truth assignments [Pre02, WS02]. A key to solving large parity learning instances by local search turns out to be a different encoding of the parity constraint [Pre02]. Decompose a large parity constraint $\bigoplus_{i=1}^n v_i = p$ into $\beta + 1$ smaller ones:

$$\bigoplus_{i=1}^{\alpha} v_i \equiv p_1 \quad \bigoplus_{i=\alpha+1}^{2\alpha} v_i \equiv p_2 \quad \dots \quad \bigoplus_{i=n-\alpha+1}^n v_i \equiv p_{\beta} \quad \text{and} \quad \bigoplus_{i=1}^{\beta} p_i \equiv p$$

where p_1, \dots, p_{β} are new variables and $n = \alpha \times \beta$ (in experiments $\beta \approx 10$ gave the best results). Now expand these small parity constraints into clauses. This exponentially increases the number of clauses in the model yet greatly boosts local search performance, allowing a standard local search algorithm to solve the notorious 32-bit instances of [CKS94]. This was previously achieved only by using an enhanced local search algorithm that exploited an analysis of the problem [PTS07]. Note that a similar result could be obtained by eliminating some of the variables in the linear encoding, thus a promising modelling technique for local search is to collapse chains of dependency by selective variable elimination.

Another hard problem for local search is the well-known Towers of Hanoi expressed as a STRIPS planning problem (see elsewhere in this book for background on modelling planning problems as SAT). Towers of Hanoi consists of P pegs (or towers) and D disks of different sizes; usually $P = 3$. All D disks are initially on the first peg. A solution is a sequence of moves that transfers all disks to the third peg with the help of the second peg so that (i) only one disk can be moved at a time; (ii) only the disk on top can be moved; (iii) no disk can be put onto a smaller disk. There always exists a plan with $2^D - 1$ steps. No SAT local search algorithm previously solved the problems with 5 and 6 disks in a reasonable time and 4 disks required a specially-designed algorithm, while DPPL algorithms can solve the 6-disk problem. However, 6 disks can be solved quite quickly by local search after remodelling the problem [Pre02]. Firstly, a more compact STRIPS

model was designed, which allowed a standard local search algorithm to solve 4 disks (it also improved DPLL performance and is not relevant here). Secondly, parallel plans were allowed, but not enforced, so that instead of a single serial plan there are a choice of many plans with varying degrees of parallelism. This increases the solution density of the SAT problem and allowed local search to solve 5 disks. Thirdly, implied clauses were added to logically connect variables that were otherwise linked only by chains of dependency. This is another way of reducing the effects of such chains on local search, and was first described in [WS02] for an artificial SAT problem. In planning-as-SAT the state at time t is directly related to the state at time $t + 1$ but not to states at more distant times, via (for example) frame axioms which in *explanatory* form are:

$$\tau_{p,t} \wedge \overline{\tau_{p,t+1}} \rightarrow \left(\bigvee_a \alpha_{a,t} \right)$$

where a ranges over the set of actions with delete effect p . This axiom states that if property p is true at time t but false at time $t + 1$ then at least one action must have occurred at time t to delete property p . (Similar axioms are added for properties that are true at time t but false at time $t + 1$.) These axioms create chains of dependency between the τ variables, which can be “short-circuited” by a generalisation of the frame axioms that connect states at arbitrary times:

$$\tau_{pt} \wedge \overline{\tau_{p,t'}} \rightarrow \left[\bigvee_{t'=t}^{t'-1} \left(\bigvee_a \alpha_{a,t'} \right) \right]$$

where $t' > t$. Interestingly, and somewhat mysteriously, in both applications optimal performance was obtained by adding only a small, randomly-chosen subset of these *long-range dependencies*.

In summary, two encoding properties that seem to make a problem hard for local search are: (i) low solution density, which can sometimes be artificially increased by remodelling the problem; and (ii) the presence of chains of dependent variables, which can either be (a) collapsed by variable elimination or (b) short-circuited by adding long-range dependencies. However, these techniques have an erratic and sometimes very bad effect on DPLL performance [Pre02].

2.4. Desirable properties of CNF encodings

What features of a CNF encoding make it better than another? In this section we discuss features that have been proposed as desirable.

2.4.1. Encoding size

By the *size* of an encoding we may mean the number of its clauses, literals or variables. Firstly, consider the number of clauses. As noted above, this can be reduced by introducing new variables as in the Tseitin encodings, possibly transforming an intractably large encoding into a manageable one. However,

the resulting encoding is not always the best in practice. For example [BM00] describes an encoding of a round robin tournament scheduling problem with n teams that has $O(n^6)$ clauses, which gave much better results than a considerably more compact encoding with auxiliary variables and only $O(n^4)$ clauses. Moreover, adding implied clauses [ABC⁺02, CI96, KD95], symmetry breaking clauses [CGLR96] and blocked clauses [Kul99] can greatly improve performance.

Secondly, the total number of literals in an encoding, computed by summing the clause lengths, also has a strong effect on runtime overheads (though this is reduced by the implementation technique of watched literals). As a measure of the memory used by an encoding it is more accurate than the number of clauses. However, the same examples show that minimising this measure of size does not necessarily give the best results. Moreover, the CSP support encoding has given superior results to the direct encoding, despite typically containing more literals.

Thirdly, consider the number of variables in an encoding. Several papers have analysed the worst- or average-case runtime of SAT algorithms in terms of the number of variables in the formula (for example [Sch99]), so it seems worthwhile to minimise the number of variables. However, a counter-example is the log encoding and its variants, which generally give poor performance both with DPLL [FP01, VG07] and local search algorithms [EMW97, Hoo98]. There may also be modelling reasons for not minimising the number of variables: Gent & Lynce [GL05] describe a SAT-encoding of the Social Golfer problem that contains several times more variables than necessary, which was found to be more convenient for expressing the problem constraints.

In practice, reducing the size of an encoding is no guarantee of performance, no matter how it is measured. Nevertheless, small encodings are worth aiming for because computational results can be very unpredictable, and all else being equal a smaller encoding is preferable.

2.4.2. Consistency properties

DPLL uses unit propagation extensively, and it is interesting to ask what type of consistency reasoning is achieved by unit propagation on a given encoding. The support encoding [Gen02, Kas90] for binary CSPs has the property that unit propagation maintains arc consistency, whereas the direct encoding maintains a weaker form of consistency called forward checking [Wal00], and the log encoding maintains a weaker form still [Wal00]. The encodings of [BHW03] generalise the support encoding to higher forms of consistency, and those of [Bac07] achieve global arc consistency for arbitrary constraints. The cardinality constraint SAT-encoding of [BB03b] has the property that unit propagation maintains generalised arc consistency. Implementing consistency in this way is much easier than directly implementing filtering algorithms, especially if we want to interleave them or combine them with techniques such as backjumping and learning [Bac07].

The strength of consistency achieved by unit propagation is reflected in DPLL performance on many problems. Despite the indirect nature of this implementation technique, in some cases it even outperforms specialised constraint solvers [QW07]. However, it is well-known in Constraint Programming that stronger consistency is not always worth achieving because of its additional overheads, and

[BHW03] report similar findings with some of their encodings. The same is true of implied clauses, symmetry breaking clauses and blocked clauses: adding them can greatly boost the power of unit propagation, but can also have unpredictable effects on performance (see [Pre03b] and the example discussed in Section 2.3.2).

2.4.3. Solution density

Another interesting property of an encoding is its solution density, which can be defined as the number of solutions divided by 2^n where n is the number of SAT variables. The multivalued CSP encoding mentioned in Section 2.2.4 increases solution density and is often used with local search. The idea that higher solution density makes a problem easier to solve seems natural, and is usually assumed to have at least some effect on search performance [CFG⁺96, CB94, HHI03, Par97, SGS00, Yok97]. It was pointed out by Clark et al. [CFG⁺96] that one might expect a search algorithm to solve a (satisfiable) problem more quickly if it has higher solution density. In detailed experiments on random problems across solvability phase transitions they did find a correlation between local and backtrack search performance and the number of solutions, though not a simple one. Problem features other than solution density also seem to affect search cost, for example Yokoo [Yok97] showed that adding more constraints to take a random problem beyond the phase transition removes local minima, making them easier for local search algorithms to solve despite removing solutions.

An obvious counter-example to the notion that higher density problems are easier is the CSP log encoding [IM94]. This has only a logarithmic number of variables in the CSP domain sizes, therefore a much higher SAT solution density than the direct encoding for any given CSP. Yet it generally performs poorly with both DPLL and local search algorithms. However, the binary transform of [FP01] is of similar form to the log encoding but with even higher solution density, and gives better results with local search (at least in terms of local search moves) [Pre03a]. It is possible to modify the direct encoding to increase its solution density, but this gives very erratic results [Pre03a].

2.4.4. Summary

It seems that no single feature of an encoding can be used to characterise how good it is. To further confuse the issue, it turns out that a good encoding for one algorithm might be a poor encoding for another algorithm. This was found with the modified models for parity learning and Towers of Hanoi in Section 2.3.4: standard encodings of these problems are hard for local search but can be solved by DPLL, while modified encodings boost local search but can have drastic effects on DPLL performance. Similarly, in Section 2.2.5 different encodings of the at-most-one constraint were found to be better for DPLL and local search. There is also evidence that adding clauses to break symmetry makes a problem harder to solve by local search but easier by DPLL [Pre03b]. Finally, new variables introduced by Tseitin encoding are *dependent* on others, and as mentioned in Section 2.3.4 these are known to slow down local search [KMS97, Pre02, WS02]. Thus the standard Tseitin approach might be inappropriate when combined with local search. However, it does not necessarily harm DPLL performance, because

the selection of these variables for branching can be delayed until unit propagation eliminates them — though this assumes a measure of control over the branching heuristic.

2.5. Conclusion

There are usually many ways to model a given problem in CNF, and few guidelines are known for choosing among them. There is often a choice of problem features to model as variables, and some might take considerable thought to discover. Tseitin encodings are compact and mechanisable but in practice do not always lead to the best model, and some subformulae might be better expanded. Some clauses may be omitted by polarity considerations, and implied, symmetry breaking or blocked clauses may be added. Different encodings may have different advantages and disadvantages such as size or solution density, and what is an advantage for one SAT solver might be a disadvantage for another. In short, CNF modelling is an art and we must often proceed by intuition and experimentation. But enumerating known techniques and results, as we have done in this chapter, helps to clarify the alternatives.

Chapter 3

Complete Algorithms

Adnan Darwiche and Knot Pipatsrisawat

3.1. Introduction

This chapter is concerned with sound and complete algorithms for testing satisfiability, i.e., algorithms that are guaranteed to terminate with a correct decision on the satisfiability/unsatisfiability of the given CNF. One can distinguish between a few approaches on which complete satisfiability algorithms have been based. The first approach is based on existential quantification, where one successively eliminates variables from the CNF without changing the status of its satisfiability. When all variables have been eliminated, the satisfiability test is then reduced into a simple test on a trivial CNF. The second approach appeals to sound and complete inference rules, applying them successively until either a contradiction is found (unsatisfiable CNF) or until the CNF is closed under these rules without finding a contradiction (satisfiable CNF). The third approach is based on systematic search in the space of truth assignments, and is marked by its modest space requirements. The last approach we will discuss is based on combining search and inference, leading to algorithms that currently underly most modern complete SAT solvers.

We start in the next section by establishing some technical preliminaries that will be used throughout the chapter. We will follow by a treatment of algorithms that are based on existential quantification in Section 3.3 and then algorithms based on inference rules in Section 3.4. Algorithms based on search are treated in Section 3.5, while those based on the combination of search and inference are treated in Section 3.6. Note that some of the algorithms presented here could fall into more than one class, depending on the viewpoint used. Hence, the classification presented in Sections 3.3-3.6 is only one of the many possibilities.

3.2. Technical Preliminaries

A *clause* is a disjunction of literals over distinct variables.¹ A propositional sentence is in *conjunctive normal form (CNF)* if it has the form $\alpha_1 \wedge \alpha_2 \wedge \dots \wedge \alpha_n$, where each α_i is a clause. For example, the sentence

¹The insistence that all literals in a clause be over distinct variables is not standard.

$$(A \vee B \vee \neg C) \wedge (\neg A \vee D) \wedge (B \vee C \vee D)$$

is in conjunctive normal form and contains three clauses. Note that according to our definition, a clause cannot contain the literals P and $\neg P$ simultaneously. Hence, a clause can never be valid. Note also that a clause with no literals, the *empty clause*, is inconsistent. Furthermore, a CNF with no clauses is valid.

A convenient way to notate sentences in CNF is using sets. Specifically, a clause $l_1 \vee l_2 \vee \dots \vee l_m$ is expressed as a set of literals $\{l_1, l_2, \dots, l_m\}$. Moreover, a conjunctive normal form $\alpha_1 \wedge \alpha_2 \wedge \dots \wedge \alpha_n$ is expressed as a set of clauses $\{\alpha_1, \alpha_2, \dots, \alpha_n\}$. For example, the CNF given above would be expressed as:

$$\{ \{A, B, \neg C\}, \{\neg A, D\}, \{B, C, D\} \}.$$

This set-based notation will prove very helpful when expressing algorithms that operate on CNFs.

Given our notational conventions, a CNF Δ is valid if Δ is the empty set: $\Delta = \emptyset$. Moreover, a CNF Δ is inconsistent if Δ contains the empty set: $\emptyset \in \Delta$. These two cases correspond to common boundary conditions that arise in recursive algorithms on CNFs.

In general, a formula Δ is said to *imply* another formula Γ , denoted $\Delta \models \Gamma$, iff every assignment that satisfies Δ also satisfies Γ . Note that if a clause C_i is a subset of another clause C_j , $C_i \subseteq C_j$, then $C_i \models C_j$. We say in this case that clause C_i *subsumes* clause C_j , as there is no need to have clause C_j in a CNF that also contains clause C_i . One important fact that we will base our future discussions on is that if a CNF formula implies the empty clause, the formula is essentially unsatisfiable.

3.2.1. Resolution

One of the simplest complete algorithms for testing satisfiability is based on the *resolution* inference rule [Rob65], which is defined as follows. Let P be a Boolean variable, and suppose that Δ is a CNF which contains clauses C_i and C_j , where $P \in C_i$ and $\neg P \in C_j$. The resolution inference rule allows us to derive the clause $(C_i - \{P\}) \cup (C_j - \{\neg P\})$, which is called a *resolvent* that is obtained by *resolving* C_i and C_j . The resolvent of a resolution is a clause implied by the resolved clauses. For example, we can resolve clause $\{A, B, \neg C\}$ with clause $\{\neg B, D\}$ to obtain the resolvent $\{A, \neg C, D\}$. We will say here that $\{A, \neg C, D\}$ is a *B-resolvent* as it results from resolving two clauses on the literals B and $\neg B$. Note that if we can use resolution to derive the empty clause from any formula, it means that the formula implies the empty clause, and, thus, is unsatisfiable.

Resolution is sound but is incomplete in the sense that it is not guaranteed to derive every clause that is implied by the given CNF. However, resolution is *refutation complete* on CNFs, i.e., it is guaranteed to derive the empty clause if the given CNF is unsatisfiable. This result is the basis for using resolution as a complete algorithm for testing satisfiability: we keep applying resolution until either the empty clause is derived (unsatisfiable CNF) or until no more applications of resolution are possible (satisfiable CNF).

Consider now the following resolution trace.

1. $\{\neg P, R\}$
2. $\{\neg Q, R\}$
3. $\{\neg R\}$
4. $\{P, Q\}$

-
5. $\{\neg P\}$ 1, 3
 6. $\{\neg Q\}$ 2, 3
 7. $\{Q\}$ 4, 5
 8. $\{\}$ 6, 7

The clauses before the line represent initial clauses, while clauses below the line represent resolvents, together with the identifiers of clauses used to obtain them. The above resolution trace shows that we can derive the empty clause from the initial set of Clauses (1–4). Hence, the original clauses, together, are unsatisfiable.

An important special case of resolution is called unit resolution. *Unit resolution* is a resolution strategy which requires that at least one of the resolved clauses has only one literal. Such clause is called a *unit clause*. Unit resolution is not refutation complete, which means that it may not derive the empty clause from an unsatisfiable CNF formula. Yet one can apply all possible unit resolution steps in time linear in the size of given CNF. Because of its efficiency, unit resolution is a key technique employed by a number of algorithms that we shall discuss later.

3.2.2. Conditioning

A number of algorithms that we shall define on CNFs make use of the *conditioning* operation. The process of conditioning a CNF Δ on a literal L amounts to replacing every occurrence of literal L by the constant **true**, replacing $\neg L$ by the constant **false**, and simplifying accordingly. The result of conditioning Δ on L will be denoted by $\Delta|L$ and can be described succinctly as follows:

$$\Delta|L = \{\alpha - \{\neg L\} \mid \alpha \in \Delta, L \notin \alpha\}.$$

To further explain this statement, note that the clauses in Δ can be partitioned into three sets:

1. The set of clauses α containing the literal L . Since we are replacing L by **true**, any clause that mentions L becomes satisfied and can be removed from the formula. As a result, these clauses do not appear in $\Delta|L$.
2. The set of clauses α containing the literal $\neg L$. Since we are replacing $\neg L$ by **false**, the occurrences of $\neg L$ in these clauses no longer have any effect. Therefore, these clauses appear in $\Delta|L$ with the literal $\neg L$ removed.
3. The set of clauses α that contain neither L nor $\neg L$. These clauses appear in $\Delta|L$ without change.

For example, if

$$\Delta = \{ \{A, B, \neg C\}, \{\neg A, D\}, \{B, C, D\} \},$$

then

$$\Delta|C = \{ \{A, B\}, \{\neg A, D\} \},$$

and

$$\Delta|\neg C = \{ \{\neg A, D\}, \{B, D\} \}.$$

The definition of conditioning can be extended to multiple literals in the obvious way. For example, $\Delta|CA\neg D = \{\emptyset\}$ (an inconsistent CNF). Moreover, $\Delta|\neg CD = \emptyset$ (a valid CNF).

3.3. Satisfiability by Existential Quantification

We will now discuss a class of complete algorithms which is based on the concept of *existential quantification*. The result of existentially quantifying variable P from a formula Δ is denoted by $\exists P \Delta$ and defined as follows:

$$\exists P \Delta \stackrel{\text{def}}{=} (\Delta|P) \vee (\Delta|\neg P).$$

Consider for example the CNF:

$$\Delta = \{ \{\neg A, B\}, \{\neg B, C\} \},$$

which effectively says that A implies B and B implies C . We then have $\Delta|B = \{\{C\}\}$, $\Delta|\neg B = \{\{\neg A\}\}$ and, hence, $\exists B \Delta = \{\{\neg A, C\}\}$ (i.e., A implies C).

Existential quantification satisfies a number of properties, but the most relevant for our purposes here is this: Δ is satisfiable if and only if $\exists P \Delta$ is satisfiable. Hence, one can replace a satisfiability test on Δ by another satisfiability test on $\exists P \Delta$, which has one fewer variable than Δ (if Δ mentions P). One can therefore existentially quantify all variables in the CNF Δ , one at a time, until we are left with a trivial CNF that contains no variables. This trivial CNF must therefore be either $\{\emptyset\}$, which is unsatisfiable, or $\{\}$, which is valid and, hence, satisfiable.

The above approach for testing satisfiability can be implemented in different ways, depending on how existential quantification is implemented. We will next discuss two such implementations, the first one leading to what is known as the Davis-Putnam algorithm (DP), and the second one leading to what is known as symbolic SAT solving.

3.3.1. The DP Algorithm

The DP algorithm [DP60] for testing satisfiability is based on the following observation. Suppose that Δ is a CNF, and let Γ be another CNF which results from adding to Δ all P -resolvents, and then throwing out all clauses that mention P

(hence, Γ does not mention variable P). It follows in this case that Γ is equivalent to $\exists P\Delta$.² Consider the following CNF,

$$\Delta = \{ \{ \neg A, B \}, \{ \neg B, C \} \}.$$

There is only one B -resolvent in this case: $\{ \neg A, C \}$. Adding this resolvent to Δ , and throwing out those clauses that mention B gives:

$$\Gamma = \{ \{ \neg A, C \} \}.$$

This is equivalent to $\exists B\Delta$ which can be confirmed by computing $\Delta|B \vee \Delta|\neg B$.

The DP algorithm, also known as *directional resolution* [DR94], uses the above observation to existentially quantify all variables from a CNF, one at a time. One way to implement the DP algorithm is using a mechanism known as *bucket elimination* [Dec97], which proceeds in two stages: *constructing and filling* a set of buckets, and then *processing* them in some order. Specifically, given a variable ordering π , we construct and fill buckets as follows:

- A *bucket* is constructed for each variable P and is *labeled* with variable P .
- Buckets are sorted top to bottom by their labels according to order π .
- Each clause α in the CNF is added to the first Bucket P from the top, such that variable P appears in clause α .

Consider for example the CNF

$$\Delta = \{ \{ \neg A, B \}, \{ \neg A, C \}, \{ \neg B, D \}, \{ \neg C, \neg D \}, \{ A, \neg C, E \} \},$$

and the variable order C, B, A, D, E . Constructing and filling buckets leads to:³

$$\begin{aligned} C &: \{ \neg A, C \}, \{ \neg C, \neg D \}, \{ A, \neg C, E \} \\ B &: \{ \neg A, B \}, \{ \neg B, D \} \\ A &: \\ D &: \\ E &: \end{aligned}$$

Buckets are then processed from top to bottom. To process Bucket P , we generate all P -resolvents using only clauses in Bucket P , and then add these resolvents to corresponding buckets below Bucket P . That is, each resolvent α is added to the first Bucket P' below Bucket P , such that variable P' appears in α . Processing Bucket P can then be viewed as a process of existentially quantifying variable P , where the result of such quantifying is now stored in the buckets below Bucket P .

Continuing with the above example, processing Bucket C adds one C -resolvent

²This follows from the fact that prime implicants of the formula can be obtained by closing the formula under resolution. After that, existentially quantifying a variable amounts dropping all clauses that mention the variable. Interested readers are referred to [LLM03, Mar00].

³It is not uncommon for buckets to be empty. It is also possible for all clauses to fall in the same bucket.

Algorithm 3.1 DP(CNF Δ , variable order π): returns UNSATISFIABLE or SATISFIABLE.

```

1: for each variable  $V$  of  $\Delta$  do
2:   create empty bucket  $B_V$ 
3: for each clause  $C$  of  $\Delta$  do
4:    $V =$  first variable of  $C$  according to order  $\pi$ 
5:    $B_V = B_V \cup \{C\}$ 
6: for each variable  $V$  of  $\Delta$  in order  $\pi$  do
7:   if  $B_V$  is not empty then
8:     for each  $V$ -resolvent  $C$  of clauses in  $B_V$  do
9:       if  $C$  is the empty clause then
10:        return UNSATISFIABLE
11:        $U =$  first variable of clause  $C$  according to order  $\pi$ 
12:        $B_U = B_U \cup \{C\}$ 
13: return SATISFIABLE

```

to Bucket A :

$$\begin{aligned}
 C &: \{\neg A, C\}, \{\neg C, \neg D\}, \{A, \neg C, E\} \\
 B &: \{\neg A, B\}, \{\neg B, D\} \\
 A &: \{\neg A, \neg D\} \\
 D &: \\
 E &:
 \end{aligned}$$

The buckets below Bucket C will now contain the result of existentially quantifying variable C . Processing Bucket B adds one B -resolvent to Bucket A :

$$\begin{aligned}
 C &: \{\neg A, C\}, \{\neg C, \neg D\}, \{A, \neg C, E\} \\
 B &: \{\neg A, B\}, \{\neg B, D\} \\
 A &: \{\neg A, \neg D\}, \{\neg A, D\} \\
 D &: \\
 E &:
 \end{aligned}$$

At this stage, the buckets below Bucket B contain the resulting of existentially quantifying both variables C and B . Processing Bucket A , leads to no new resolvents. We therefore have $\exists C, B, A \Delta = \{\}$ and the original CNF is consistent.

Algorithm 3.1 contains the pseudocode for directional resolution. Note that the amount of work performed by directional resolution is quite dependent on the chosen variable order. For example, considering the same CNF used above with the variable order E, A, B, C, D leads to the following buckets:

$$\begin{aligned}
 E &: \{A, \neg C, E\} \\
 A &: \{\neg A, B\} \{\neg A, C\} \\
 B &: \{\neg B, D\} \\
 C &: \{\neg C, \neg D\} \\
 D &:
 \end{aligned}$$

Processing the above buckets yields no resolvents in this case! This is another proof for the satisfiability of the given CNF, which was obtained by doing less work due to the chosen variable order.

In the case that the formula is satisfiable, we can extract a satisfying assignment from the trace of directional resolution in time that is linear to the size of

Figure 3.1. A connectivity graph for a CNF.

the formulas in all buckets [DR94]. To do so, we process the variables in the reverse order of the elimination (bottom bucket to top bucket). Let the elimination order be $\pi = V_1, V_2, \dots, V_n$. For each variable V_i , if its bucket is empty, it can be assigned any value. Otherwise, we assign to V_i the value that, together with the values of $V_j, i < j < n$, satisfies all clauses in its bucket.

Using a suitable variable order, the time and space complexity of directional resolution can be shown to be $O(n \exp(w))$ [DR94], where n is the size of CNF Δ and w is the treewidth of its *connectivity graph*: an undirected graph G over the variables of Δ , where an edge exists between two variables in G iff these variables appear in the same clause in Δ . Figure 3.1 depicts the connectivity graph for CNF we considered earlier:

$$\Delta = \{ \{\neg A, B\}, \{\neg A, C\}, \{\neg B, D\}, \{\neg C, \neg D\}, \{A, \neg C, E\} \}.$$

The complexity of this algorithms is discussed in more details in [DR94], which also shows that directional resolution becomes tractable on certain classes of CNF formula and that it can be used to answer some entailment queries on the formula.

3.3.2. Symbolic SAT Solving

The main problem observed with the DP algorithm is its space complexity, as it tends to generate too many clauses. A technique for dealing with this space complexity is to adopt a more compact representation of the resulting clauses. One such representation is known as *Binary Decision Diagrams (BDDs)* whose adoption leads to the class of *symbolic SAT algorithms* [CS00, AV01, MM02, PV04, FKS⁺04, JS04, HD04, SB06]. Many variations of this approach have been proposed over the years, but we discuss here only the basic underlying algorithm of symbolic SAT solving.

Figure 3.2 depicts an example BDD over three variables together with the models it encodes. Formally, a BDD is a rooted directed acyclic graph where there are at most two sinks, labeled with 0 and 1 respectively, and every other node is labeled with a Boolean variable and has exactly two children, distinguished as *low* and *high* [Bry86]. A BDD represents a propositional sentence whose models can be enumerated by taking all paths from the root to the 1-sink: taking the low

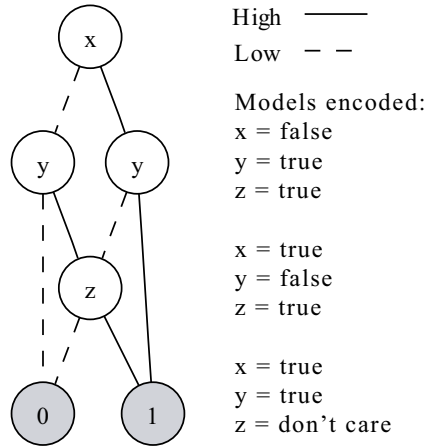

Figure 3.2. A BDD and the models it encodes.

(high) child of a node labeled with a variable X corresponds to assigning **false** (**true**) to X ; in case X does not appear on the path, it is marked as “don’t care” which means either value can be assigned.

In practice, BDDs are usually maintained so that variables appear in the same order on any path from the root to a sink, leading to Ordered BDDs (OBDDs). Two additional properties are often imposed: that there is no node whose two children are identical, and that there are no isomorphic sub-graphs. Under these conditions OBDDs are known to be a canonical form, meaning that there is a unique OBDD for any propositional sentence under a given variable order [Bry86]. Moreover, any binary operation on two OBDDs with the same variable order can be carried out using the *Apply* algorithm [Bry86], whose complexity is linear in the product of the operand sizes. Hence, one can existentially quantify a variable X from an OBDD by first conditioning it on X and then on $\neg X$, each of which can be done in time linear in the OBDD size. One can then disjoin the resulting OBDDs to obtain the result of existential quantification. The whole process can therefore be implemented in time which is quadratic in the size of the OBDD.

To solve SAT, one may convert the CNF formula into the equivalent OBDD and existentially quantify all variables from it. However, this naïve approach is hardly practical as the size of the OBDD will be too large. Therefore, to make this approach viable, symbolic SAT solving appeals to the following property of existential quantification:

$$\exists X \Delta = (\exists X \Gamma_X) \wedge \Gamma,$$

where $\Delta = \Gamma_X \wedge \Gamma$ and Γ_X contains all clauses of CNF Δ that mention variable X . Symbolic SAT solving starts by converting each clause C into a corresponding OBDD, $OBDD(C)$, a process which can be done in time linear in the clause size. To existentially quantify variable X , all OBDDs $\Gamma_1, \dots, \Gamma_n$ that mention variable X are conjoined together to produce one OBDD Γ_X , from which X is existentially quantified. This technique is called *early quantification* [BCM⁺90,

Algorithm 3.2 SYMBOLIC_SAT(CNF Δ , variable order π): returns UNSATISFIABLE or SATISFIABLE.

```

1: for each variable  $V$  of  $\Delta$  do
2:   create empty bucket  $B_V$ 
3: for each clause  $C$  of  $\Delta$  do
4:    $V =$  first variable of  $C$  according to order  $\pi$ 
5:    $B_V = B_V \cup \{OBDD(C)\}$ 
6: for each variable  $V$  of  $\Delta$  according to order  $\pi$  do
7:   if  $B_V$  is not empty then
8:      $\Gamma_V =$  conjunction of all OBDDs in  $B_V$ 
9:     if  $\Gamma_V =$  zero then
10:      return UNSATISFIABLE
11:      $\Gamma_V = \exists V \Gamma_V$ 
12:      $U =$  first variable of  $\Gamma_V$  according to order  $\pi$ 
13:      $B_U = B_U \cup \{\Gamma_V\}$ 
14: return SATISFIABLE

```

HKB96, TSL⁺90]. The resulting OBDD $\exists X \Gamma_X$ will then replace the OBDDs $\Gamma_1, \dots, \Gamma_n$, and the process is continued. If a zero-OBDD (one which is equivalent to false) is produced in the process, the algorithm terminates while declaring the original CNF unsatisfiable. However, if all variables are eliminated without producing a zero-OBDD, the original CNF is declared satisfiable.

The strategy for scheduling conjunctions and variable quantifications plays an important role in the performance of this algorithm. One goal is to try to minimize the size of intermediate OBDDs to reduce space requirement, which is often a major problem. Unfortunately, this problem is known to be NP-Hard [HKB96]. In [HD04], bucket elimination has been studied as a scheduling strategy. Algorithm 3.2 illustrates a symbolic SAT algorithm with bucket elimination. In [HD04], recursive decomposition [Dar01] and min-cut linear arrangement [AMS01] have been used as methods for ordering variables. Another approach for scheduling quantification is clustering [RAB⁺95]. In [PV04], this approach was studied together with the maximum cardinality search (MCS) [TY84] as a variable ordering heuristic.

3.4. Satisfiability by Inference Rules

We have already discussed in Section 3.2 the use of the resolution inference rule in testing satisfiability. We will now discuss two additional approaches based on the use of inference rules.

3.4.1. Stålmarck's Algorithm

Stålmarck's algorithm was originally introduced in 1990 [SS90], and later patented in 1994 [Stå94], as an algorithm for checking tautology of arbitrary propositional formulas (not necessarily in CNF). To test the satisfiability of a CNF, we can equivalently check whether its negation is a tautology using Stålmarck's algorithm [SS90, Wid96, Har96]. Here, we will discuss Stålmarck's algorithm in its original form—as a tautology prover.

The algorithm starts with a preprocessing step in which it transforms implications into disjunctions, removes any double negations and simplifies the formula by applying rudimentary inference rules (such as removing **true** from conjunctions and **false** from disjunctions). If preprocessing is able to derive the truth value of the formula (as **true** or **false**), then the algorithm terminates. Otherwise, the algorithm continues on to the next step.

The preprocessed formula is converted into a conjunction of “triplets.” Each triplet has the form $p \Leftrightarrow (q \otimes r)$, where \otimes is either a conjunction or an equivalence and p must be a Boolean variable, while r and q are literals. During this process, new Boolean variables may need to be introduced to represent sub-formulas. For example, the formula $\neg((a \Leftrightarrow b \wedge c) \wedge (b \Leftrightarrow \neg c) \wedge a)$ may be transformed into

$$\begin{aligned} v_1 &\Leftrightarrow (b \wedge c) \\ v_2 &\Leftrightarrow (a \Leftrightarrow v_1) \\ v_3 &\Leftrightarrow (b \Leftrightarrow \neg c) \\ v_4 &\Leftrightarrow (v_3 \wedge a) \\ v_5 &\Leftrightarrow (v_2 \wedge v_4) \end{aligned}$$

Here, $\neg v_5$ is a literal whose truth value is equivalent to that of the original formula.⁴ This conversion is meant to allow the algorithm to apply inference rules efficiently and to partially decompose the original formula into smaller sub-formulas that involve fewer variables. After this transformation, the algorithm assumes, for the sake of contradiction, that the whole formula has truth value **false**. For the remaining part, the algorithm tries to derive a contradiction, which would show that the original formula was actually a tautology.

In order to achieve this, the algorithm applies a set of inference rules called *simple rules* (or *propagation rule*) to the triplets to obtain more conclusions. Each conclusion either assigns a value to a variable or ties the value of 2 literals together. Some examples of simple rules are

$$\begin{aligned} p \Leftrightarrow (q \wedge r) &:\text{if } p = \neg q \text{ then } q = \mathbf{true} \text{ and } r = \mathbf{false} \\ p \Leftrightarrow (q \wedge r) &:\text{if } p = \mathbf{true} \text{ then } q = \mathbf{true} \text{ and } r = \mathbf{true} \\ p \Leftrightarrow (q \Leftrightarrow r) &:\text{if } p = q \text{ then } r = \mathbf{true} \\ p \Leftrightarrow (q \Leftrightarrow r) &:\text{if } p = \mathbf{true} \text{ then } q = r. \end{aligned}$$

The reader is referred to [Har96] for a complete set of simple rules used by the algorithm. The process of repeatedly and exhaustively applying simple rules to the formula is called *0-saturation*. After 0-saturation, if the truth value of the formula can be determined, then the algorithm terminates. Otherwise, the algorithm proceeds by applying the *dilemma rule*.

⁴This example is taken from [Har96].

The dilemma rule is a way of deducing more conclusions about a formula by making assumptions, which aid the application of simple rules. The rule operates as follows. Let Δ be the formula after 0-saturation. For each Boolean variable v in Δ , the algorithm 0-saturates $\Delta|v$ and $\Delta|\neg v$ to produce conclusions Γ_v and $\Gamma_{\neg v}$, respectively. Then, all conclusions that are common between Γ_v and $\Gamma_{\neg v}$ are added to Δ . In other words, the algorithm tries both values of the variable v and keeps all the conclusions derivable from both branches. These conclusions necessarily hold regardless of the value of v . The process is repeated for all variables until no new conclusions can be derived. The algorithm terminates as soon as contradicting conclusions are added to the knowledge base or the truth value of the formula can be determined from the conclusions. The process of applying the dilemma rule exhaustively on all variables is called 1-saturation. As one might expect, the algorithm can apply the dilemma rule with increasing depths of assignment. In particular, n -saturation involves case-splitting over all combinations of n variables simultaneously and gathering common conclusions. If we allow n to be large enough, the algorithm is guaranteed to either find a contradiction or reach a satisfying assignment. Because Stålmarck's algorithm n -saturates formulas starting from $n = 0$, it is oriented toward finding short proofs for the formula's satisfiability or unsatisfiability.

3.4.2. HeerHugo

HeerHugo [GW00] is a satisfiability prover that was largely inspired by Stålmarck's algorithm. Although, strictly speaking, HeerHugo is not a tautology prover, many techniques used in this algorithm have lots of similarity to those of Stålmarck's algorithm.

According to this algorithm, the input formula is first converted into CNF with at most three literals per clause. Then, HeerHugo applies a set of basic inference rules, which are also called simple rules, to the resulting formula. Although these inference rules share the name with those rules in Stålmarck's algorithm, the two set of rules are rather different. Simple rules used in HeerHugo appear to be more powerful. They include unit resolution, subsumption, and a restricted form of resolution (see [GW00] for more details).

Resolution is selectively performed by HeerHugo, in order to existentially quantify some variables. This technique is similar to the one used in DP [DP60]. However, in HeerHugo, resolution is only carried out when it results in a smaller formula. Because of these rules, clauses are constantly added and removed from the knowledge base. Consequently, HeerHugo incorporates some subsumption and ad-hoc resolution rules for removing subsumed clauses and opportunistically generating stronger clauses.

During the process of applying simple rules, conclusions may be drawn from the formula. Like in Stålmarck's algorithm, a conclusion is either an assignment of a variable or an equivalence constraint between two literals. If a contradiction is found during this step, the formula is declared unsatisfiable. Otherwise, the algorithm continues with the *branch/merge* rule, which is essentially the same as the dilemma rule of Stålmarck's. The algorithm also terminates as soon as the truth value of the formula can be determined from the conclusions. The

Figure 3.3. A search tree for enumerating all truth assignments over variables A , B and C .

completeness of HeerHugo is achieved by successively increasing the number of variables in the branch/merge rule, in a manner that is similar to applying n -saturation in Stålmarck's.

3.5. Satisfiability by Search: The DPLL Algorithm

We will discuss in this section the DPLL algorithm [DLL62], which is based on systematic search in the space of truth assignments. This algorithm is marked by its modest space requirements and was developed in response to the challenges posed by the space requirements of the DP algorithm.

Figure 3.3 depicts a search tree that enumerates the truth assignments over three variables. The first observation about this tree is that its leaves are in one-to-one correspondence with the truth assignments under consideration. Hence, testing satisfiability can be viewed as a process of searching for a leaf node that satisfies the given CNF. The second observation is that the tree has a finite depth of n , where n is the number of Boolean variables. Therefore, it is best to explore the tree using depth-first-search as given in Algorithm 3.3, which is called initially with depth $d = 0$. The algorithm makes use of the conditioning operator on CNFs, which leads to simplifying the CNF by either removing clauses or reducing their size.

Consider now the CNF:

$$\Delta = \{ \{-A, B\}, \{-B, C\} \},$$

and the search node labeled with **F** in Figure 3.4. At this node, Algorithm 3.3 will condition Δ on literals $A, \neg B$, leading to:

$$\Delta|A, \neg B = \{ \{\text{false}, \text{false}\}, \{\text{true}, C\} \} = \{ \{ \} \}.$$

Algorithm 3.3 DPLL-(CNF Δ , depth d): returns a set of literals or UNSATISFIABLE. Variables are named P_1, P_2, \dots

```

if  $\Delta = \{\}$  then
  return  $\{\}$ 
else if  $\{\} \in \Delta$  then
  return UNSATISFIABLE
else if  $\mathbf{L} = \text{DPLL}(\Delta | P_{d+1}, d+1) \neq \text{UNSATISFIABLE}$  then
  return  $\mathbf{L} \cup \{P_{d+1}\}$ 
else if  $\mathbf{L} = \text{DPLL}(\Delta | \neg P_{d+1}, d+1) \neq \text{UNSATISFIABLE}$  then
  return  $\mathbf{L} \cup \{\neg P_{d+1}\}$ 
else
  return UNSATISFIABLE

```

Figure 3.4. A search tree for that enumerates all truth assignments over variables A , B and C . Assignments marked by \times are not models of the CNF $\{\neg A, B\}, \{\neg B, C\}$.

Hence, the algorithm will immediately conclude that neither truth assignment ω_3 nor ω_4 are models of Δ . The ability to detect contradictions at internal nodes in the search is quite significant as it allows one to dismiss all truth assignments that are characterized by that node, without having to visit each one of them explicitly. Algorithm 3.3 can also detect success at an internal node, which implies that all truth assignments characterized by that node are models of the CNF. Consider for example the internal node labelled with **S** in Figure 3.4. This node represents truth assignments ω_7 and ω_8 , which are both models of Δ . This can be detected by conditioning Δ on literals $\neg A, \neg B$:

$$\Delta | \neg A, \neg B = \{ \{\text{true}, \text{false}\}, \{\text{true}, C\} \} = \{\}.$$

Hence, all clauses are subsumed immediately after we set the values of A and B to false, and regardless of how we set the value of C . This allows us to conclude that both ω_7 and ω_8 are models of Δ , without having to inspect each of them

Figure 3.5. A termination tree, where each node is labelled by the corresponding CNF. The last node visited during the search is labelled with $\{\}$. The label \times indicates the detection of a contradiction at the corresponding node.

individually. Given that Algorithm 3.3 may detect success before reaching a leaf node, it may return less than n literals, which would characterize a set of truth assignments in this case, all of which are guaranteed to be models of the input formula.

3.5.1. Termination Trees

One way to measure the amount of work done by Algorithm 3.3 is using the notion of a *termination tree*: the subset of search tree that is actually explored during search. Figure 3.5 depicts an example termination tree for the CNF:

$$\Delta = \{ \{ \neg A, B \}, \{ \neg B, \neg C \}, \{ C, \neg D \} \}.$$

According to this figure, Δ is satisfiable and the truth assignment $A, B, \neg C, \neg D$ is a satisfying assignment. The figure also provides a trace of Algorithm DPLL (Algorithm 3.3) as it shows the conditioned CNF at each node visited during the search process. The nodes in a termination tree belong to different levels as shown in Figure 3.5, with the root node being at Level 0. Termination trees are also useful in characterizing different satisfiability problems since the size and depth of tree appear to be good indicators of the problem character and difficulty.

3.5.2. Unit Resolution

Consider the termination tree of Figure 3.5, and corresponding CNF:

$$\Delta = \{ \{ \neg A, B \}, \{ \neg B, \neg C \}, \{ C, \neg D \} \}.$$

Consider also the node at Level 1, which results from setting variable A to true, and its corresponding CNF:

$$\Delta|A = \{ \{ B \}, \{ \neg B, \neg C \}, \{ C, \neg D \} \}.$$

This CNF is neither empty, nor contains the empty clause. Therefore, we cannot yet declare early success or early failure, which is why Algorithm 3.3 continues searching below Level 1 as shown in Figure 3.5. We will show now, however, that by employing unit resolution, we can indeed declare success and end the search at this node.

The *unit resolution technique* (or *unit propagation*) is quite simple: Before we perform the tests for success or failure on Lines 1 and 2 of Algorithm 3.3, we first close the CNF under unit resolution and collect all unit clauses in the CNF. We then assume that variables are set to satisfy these unit clauses. That is, if the unit clause $\{P\}$ appears in the CNF, we set P to true. And if the unit clause $\{\neg P\}$ appears in the CNF, we set P to false. We then simplify the CNF given these settings and check for either success (all clauses are subsumed) or failure (the empty clause is derived).

To incorporate unit resolution into our satisfiability algorithms, we will introduce a function UNIT-RESOLUTION, which applies to a CNF Δ and returns two results:

- \mathbf{I} : a set of literals that were either present as unit clauses in Δ , or were derived from Δ by unit resolution.
- Γ : a new CNF which results from conditioning Δ on literals \mathbf{I} .

For example, if the CNF

$$\Delta = \{ \{ \neg A, \neg B \}, \{ B, C \}, \{ \neg C, D \}, \{ A \} \},$$

then $\mathbf{I} = \{A, \neg B, C, D\}$ and $\Gamma = \{\}$. Moreover, if

$$\Delta = \{ \{ \neg A, \neg B \}, \{ B, C \}, \{ \neg C, D \}, \{ C \} \},$$

then $\mathbf{I} = \{C, D\}$ and $\Gamma = \{ \{ \neg A, \neg B \} \}$. Unit resolution is a very important component of search-based SAT solving algorithms. Part 1, Chapter 4 discusses in details the modern implementation of unit resolution employed by many SAT solvers of this type.

Algorithm DPLL, for Davis, Putnam, Logemann and Loveland, is a refinement on Algorithm 3.3 which incorporates unit resolution. Beyond applying unit resolution on Line 1, we have two additional changes to Algorithm 3.3. First of all, we no longer assume that variables are examined in the same order as we go down the search tree. Secondly, we no longer assume that a variable is set to true first, and then to false; see Line 7. The particular choice of a literal L on Line 7

Algorithm 3.4 DPLL(CNF Δ): returns a set of literals or UNSATISFIABLE.

```

1:  $(\mathbf{I}, \Gamma) = \text{UNIT-RESOLUTION}(\Delta)$ 
2: if  $\Gamma = \{\}$  then
3:   return  $\mathbf{I}$ 
4: else if  $\{\} \in \Gamma$  then
5:   return UNSATISFIABLE
6: else
7:   choose a literal  $L$  in  $\Gamma$ 
8:   if  $\mathbf{L} = \text{DPLL}(\Gamma|L) \neq \text{UNSATISFIABLE}$  then
9:     return  $\mathbf{L} \cup \mathbf{I} \cup \{L\}$ 
10:  else if  $\mathbf{L} = \text{DPLL}(\Gamma|\neg L) \neq \text{UNSATISFIABLE}$  then
11:    return  $\mathbf{L} \cup \mathbf{I} \cup \{\neg L\}$ 
12:  else
13:    return UNSATISFIABLE

```

can have a dramatic impact on the running time of DPLL. Part 1, Chapter 8 is dedicated to heuristics for making this choice, which are known as *variable ordering* or *splitting* heuristics when choosing a variable, and *phase selection* heuristics when choosing a particular literal of that variable.

3.6. Satisfiability by Combining Search and Inference

We will now discuss a class of algorithms for satisfiability testing which form the basis of most modern complete SAT solvers. These algorithms are based on the DPLL algorithm, and have undergone many refinements over the last decade, making them the most efficient algorithms discussed thus far. Yet, these refinements have been significant enough to change the behavior of DPLL to the point where the new algorithms are best understood in terms of an interplay between search and inference. Early successful solvers employing this approach, such as GRASP [MSS99] and Rel_{sat} [BS97], gave rise to modern solvers namely BerkMin [GN02], JeruSAT [DHN05a], MiniSAT [ES03], PicoSAT [Bie07], Rsat [PD07], Siege [Rya04], TiniSAT [Hua07a], and zChaff [MMZ⁺01]. We start this next section by discussing a main limitation of the DPLL algorithm, which serves as a key motivation for these refinements.

3.6.1. Chronological Backtracking

Algorithm DPLL is based on *chronological backtracking*. That is, if we try both values of a variable at level l , and each leads to a contradiction, we move to level $l - 1$, undoing all intermediate assignments in the process, and try another value at that level (if one remains to be tried). If there are no other values to try at level $l - 1$, we move to level $l - 2$, and so on. If we move all the way to Level 0, and each value there leads to a contradiction, we know that the CNF is inconsistent.

The process of moving from the current level to a lower level is known as *backtracking*. Moreover, if backtracking to level l is done only after having tried both values at level $l + 1$, then it is called *chronological backtracking*, which is the kind of backtracking used by DPLL. The problem with this type of backtracking is that it does not take into account the information of the contradiction that triggers the backtrack.

Figure 3.6. A termination tree. Assignments shown next to nodes are derived using unit resolution.

To consider a concrete example, let us look at how standard DPLL behaves on the following CNF, assuming a variable ordering of A, B, C, X, Y, Z :

$$\Delta = \begin{array}{l} 1. \{A, B\} \\ 2. \{B, C\} \\ 3. \{\neg A, \neg X, Y\} \\ 4. \{\neg A, X, Z\} \\ 5. \{\neg A, \neg Y, Z\} \\ 6. \{\neg A, X, \neg Z\} \\ 7. \{\neg A, \neg Y, \neg Z\} \end{array} \quad (3.1)$$

Figure 3.6 depicts the termination tree for DPLL on the above CNF. We start first by setting A to true and explore the subtree below that node, only to find that all branches lead to contradictions. This basically means that $A = \text{true}$ is not a part of any solution. In other words, the formula $\Delta \wedge A$ is inconsistent. Note, however, that DPLL is unable to discover this fact in the knowledge until it has set variables B, C and X . Recall that DPLL uses unit resolution, which is not refutation complete. This explains why DPLL cannot detect the contradiction early on.

To provide more examples of the previous phenomena, note that DPLL is able to detect a contradiction in $\Delta|A, B, C, X$ and in $\Delta|A, B, C, \neg X$, which immediately implies a contradiction in $\Delta|A, B, C$. Yet DPLL is unable to detect a contradiction in $\Delta|A, B, C$.

When DPLL detects the contradiction in $\Delta|A, B, C, X$, it backtracks and tries the other value of X , leading also to a contradiction in $\Delta|A, B, C, \neg X$. DPLL then backtracks again and tries the second value of variable C . Again, no contradiction

is detected by DPLL in $\Delta|A, B, \neg C$, yet it later discovers that both $\Delta|A, B, \neg C, X$ and $\Delta|A, B, \neg C, \neg X$ are contradictory, leading it to backtrack again, and so on.

The key point here is that all these contradictions that are discovered deep in the search tree are actually caused by having set A to `true` at Level 0. That is, the settings of variables B and C at Levels 1 and 2 are irrelevant here. However, chronological backtracking is not aware of this fact. As a result, it tries different values of variables B, C , hoping to fix the contradiction. As shown in Figure 3.6, DPLL with chronological backtracking encounters 6 contradictions before realizing that $A = \text{true}$ was a wrong decision. In general, there can be many irrelevant variables between the level of conflict and the real cause of the conflict. Chronological backtracking may lead the solver to repeat the same conflict over and over again in different settings of irrelevant variables.

3.6.2. Non-Chronological Backtracking

Non-chronological backtracking addresses this problem by taking into account the set of variables that actually are involved in the contradiction. Originally proposed as a technique for solving constraint satisfaction problems (CSPs), *non-chronological backtracking* is a method for the solver to quickly get out of the portion of the search space that contains no solution [SS77, Gas77, Pro93, BS97]. This process involves backtracking to a lower level l without necessarily trying every possibility between the current level and l .⁵ Non-chronological backtracking is sometimes called for as it is not uncommon for the contradiction discovered at level l to be caused by variable settings that have been committed at levels much lower than l . In such a case, trying another value at level l , or at level $l - 1$, may be fruitless.

Non-chronological backtracking can be performed by first identifying every assignment that contributes to the derivation of the empty clause [BS97]. This set of assignments is referred to as the *conflict set* [Dec90]. Then, instead of backtracking to the last unflipped decision variable as in the case of chronological backtracking, non-chronological backtracking backtracks to the most recent decision variable that appears in the conflict set and tries its different value. Note that, during this process, all intermediate assignments (between the current level and the backtrack level) are erased.

In the above example, after the algorithm assigns $A = \text{true}, B = \text{true}, C = \text{true}, X = \text{true}$, unit resolution will derive $Y = \text{true}$ (Clause 3), $Z = \text{true}$ (Clause 5), and detect that Clause 7 becomes empty (all literals are already false). In this case, the conflict set is $\{A = \text{true}, X = \text{true}, Y = \text{true}, Z = \text{true}\}$. Note that B and C do not participate in this conflict. Non-chronological backtracking will backtrack to try a different value of X —the most recent decision variable in the conflict set. After setting $X = \text{false}$, the algorithm will detect another conflict. This time, the conflict set will be $\{A = \text{true}, X = \text{true}, Z = \text{true}\}$. Since we have exhausted the values for X , non-chronological backtracking will now backtrack to A and set $A = \text{false}$ and continue. Note that, this time, the algorithm is able

⁵There are several variations of non-chronological backtracking used in CSP and SAT [Gas77, Pro93, MSS99, BS97, ZMMM01].

to get out of the conflict without trying different values of B or C . Moreover, it only ran into 2 contradictions in the process.

Non-chronological backtracking partially prevents the algorithm from repeating the same conflict. However, as soon as the algorithm backtracks past every variable in the conflict set (possibly due to a different conflict), it can still repeat the same mistake in the future.

One can address this problem by empowering unit resolution through the addition of clauses to the CNF. For example, the clause $\{\neg A, \neg X\}$ is implied by the above CNF. Moreover, if this clause were present in the CNF initially, then unit resolution would have discovered a contradiction immediately after setting A to true. This leaves the question of how to identify such clauses in the first place. As it turns out, each time unit resolution discovers a contradiction, there is an opportunity to identify a clause which is implied by the CNF and which would be allow unit resolution to realize new implications. This clause is known as a *conflict-driven clause* (or *conflict clause*) [MSS99, BS97, ZMMM01, BKS04]. Adding it to the CNF will allow unit resolution to detect this contradiction earlier and to avoid the same mistake in the future.⁶

3.6.3. Non-Chronological Backtracking and Conflict-Driven Clauses

The use of non-chronological backtracking in modern SAT solvers is tightly coupled with the derivation of conflict-driven clauses. We will now discuss the method that modern SAT solvers use to derive conflict-driven clauses from conflicts and the specific way they perform non-chronological backtracking. The combination of these techniques makes sure that unit resolution is empowered every time a conflict arises and that the solver will not repeat any mistake. The identification of conflict-driven clauses is done through a process known as *conflict analysis*, which analyzes a trace of unit resolution known as the *implication graph*.

3.6.3.1. Implication Graph

An implication graph is a bookkeeping device that allows us to record dependencies among variable settings as they are established by unit resolution. Figure 3.7 depicts two implication graphs for the knowledge base in (3.1). Figure 3.7(a) is the implication graph after setting variables A, B, C and X to true.

Each node in an implication graph has the form $l/V=v$, which means that variable V has been set to value v at level l . Note that a variable is set either by a *decision* or by an *implication*. A variable is set by an implication if the setting is due to the application of unit resolution. Otherwise, it is set by a decision.

Whenever unit resolution is used to derive a variable assignment, it uses a clause and a number of other variable assignments to justify the implication. In this case, we must have an edge into the implied assignment from each of the assignments used to justify the implication. For example, in the implication graph of Figure 3.7(a), variable Y is set to true at Level 3 by using Clause 3 and the variable settings $A=\text{true}$ and $X=\text{true}$. Hence, we have an edge from $A=\text{true}$

⁶The idea of learning from conflicts originated from the successful applications in CSP [SS77, Gen84, Dav84, Dec86, dKW87].

Figure 3.7. Two implication graphs.

Figure 3.8. Three cuts in an implication graph, leading to three conflict sets.

to $Y=\text{true}$, and another from $X=\text{true}$ to $Y=\text{true}$. Moreover, both of these edges are labeled with 3, which is the ID of clause used in implying $Y=\text{true}$.

An implication graph may also have a special node representing a contradiction derived by unit resolution. This is indicated by $\{\}$ in the implication graph, with its parents being all variable settings that were used in deriving an empty clause. For example, in Figure 3.7(a), the settings $A=\text{true}$, $Y=\text{true}$ and $Z=\text{true}$ were used with Clause 7 to derive the empty clause.

3.6.3.2. Deriving a Conflict-Driven Clause

The process of deriving a conflict-driven clause involves identifying a conflict set from the implication graph and converting this set into a clause. A conflict set can be obtained in the following manner. Every *cut* in the implication graph defines a conflict set as long as that cut separates the decision variables (root nodes) from the contradiction (a leaf node) [MSS99, ZMMM01, Rya04].⁷ Any node (variable assignment) with an outgoing edge that crosses the cut will then be in the conflict set. Intuitively, a conflict set contains assignments that are sufficient to cause the conflict. Figure 3.8 depicts a few cuts in the implication graph of Figure 3.7(a), leading to conflict sets $\{A=\text{true}, X=\text{true}\}$, $\{A=\text{true}, Y=\text{true}\}$ and $\{A=\text{true}, Y=\text{true}, Z=\text{true}\}$.

⁷Note that we may have multiple, disconnected components of the implication graph at any point in the search. Our analysis always concerns the component which contains the contradiction node.

Given the multiplicity of these conflict sets, one is interested in choosing the most useful one. In practice, virtually all modern SAT solvers insist on selecting cuts that involve exactly one variable assigned at the level of conflict for a reason that we become apparent later. For the implication graph in Figure 3.7(a), the sets $\{Y = \text{true}, A = \text{true}\}$ and $\{X = \text{true}, A = \text{true}\}$ meet this criterion. Similarly, for the graph in Figure 3.7(b), $\{A = \text{true}\}$ is a conflict cut with such property. An actual implementation that analyzes the implication graph for the right conflict set with desired properties will be described in Part 1, Chapter 4.

Once a conflict set is identified, a conflict-driven clause can be obtained by simply negating the assignments in the set. For example, if the conflict set is $\{A = \text{true}, B = \text{false}, C = \text{false}\}$, then the conflict-driven clause derived is $\{\neg A, B, C\}$. This clause represents the previously-implicit constraint that the assignments in the conflict set cannot be made simultaneously ($A = \text{true}, B = \text{false}, C = \text{true}$ will now violate this new clause). Conflict-driven clauses generated from cuts that contain exactly one variable assigned at the level of conflict are said to be *asserting* [ZMMM01]. Modern SAT solvers insist on learning only asserting clauses. We will discuss later the properties of asserting clauses that make them useful and even necessary for the completeness of the algorithm. From now on, we assume that every conflict-driven clause is asserting, unless stated otherwise.

3.6.3.3. Learning a Conflict-Driven Clause and Backtracking

Once the conflict-driven clause is derived from the implication graph, it is added to the formula. The process of adding a conflict-driven clause to the CNF is known as *clause learning* [MSS99, BS97, ZMMM01, BKS04]. A key question in this regard is when exactly to add this clause. Consider the termination tree in Figure 3.6 and the left most leaf node corresponding to the CNF $\Delta|A, B, C, X$. Unit resolution discovers a contradiction in this CNF and by analyzing the implication graph in Figure 3.7(a), we can identify the conflict-driven clause $\neg A \vee \neg X$. The question now is: What to do next?

Since the contradiction was discovered after setting variable X to **true**, we know that we have to at least undo that decision. Modern SAT solvers, however, will undo all decisions made after the *assertion level*, which is the second highest level in a conflict-driven clause. For example, in the clause $\neg A \vee \neg X$, A was set at Level 0 and X was set at level 3. Hence, the assertion level is 0 in this case. If the clause contains only literals from one level, its assertion level is then -1 by definition. The assertion level is special in the sense that it is the deepest level at which adding the conflict-driven clause would allow unit resolution to derive a new implication using that clause. This is the reason why modern SAT solvers would actually backtrack all the way to the assertion level, add the conflict-driven clause to the CNF, apply unit resolution, and then continue the search process. This particular method of performing non-chronological backtracking is referred to as *far-backtracking* [SBK05].

3.6.3.4. Clause Learning and Proof Complexity

The advantages of clause learning can also be shown from proof complexity perspective [CR79]. Whenever the CNF formula is unsatisfiable, a SAT solver can

Algorithm 3.5 DPLL+(CNF Δ): returns UNSATISFIABLE or SATISFIABLE.

```

1:  $D \leftarrow ()$  {empty decision sequence}
2:  $\Gamma \leftarrow \{\}$  {empty set of learned clauses}
3: while true do
4:   if unit resolution detects a contradiction in  $(\Delta, \Gamma, D)$  then
5:     if  $D = ()$  then {contradiction without any decisions}
6:       return UNSATISFIABLE
7:     else {backtrack to assertion level}
8:        $\alpha \leftarrow$  asserting clause
9:        $m \leftarrow$  assertion level of clause  $\alpha$ 
10:       $D \leftarrow$  first  $m$  decisions in  $D$  {erase decisions  $\ell_{m+1}, \dots$ }
11:      add clause  $\alpha$  to  $\Gamma$ 
12:   else {unit resolution does not detect a contradiction}
13:     if  $\ell$  is a literal where neither  $\ell$  nor  $\neg\ell$  are implied by unit resolution from  $(\Delta, \Gamma, D)$ 
14:       then
15:          $D \leftarrow D; \ell$  {add new decision to sequence  $D$ }
16:       else
17:         return SATISFIABLE

```

be thought of as a resolution proof engine that tries to produce a (short) proof for the unsatisfiability of the formula. From this viewpoint, the goal of the solver is to derive the empty clause. Generating short resolution proofs is difficult to implement in practice, because the right order of clauses to resolve is often hard to find. As a result, SAT solvers only apply a restricted version of resolution, which may generate longer proofs, to allow the solvers to run efficiently.

In [BKS04], the authors show that DPLL-based SAT solvers that utilize clause learning can generate exponentially shorter proofs than those that do not use clause learning. Moreover, it has been shown, in the same paper, that if the solver is allowed to branch on assigned variables and to use unlimited restarts, the resulting proof engine is theoretically as strong as an unrestricted resolution proof system.

3.6.4. Putting It All Together

Algorithm DPLL+ is the final SAT algorithm in this chapter which incorporates all techniques we discussed so far in this section. The algorithm maintains a triplet (Δ, Γ, D) consisting of the original CNF Δ , the set of learned clauses Γ and a decision sequence $D = (\ell_0, \dots, \ell_n)$, where ℓ_i is a literal representing a decision made at level i . Algorithm DPLL+ starts initially with an empty decision sequence D and an empty set of learned clauses Γ . It then keeps adding decisions to the sequence D until a contradiction is detected by unit resolution. If the contradiction is detected in the context of some decisions, a conflict-driven clause α is constructed and added to the set of learned clauses, while backtracking to the assertion level of clause α . The process keeps repeating until either a contradiction is detected without any decisions (unsatisfiable), or until every variable is set to a value without a contradiction (satisfiable). Part 1, Chapter 4 discusses in details the implementation of this type of SAT solvers.

3.6.4.1. An Example

To consider a concrete example of DPLL+, let us go back to the CNF 3.1 shown again below:

$$\Delta = \begin{array}{l} 1. \{A, B\} \\ 2. \{B, C\} \\ 3. \{\neg A, \neg X, Y\} \\ 4. \{\neg A, X, Z\} \\ 5. \{\neg A, \neg Y, Z\} \\ 6. \{\neg A, X, \neg Z\} \\ 7. \{\neg A, \neg Y, \neg Z\} \end{array}$$

DPLL+ starts with an empty decision sequence and an empty set of learned clauses:

$$\begin{array}{l} D = (), \\ \Gamma = \{ \}. \end{array}$$

Suppose now that the algorithm makes the following decisions in a row:

$$D = (A=\text{true}, B=\text{true}, C=\text{true}, X=\text{true}).$$

Unit resolution will not detect a contradiction until after the last decision $X=\text{true}$ has been made. This triggers a conflict analysis based on the implication graph in Figure 3.7(a), leading to the conflict-driven clause

$$8. \{\neg A, \neg X\},$$

whose assertion level is 0. Backtracking to the assertion level gives:

$$\begin{array}{l} D = (A=\text{true}), \\ \Gamma = \{\{\neg A, \neg X\}\}. \end{array}$$

Unit resolution will then detect another contradiction, leading to conflict analysis based on the implication graph in Figure 3.7(b). The conflict-driven clause in this case is

$$9. \{\neg A\}$$

with an assertion level of -1 . Backtracking leads to:

$$\begin{array}{l} D = (), \\ \Gamma = \{\{\neg A, \neg X\}, \{\neg A\}\}. \end{array}$$

No contradiction is detected by unit resolution at this point, so the algorithm proceeds to add a new decision and so on.

Figure 3.9. An example of a unique implication point (UIP).

3.6.4.2. More on Asserting Clauses

Modern SAT solvers insist on generating asserting conflict-driven clauses as they are guaranteed to become unit clauses when added to the CNF. Recall that a conflict-driven clause is asserting if it includes exactly one variable that has been set at the decision level where the contradiction is found. A popular refinement on this definition, however, appeals to the notion of *unique implication point (UIP)* [MSS99, ZMMM01]. In particular, a UIP of a decision level in an implication graph is a variable setting at that decision level which lies on every path from the decision variable of that level to the contradiction. Intuitively, a UIP of a level is an assignment at the level that, by itself, is sufficient for implying the contradiction. In Figure 3.9, the variable setting $3/Y=\text{true}$ and $3/X=\text{true}$ would be UIPs as they lie on every path from the decision $3/X=\text{true}$ to the contradiction $3/\{\}$.

Note that there may be more than one UIP for a given level and contradiction. In such a case, we will order the UIPs according to their distance to the contradiction node. The first UIP is the one closest to the contradiction. Even though there are many possible ways of generating asserting conflict-driven clauses from different UIPs, asserting clauses that contain the first UIP of the conflict level are preferred because they tend to be shorter.⁸ This scheme of deriving asserting clauses is called the *1UIP scheme*. One could also derive clauses that contain the first UIPs of other levels as well. However, the studies in [ZMMM01] and [DHN05b] showed that insisting on the first UIPs of other levels tends to worsen the solver's performance. Considering Figure 3.9, the conflict set $\{A=\text{true}, Y=\text{true}\}$ contains the first UIP of the conflict level (Y), leading to the asserting conflict-driven clause $\neg A \vee \neg Y$.

⁸A short clause is preferable because it potentially allows the solver to prune more search space.

Figure 3.10. An implication graph with three different asserting, conflict-driven clauses.

3.6.4.3. Repeating Decision Sequences

Consider now the following CNF:

$$\Delta = \begin{array}{l} 1. \{A, B\} \\ 2. \{\neg B, C\} \\ 3. \{\neg B, D\} \\ 4. \{\neg C, \neg D, E\} \\ 5. \{\neg E, F\} \\ 6. \{\neg E, \neg F\} \end{array}$$

After DPLL+ has decided $\neg A$, unit resolution will detect a contradiction as given by the implication graph in Figure 3.10. There are three asserting clauses in this case, $\{A\}$, $\{\neg B\}$ and $\{\neg E\}$, where $\{\neg E\}$ is the first UIP clause. Suppose that DPLL+ generates $\{\neg E\}$. DPLL+ will then erase the decision $\neg A$ and add clause $\{\neg E\}$ to the formula. Unit resolution will not detect a contradiction in this case. Moreover, since neither A nor $\neg A$ is implied by unit resolution, DPLL+ may decide $\neg A$ again!

This example illustrates the extent to which DPLL+ deviates from the standard depth-first search used by DPLL. In particular, in such a search no decision sequence will be examined more than once as the search tree is traversed in a systematic fashion, ensuring that no node in the tree will be visited more than once. The situation is different with DPLL+ which does not have a memory of what decision sequences it has considered, leading it to possibly consider the same decision sequence more than once. This, however, should not affect the completeness of the algorithm, because the assignments at the time of future visits will be different. In this sense, even though the algorithm repeats the decision sequence, it does so in a different context. A completeness proof of DPLL+ is presented in [ZM03, Rya04].

3.6.4.4. Deleting Conflict-Driven Clauses

The addition of conflict-driven clauses is quite useful as it empowers unit resolution, allowing it to detect certain contradictions that it could not detect before. The addition of conflict-driven clauses may carry a disadvantage though, as it may considerably increase the size of given CNF, possibly causing a space problem. Moreover, the more clauses the CNF has, the more time it takes for the

solver to perform unit resolution. In practice, it is not uncommon for the number of added clauses to be much greater than the number of clauses in the original CNF on a difficult problem.

This issue can be dealt with in at least two ways. First, newly added conflict-driven clauses may actually subsume older conflict-driven clauses, which can be removed in this case. Second, one may decide to delete conflict-driven clauses if efficiency or space becomes an issue. In this case, the size, age, and activity of a conflict-driven clause are typically used in considering its deletion, with a preference towards deleting longer, older and less active clauses. Different conflict-driven clause deletion policies, mostly based on some heuristics, have been proposed in different SAT solvers [MSS99, MMZ⁺01, ES03].

3.6.4.5. Restarts

Another important technique employed by all modern SAT solvers in this category is *restarts* [GSC97]. When a SAT solver restarts, it abandons the current assignments and starts the search at the root of the search tree, while maintaining other information, notably conflict-directed clauses, obtained during earlier search. Restarting is a way of dealing with the heavy-tailed distribution of running time often found in combinatorial search [GSC97, BMS00]. Intuitively, restarting is meant to prevent the solver from getting stuck in a part of the search space that contains no solution. The solver can often get into such situation because some incorrect assignments were committed early on and unit resolution was unable to detect them. If the search space is large, it may take very long for these incorrect assignments to be fixed. Hence, in practice, SAT solvers usually restart after a certain number of conflicts is detected (indicating that the current search space is difficult), hoping that, with additional information, they can make better early assignments. The extensive study of different restarting policies in [Hua07b] shows that it is advantageous to restart often. The policy that was found to be empirically best in [Hua07b] is also becoming a standard practice in state-of-the-art SAT solvers.

Note that restarts may compromise the solver's completeness, when it is employed in a solver that periodically deletes conflict-driven clauses. Unless the solver allows the number of conflict-driven clauses to grow sufficiently large or eventually allows a sufficiently long period without restarting, it may keep exploring the same assignments after each restart. Note that both restarting and clause deletion strategies are further discussed in Part 1, Chapter 4.

3.6.5. Other Inference Techniques

Other than the standard techniques mentioned in the previous sub-sections, over the years, other inference techniques have been studied in the context of DPLL-based algorithm. Even though most of these techniques are not present in leading general complete SAT solvers, they could provide considerable speedup on certain families of problems that exhibit the right structure. We discuss some of these techniques in this brief section.

One natural extension of unit resolution is binary resolution. Binary resolution is a resolution in which at least one resolved clause has size two. Binary

resolution allows more implications to be realized at the expense of efficiency. In [VG01], Van Gelder presented a SAT solver, 2cIVER, that utilized a limited form of binary resolution. Bacchus also studied, in [Bac02], the same form of binary resolution, termed BinRes, in DPLL-based solver called 2CLS+EQ. This solver also employed other rules such as hyper resolution (resolution involving more than two clause at the same time) and equality reduction (replacing equivalent literals). The solver was shown to be competitive with zChaff [MMZ⁺01] (which only used unit resolution) on some families. Another solver that utilized equivalency reasoning was developed by Li [Li00]. The solver, called EqSatz, employed six inference rules aimed at deriving equivalence relations between literals and was shown to dominate other solvers on the DIMACS 32-bit parity problems [SKM97] (among others). SymChaff [Sab05], developed by Sabharwal, takes advantage of symmetry information (made explicit by the problem creator) to prune redundant parts of the search space to achieve exponential speedup.

3.6.6. Certifying SAT Algorithms

As satisfiability testing becomes vital for many applications, the need to ensure the correctness of the answers produced by SAT solving algorithms increases. In some applications, SAT algorithms are used to verify the correctness of hardware and software designs. Usually, unsatisfiability tells us that the design is free of certain types of bug. If the design is critical for safety or the success of the mission, it would be a good idea to check that the SAT solvers did not produce a buggy result.

Verifying that a SAT solving algorithm produces the right result for satisfiable instances is straightforward. We could require the SAT solving algorithm to output a satisfying assignment. The verifier then needs to check whether every clause in the instance mention at least a literal from the satisfying assignment. Verifying that a SAT solving algorithm produces the right result for unsatisfiable instances is more problematic, however. The complications are caused by the needs to make the verifying procedure simple and the “certificate” concise; see [Van02]. The main method used for showing unsatisfiability of a formula is to give a resolution proof of the empty clause from the original set of clauses.

One of the most basic certificate formats is the explicit resolution derivation proof. A certificate in this format contains the complete resolution proof of unsatisfiability (the empty clause). The proof is simply a sequence of resolutions. First of all, all variables and clauses in the original formula are indexed. Each resolution is made explicit by listing the indices of the two operands, the index of the variable to be resolved on, and the literals in the resolvent. This certificate format was referred to as %RES and was used for the verification track of the SAT’05 competition [BS05].

A closely related format called resolution proof trace (%RPT) [BS05] does not require the resolvent of each resolution to be materialized. Hence, the certificate will only list the clauses to be resolved for each resolution operation.

Zhang and Malik proposed in [ZM03] a less verbose variant which relies on the verifier’s ability to reconstruct implication graphs in order to derive learned clauses. According to this format, the certificate contains, for each learned clause

generated by the solving algorithm, the indices of all clauses that were used in the derivation of the conflict-driven clause. The verifier then has the burden of reconstructing the conflict-driven clauses that are required to arrive at the proof of the empty clause.

Another certificate format was proposed by Goldberg and Novikov in [GN03]. This format lists all conflict-driven clauses generated by the SAT solving algorithm in the order of their creation. This type of certificate employs the fact that if a learned clause C is derived from the CNF Δ , then applying unit resolution to $\Delta \wedge \neg C$ will result in a contradiction. By listing every conflict-driven clause (including the empty clause at the end) in order, the verifier may check to make sure that each conflict-driven clause can actually be derived from the set of preceding clauses (including the original formula) by using unit resolution.

3.7. Conclusions

We have discussed in this chapter various complete algorithms for SAT solving. We categorized these algorithms based on their approaches for achieving completeness: by existential quantification, by inference rules, and by search. While much work has been done in each category, nowadays, it is the search-based approach that receives the most attention because of its efficiency and versatility on many real-world problems. We presented in this chapter the standard techniques used by leading contemporary SAT solvers and some less common inference techniques studied by others. Current research in this area focuses on both theory and applications of satisfiability testing. Recently, however, there is a growing emphasis on applying a SAT solver as a general-purpose problem solver for different problem domains (see Part 3). As a result, a branch of current research focuses on finding efficient ways to encode real-world problems compactly as CNF formulas. When it comes to using a SAT solver as a general-purpose solver, efficiency is the most important issue. Consequently, techniques that are theoretically attractive may not necessarily be adopted in practice, unless they can be efficiently implemented and shown to work on a broad set of problems.

Chapter 4

Conflict-Driven Clause Learning SAT Solvers

Joao Marques-Silva, Ines Lynce, and Sharad Malik

4.1. Introduction

The decision problem for propositional logic, commonly referred to as the Boolean Satisfiability (SAT) problem, is well-known to be NP-complete [Coo71].¹ Although NP-completeness implies (under the reasonable assumption that $P \neq NP$) that any complete SAT algorithm runs in worst-case exponential time, it is also the case that SAT solvers most often defy this predicted worst-case behavior. Indeed, SAT can be viewed as a success story of computer science. From an academic curiosity in the early 90s, when solving a formula with a few hundred variables would be considered a significant success, SAT solvers have metamorphosed into highly efficient engines that routinely solve formulas with millions of variables, and which find widespread industrial deployment. Conflict-Driven Clause Learning (CDCL) SAT solving is the sole reason for this success.

The development of CDCL SAT solvers was from the outset motivated by practical applications. During the late 80s and early 90s, applications of SAT in automatic test pattern-generation (ATPG) [Lar89, Lar92] and timing analysis [MSS⁺91, SBSV96] motivated the development of clause learning and the GRASP SAT algorithm [MS95, MSS96c, MSS99]. Another development was the application of SAT to automated planning [KS92, KS96], but here the initial focus was on exploiting (incomplete) local-search SAT solvers, which reflected the strong prominence of incomplete SAT throughout the 90s [SLM92]. The initial practical success of GRASP [MSS96a] led to the inclusion of GRASP-like clause learning in SATO [Zha97], which in turn was featured in the original SAT-based model checking papers [BCCZ99, BCC⁺99]. The immediate impact of SAT-based model checking, and the performance improvements achieved with Chaff [MMZ⁺01, ZMMM01], resulted in a stream of improvements in SAT solvers, and later in SMT solvers [BSST09], which catalyzed the many applications we see today.

¹Besides the work of S. Cook, NP-completeness was investigated independently by L. Levin [Lev73].

The range of practical applications of CDCL SAT solving has continued to expand in recent years, arguably at an ever increasing pace. The practical significance of CDCL SAT solvers has also influenced the organization of a number of other automated reasoning engines, ranging from the propositional domain to the first-order logic setting, and also finding applications for reasoning about logics more expressive than first-order [GK03, Kor08, KV13, Vor14]. Moreover, CDCL SAT solvers have impacted research in several other areas. The applications of CDCL SAT solvers motivated the development of new propositional encodings [Wal00, Gen02, BB03, GN04, AM04, Sin05, ES06, Pre07, Pre09, RM09, BBR09, ANORC09, CZI10, ANORC11b, ANORC11a, ANO⁺12, OLH⁺13, Kar18, MJML14, MPS14]. The usage of CDCL SAT solvers as oracles (for the class NP) motivated extensive revisions of the algorithms for a number of problems, including maximum satisfiability [MSP07, MMSP09, ABL09, DB11, ABL13, IMM⁺14, MJML14, MDMS14, MHL⁺13, SBJ16], tackling enumeration problems [NBE12, JMSS14, PIMMS15, LPMMS16, PMJaMS18, GIL18], solving various quantification problems [JMS11, JKMSC12, RT15, JKMSC16, RS16, IPMS15, IJMS16, SWJ16, IMMS16, CLLB⁺17, LLBdLM18], and finding minimal sets [GMP08, MSJB13, MS10, Nad10, MSL11, BLMS12, MSHJ⁺13, NRS13, GLM14a, BDTK14, BK15, MPMS15, NBMS18], among others. Furthermore, CDCL SAT solvers have also led to a series of new results in propositional proof complexity, but also to the search for the automation of proof systems stronger than resolution [BKS04, PD09, AFT09, Hua10, AKS10, PD11, AFT11, IMMS17b, BBI⁺18, EN18, EGCNV18]. Given the above, it is reasonable to argue that CDCL SAT solving has become one of the mainstays of research in the general areas of constraint solving and optimization, computational logic and automated reasoning.

The purpose of this chapter is to provide an overview of the organization and practical uses of CDCL SAT solvers, but also to give an historical perspective to the key ideas that integrate CDCL SAT solvers. The chapter covers the organization of CDCL SAT solvers as instantiated in most modern tools.² Promising techniques, that have been integrated in a smaller number of solvers, will also be described. The approach taken is to describe the key ideas behind CDCL SAT solvers, providing a comprehensive range of examples that illustrate how these ideas work in practice. The chapter also provides a brief overview of the many uses of CDCL SAT solvers, some of which represent existing lines of research. For somewhat different treatments of the same subject, the interested reader is referred to a number of related overviews which have been published over the years [MS98, MSS00, ZM02, LMS02, LMS03, Mit05, CESS08, MS08, Bie08b, GKSS08, MSLM09, MZ09, Knu15, VWM15, MSM18].

The chapter is organized as follows. Section 4.2 introduces the notation used in the remainder of the chapter. Section 4.3 describes the implementation of CDCL SAT solvers. Section 4.4 outlines the ways in which CDCL SAT solvers are used in practical settings. Section 4.5 provides a glimpse of the practical and theoretical significance of CDCL SAT solving. Moreover, Section 4.6 pro-

²Compared to the first edition of the Handbook of Satisfiability, the chapter has been extensively rewritten, with the purpose of providing a more modern treatment of CDCL, taking into account relevant work over the last decade, but also aiming to provide a glimpse into the many practical successes of CDCL SAT solving.

vides a brief historical perspective on the development of CDCL SAT solvers. Section 4.7 provides additional pointers for examples of SAT solvers as well as the PySAT framework for prototyping with SAT solvers [IMMS18]. Finally, Section 4.8 summarizes the chapter but also research directions for the improvement and application of CDCL SAT solvers.

4.2. Preliminaries

This section introduces the notation and definitions used throughout. The goal is to describe variants of backtrack search algorithms, and so the definitions reflect this goal. Some notation is adapted from [BL99, BHvMW09].

A set \mathbb{V} of propositional variables is assumed. Variables will be lower case letters, with or without indices, e.g. $\{a, b, c, \dots, x_1, x_2, \dots, y_1, y_2, \dots\}$. Propositional formulas are defined inductively over \mathbb{V} , using the standard logical connectives \neg , \vee and \wedge , as follows:

1. $\mathcal{F} = x$, with $x \in \mathbb{V}$, is a propositional formula.
2. If \mathcal{F} is a propositional formula, then $(\neg\mathcal{F})$ is a propositional formula.
3. If \mathcal{F} and \mathcal{G} are propositional formulas, then $(\mathcal{F} \vee \mathcal{G})$ is a propositional formula.
4. If \mathcal{F} and \mathcal{G} are propositional formulas, then $(\mathcal{F} \wedge \mathcal{G})$ is a propositional formula.

The definition can be extended to consider other logical connectives.

Most SAT solvers operate on the more restricted representation of Conjunctive Normal Form (CNF) formulas. Each clause c_i is defined as a set of literals. A literal is either a variable $x \in \mathbb{V}$ or its complement \bar{x} .³ We also use $var(l_i)$ to denote the variable associated with some literal l_i . A set of clauses will be interpreted as a conjunction of clauses. A clause will be interpreted as a disjunction of literals. Throughout this chapter, both representations will be used.

Example 4.2.1 (CNF Formula). An example of a CNF formula is:

$$\mathcal{F} = \{\{a, \bar{b}\}, \{b, c\}, \{b, \bar{d}\}, \{\bar{a}, \bar{c}, d\}\} \quad (4.1)$$

The alternative clausal representation is:

$$\mathcal{F} = (a \vee \bar{b}) \wedge (b \vee c) \wedge (b \vee \bar{d}) \wedge (\bar{a} \vee \bar{c} \vee d) \quad (4.2)$$

Propositional variables can be assigned a propositional value, taken from $\{0, 1\}$. However, in the context of search algorithms for SAT, variables may also be *unassigned*. As a result, assignments to propositional variables are defined as a function $\nu : \mathbb{V} \rightarrow \{0, u, 1\}$, where u denotes an *undefined* value used when a variable has not been assigned a value in $\{0, 1\}$. (ν could also be defined as a partial map from \mathbb{V} to $\{0, 1\}$, but we opt to use the additional value u .) Given an assignment ν , if all variables are assigned a value in $\{0, 1\}$, then ν is referred to as a *complete assignment*. Otherwise it is a *partial assignment*.

Given a truth assignment ν , the value taken by a propositional formula, denoted \mathcal{F}^ν , is defined inductively as follows:

³To keep the notation as simple as possible, we will represent negative literals by \bar{x} instead of the often used notation $\neg x$.

1. If $\mathcal{F} = x$, with $x \in \mathbb{V}$, then $\mathcal{F}^\nu = \nu(x)$.
2. If $\mathcal{F} = (\neg\mathcal{G})$, then

$$\mathcal{F}^\nu = \begin{cases} 0 & \text{if } \mathcal{G}^\nu = 1 \\ 1 & \text{if } \mathcal{G}^\nu = 0 \\ u & \text{otherwise} \end{cases}$$

3. If $\mathcal{F} = (\mathcal{E} \vee \mathcal{G})$, then

$$\mathcal{F}^\nu = \begin{cases} 1 & \text{if } \mathcal{E}^\nu = 1 \text{ or } \mathcal{G}^\nu = 1 \\ 0 & \text{if } \mathcal{E}^\nu = 0 \text{ and } \mathcal{G}^\nu = 0 \\ u & \text{otherwise} \end{cases}$$

4. If $\mathcal{F} = (\mathcal{E} \wedge \mathcal{G})$, then

$$\mathcal{F}^\nu = \begin{cases} 1 & \text{if } \mathcal{E}^\nu = 1 \text{ and } \mathcal{G}^\nu = 1 \\ 0 & \text{if } \mathcal{E}^\nu = 0 \text{ or } \mathcal{G}^\nu = 0 \\ u & \text{otherwise} \end{cases}$$

The definition of value of a formula applies to arbitrary propositional formulas, and so also to CNF formulas. An assignment that satisfies a propositional formula is referred to as a *model* (or as a *satisfying assignment*).

The assignment function ν will also be viewed as a set of tuples (x_i, v_i) , with $v_i \in \{0, 1\}$. Adding a tuple (x_i, v_i) to ν corresponds to assigning v_i to x_i , such that $\nu(x_i) = v_i$. Removing a tuple (x_i, v_i) from ν , with $\nu(x_i) \neq u$, corresponds to assigning u to x_i . With a mild abuse of notation, we use $x_i = v_i$ when $\nu(x_i) = v_i$ and ν is clear from the context. Moreover, variable assignments will also be represented as (true) literals. Concretely, if x_i is used, then it indicates that $\nu(x_i) = 1$, whereas if \bar{x}_i is used, then it indicates that $\nu(x_i) = 0$.

Clauses are characterized as *falsified*, *satisfied*, *unit* or *unresolved*. A clause is falsified if all its literals are assigned value 0. A clause is satisfied if at least one of its literals is assigned value 1. A clause is unit if all literals but one are assigned value 0, and the remaining literal is unassigned. Finally, a clause is unresolved if it is neither unsatisfied, nor satisfied, nor unit.

A key procedure in SAT solvers is the *unit clause rule* [DP60]: if a clause is unit, then its sole unassigned literal must be assigned value 1 for the clause to be satisfied. The iterated application of the unit clause rule is referred to as *unit propagation* or *Boolean constraint propagation* (BCP) [ZM88]. In modern CDCL solvers, as in most implementations of the DPLL algorithm [DP60, DLL62], logical consequences are derived with unit propagation. Unit propagation is applied after each branching step but also during preprocessing,⁴ and is used for identifying variables which must be assigned a specific Boolean value. If an unsatisfied clause is identified, a *conflict* condition is declared, and the algorithm needs to backtrack, and may implement some sort of conflict analysis procedure.

Example 4.2.2. Consider the following formula:

$$\begin{aligned} \mathcal{F} &= \mathbf{c}_1 \wedge \mathbf{c}_2 \wedge \mathbf{c}_3 \wedge \mathbf{c}_4 \\ &= (a) \wedge (\bar{a} \vee b) \wedge (\bar{a} \vee c) \wedge (\bar{b} \vee \bar{c} \vee d) \end{aligned}$$

⁴A branching step is a choice of a variable and a propositional value to assign to the variable.

The operation of unit propagation in this example works as follows. Clause \mathbf{c}_1 is unit. As a result, a must be assigned value 1. Moreover, since $a = 1$, then the clauses \mathbf{c}_2 and \mathbf{c}_3 are also unit (since the literal $\bar{a} = 0$). Thus, the assignments $b = 1$ and $c = 1$ are necessary. Finally, because of these two assignments, then clause \mathbf{c}_4 is also unit, and so the assignment $d = 1$ is also necessary.

In CDCL SAT solvers, each variable x_i is characterized by a number of properties, including the *value*, the *antecedent* (or *reason*) and the *decision level*, denoted respectively by $\nu(x_i) \in \{\mathbf{0}, \mathbf{u}, 1\}$ (introduced above), $\alpha(x_i) \in \mathcal{F} \cup \{\mathbf{n}, \mathfrak{d}\}$ (where \mathbf{n}, \mathfrak{d} are special symbols introduced below), and $\delta(x_i) \in \{\mathbf{u}, 0, 1, \dots, |X|\}$. A variable x_i that is assigned a value as the result of applying the unit clause rule is said to be *implied*. The unit clause \mathbf{c}_j used for implying variable x_i is said to be the antecedent of x_i , $\alpha(x_i) = \mathbf{c}_j$. For variables that are decision variables the antecedent is \mathfrak{d} and the decision level is the depth of the search tree associated with that decision variable. For unassigned variables, the antecedent is set to \mathbf{n} and the decision level is set to \mathbf{u} . Hence, antecedents are only assigned a clause identifier for variables whose value is implied by other assignments. Literals inherit decision level and antecedent information from the corresponding variable. For assigned variables, the value of a literal x_i is given by the value of variable x_i and the value of a literal \bar{x}_i is given by $1 - \nu(x_i)$. For unassigned variables, the value of any literal is given by $\nu(x_i) = \nu(\bar{x}_i) = \mathbf{u}$.

The decision level of a literal l_i , $\delta(l_i)$ is defined as the decision level of corresponding variable x_i , $\delta(x_i)$, if $l_i = x_i$ or $l_i = \neg x_i$. The decision level of a variable x_i (either if implied or if it is a decision variable) denotes the depth of the decision tree at which the variable is assigned a value in $\{0, 1\}$. The decision level for an unassigned variable x_i is \mathbf{u} . Moreover, $\delta(x_i) = \mathbf{u}$ when $\alpha(x_i) = \mathbf{n}$. The decision level associated with variables used for branching steps (i.e. *decision assignments*) is specified by the search process, and denotes the current depth of the *decision stack*. Hence, a variable x_i associated with a decision assignment is characterized by having $\alpha(x_i) = \mathfrak{d}$, $\delta(x_i) > 0$, and $\nu(x_i) \neq \mathbf{u}$. For a variable that is not a decision assignment, the decision level is defined as follows:

$$\delta(l_i) = \begin{cases} \mathbf{u} & \text{if } \alpha(l_i) = \mathbf{n} \\ \max(\{\mathbf{0}\} \cup \{\delta(l_j) \mid l_j \in \text{lits}(\alpha(l_i)) \setminus \{l_i\}\}) & \text{otherwise} \end{cases} \quad (4.3)$$

i.e. the decision level of an implied literal is either the highest decision level of the implied literals in a non-unit clause, or it is 0 if the antecedent is unit, i.e. there are no literals in $\alpha(l_i)$ other than l_i . The notation $x_i = v@d$ is used to denote that $\nu(x_i) = v$ and $\delta(x_i) = d$. Finally, the notation $@d$ may be used just to identify the decision level of some anonymous literal.

Example 4.2.3 (Decision Levels & Antecedents). Consider the CNF formula:

$$\begin{aligned} \mathcal{F} &= \mathbf{c}_1 \wedge \mathbf{c}_2 \wedge \mathbf{c}_3 \\ &= (x_1 \vee \bar{x}_4) \wedge (x_1 \vee x_3) \wedge (\bar{x}_3 \vee x_2 \vee x_4) \end{aligned}$$

Assume that the decision assignment is $x_4 = 0@1$. Unit propagation yields no additional implied assignments. Assume the second decision is $x_1 = 0@2$. Unit propagation yields the implied assignments $x_3 = 1@2$ and $x_2 = 1@2$. Moreover, $\alpha(x_3) = \mathbf{c}_2$ and $\alpha(x_2) = \mathbf{c}_3$.

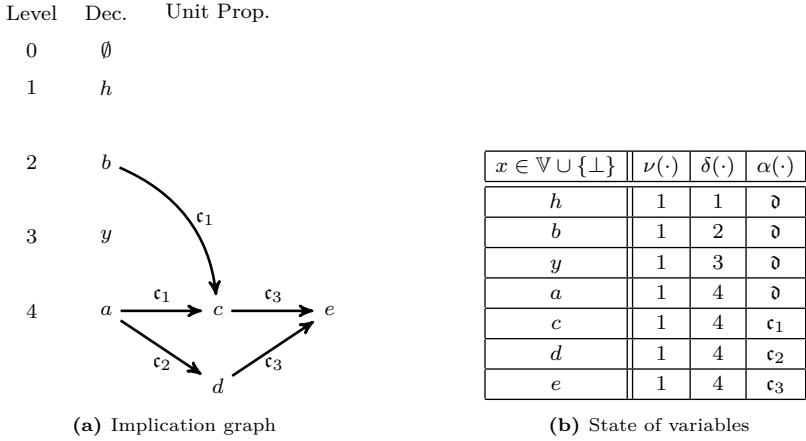

Figure 4.1. Implication graph for example 4.2.4

During the execution of a search-based SAT solver (which will be detailed later in this chapter), assigned variables as well as their antecedents define a directed acyclic graph $I = (V_I, E_I)$, referred to as the *implication graph* [MS95, MSS96c].

The vertices in the implication graph are defined by all assigned variables and one special node \perp , $V_I \subseteq \mathbb{V} \cup \{\perp\}$. The edges in the implication graph are obtained from the antecedent of each assigned variable: if $c_j = \alpha(x_i)$, then there is a directed edge from each variable in c_j , other than x_i , to x_i . If unit propagation yields an falsified clause c_j , then a special vertex \perp is used to represent the unsatisfied clause. In this case, the antecedent of \perp is defined by $\alpha(\perp) = c_j$.

Example 4.2.4 (Implication Graph without Conflict). Consider the CNF formula:

$$\begin{aligned} \mathcal{F}_1 &= c_1 \wedge c_2 \wedge c_3 \\ &= (\bar{a} \vee \bar{b} \vee c) \wedge (\bar{a} \vee d) \wedge (\bar{c} \vee \bar{d} \vee e) \end{aligned} \quad (4.4)$$

Assume the decision assignment $b = 1@2$. Moreover, assume that the current decision assignment is $a = 1@4$. The resulting implication graph is shown in figure 4.1.⁵

Example 4.2.5 (Implication Graph with Conflict). Consider the CNF formula:

$$\begin{aligned} \mathcal{F}_2 &= c_1 \wedge c_2 \wedge c_3 \wedge c_4 \wedge c_5 \wedge c_6 \\ &= (\bar{a} \vee \bar{b} \vee c) \wedge (\bar{a} \vee d) \wedge (\bar{c} \vee \bar{d} \vee e) \wedge (\bar{h} \vee \bar{e} \vee f) \wedge (\bar{e} \vee g) \wedge (\bar{f} \vee \bar{g}) \end{aligned} \quad (4.5)$$

Assume decision assignments $h = 1@1$, $b = 1@2$ and $y = 1@3$. Moreover, assume that the current decision assignment is $a = 0@4$. The resulting implication graph, that takes into account unit propagation at decision level 4, is shown in figure 4.2, and yields a conflict because clause $(\bar{f} \vee \bar{g})$ becomes falsified.

⁵To keep the notation as simple as possible, all variables are assigned value 1 in the examples, either as decision assignments or as implied assignments. A few exceptions will be noted.

Algorithm 1: The DPLL Algorithm

It should be observed that the notation introduced above is relevant for describing the operation of a modern CDCL SAT solver. A DPLL-like SAT solver usually manipulates significantly less information.

The high-level organization of DPLL [DLL62] is shown in Algorithm 1.

Finally, the original justification for the DPLL algorithm was the propositional resolution operation [DP60]:⁶

$$\frac{x \vee \alpha \quad \bar{x} \vee \beta}{\alpha \vee \beta} \tag{4.6}$$

⁶Robinson’s well-known resolution principle for first-order logic was proposed at a later date [Rob65].

Resolution is a complete decision procedure for CNF formulas [DP60], but impractical in practice. The DPLL algorithm represented an attempt at devising a practically effective solution based on resolution [DLL62]. For historical reasons, the acronym DPLL (Davis-Putnam-Logemann-Loveland) reflects the origins of the DPLL algorithm.

4.3. Implementing CDCL SAT Solvers

This section describes the organization of CDCL SAT solvers, starting from the implementation of DPLL outlined in the previous section. The section is broadly organized into two main parts. The first part covers the CDCL techniques that are commonly employed by most modern CDCL SAT solvers. The second part covers other less used techniques.

4.3.1. Organization of a CDCL SAT Solver

The CDCL SAT algorithm shares similarities with the standard backtracking search procedure also used in the DPLL algorithm, where unit propagation is executed after each decision assignment (which creates a new decision level). However, a few fundamental differences exist. First, backtracking can be non-chronological and be related with learning clauses from conflicts [MS95, MSS96c, MSS99]. Second, backtracking occurs after every conflict [MMZ⁺01, ZMMM01]. Third, the algorithm may decide to *restart* the search from the first decision level [GSC97, GSK98, GSCK00, BMS00]. Furthermore, there are a few additional differences with respect to DPLL, in that learned clauses may eventually be deleted, and highly efficient (lazy) data structures are used. The top-level organization of the CDCL algorithm is shown in Algorithm 2. The following sections detail the differences of CDCL-like algorithms with respect to the DPLL algorithm.

4.3.1.1. Clause Learning

This section provides an overview of one of the hallmarks of CDCL SAT solvers, namely *clause learning*. During backtrack search, clauses are learned after falsified clauses are identified, using a procedure referred to as *conflict analysis* [MS95, MSS96c, MSS96b, MSS96a, MSS99].

4.3.1.1.1. Conflict Analysis. Given a falsified clause, conflict analysis iteratively traces antecedents of variables assigned at the current decision level, and records dependencies of variables assigned at smaller decision levels. The algorithm operates as follows. Variables assigned at the current decision level are analyzed in a first-in first-out fashion (thus being manipulated through a queue), ensuring that a variable is analyzed only after all variables it implies have been analyzed. At each step, the head of the queue is extracted, and its antecedent analyzed. Any literals assigned at decision levels smaller than the current one are added to (i.e. recorded in) the clause being learned. The antecedent tracing procedure terminates when the decision variable for the current decision level is visited. Clearly,

```

Input : CNF Formula  $\mathcal{F}$ 
Output: Outcome  $st$ 

CDCL ( $\mathcal{F}$ )
  DLevel  $\leftarrow$  0
  if not UnitPropagation() then
    return false
  while not AllVariablesAssigned() do
    DLevel  $\leftarrow$  DLevel + 1
    (var, val)  $\leftarrow$  PickBranchVariable()
    Assign(var, val, DLevel,  $\varnothing$ )
    while not UnitPropagation() do
      if DLevel == 0 then
        return false
      BLevel  $\leftarrow$  ConflictAnalysis()
      Backtrack(BLevel)
      DLevel  $\leftarrow$  BLevel
      if TimeToRestart() then
        Backtrack(0)
        DLevel  $\leftarrow$  0
  return true

```

Algorithm 2: The CDCL Algorithm**Table 4.1.** Execution of conflict analysis procedure

Step	Var Queue	Extract Var	Antecedent	Recorded Lits	Added to Queue
0	–	\perp	c_6	\emptyset	$\{f, g\}$
1	$[f, g]$	f	c_4	$\{\bar{h}\}$	$\{e\}$
2	$[g, e]$	g	c_5	$\{\bar{h}\}$	\emptyset
3	$[e]$	e	c_3	$\{\bar{h}\}$	$\{c, d\}$
4	$[c, d]$	c	c_1	$\{\bar{h}, \bar{b}\}$	$\{a\}$
4	$[d, a]$	d	c_2	$\{\bar{h}, \bar{b}\}$	\emptyset
5	$[a]$	a	\varnothing	$\{\bar{h}, \bar{b}, \bar{a}\}$	–
6	$[]$	–	–	$\{\bar{h}, \bar{b}, \bar{a}\}$	–

the conflict analysis procedure runs in worst-case linear time in the number of literals.

Example 4.3.1. For the implication graph from Example 4.2.5, the conflict analysis procedure is illustrated in Table 4.1. At step 0, the initialization step, the falsified clause (c_6) is analyzed and its variables, f and g , both assigned at decision level 4, are added to the queue of variables to visit. At step 1, the top of the queue is (for example) f . The antecedent of f is c_4 . As a result, the literal \bar{h} is recorded, and the variable e is added to the queue. The same process is repeated for steps 2 to 6. As can be observed, all variables assigned at the current decision level are analyzed in order. Any recorded literals are assigned at decision levels smaller than the current one. Hence, in this case, the learned clause is $(\bar{h} \vee \bar{b} \vee \bar{a})$. For this example, the variables and antecedents that are traced are highlighted in Figure 4.3.

Although CDCL SAT solvers implement the conflict analysis procedure as

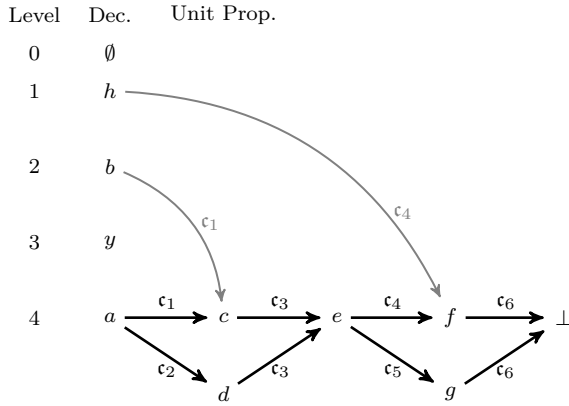

Figure 4.3. Traced antecedents during conflict analysis

Figure 4.4. Explaining a learned clause with resolution steps

outlined above, there is a tight relationship with resolution, in that learned clauses can be explained with sequences of resolution steps. Concretely, each learned clause obtained from an implication sequence can be explained by *linear input regular resolution* [VG11] (also referred to as trivial resolution steps [BKS04]). As a result, there is a direct mapping between the conflict analysis procedure and linear input regular resolution steps.

Example 4.3.2. Regarding Example 4.3.1, the sequence of resolution steps that explains the learned clause $(\bar{h} \vee \bar{b} \vee \bar{a})$ is shown in Figure 4.4.

A key observation is that although conflict analysis can be explained with resolution steps, to our best knowledge there exists no other approach for automating resolution that is as effective as the conflict analysis procedure devised for CDCL SAT solvers. Even the DPLL algorithm [DLL62, DP60] corresponds to a weaker proof system, i.e. tree-like resolution [BKS04].

Table 4.2. First UIP clause learning

Step	Var Queue	Extract Var	Antecedent	Recorded Lits	Added to Queue
0	–	\perp	c_6	\emptyset	$\{f, g\}$
1	$[f, g]$	f	c_4	$\{\bar{h}\}$	$\{e\}$
2	$[g, e]$	g	c_5	$\{\bar{h}\}$	\emptyset
3	$[e]$	e	c_3	$\{\bar{h}, \bar{e}\}$	\emptyset
6	\square	–	–	$\{\bar{h}, \bar{e}\}$	–

**Figure 4.5.** Resolution steps with first UIP learning

4.3.1.1.2. Unique Implication Points. The basic clause learning algorithm can be further optimized by taking into account the *structure* of the conflicting implication sequence. As can be observed in the execution of the clause learning procedure in Table 4.1, in step 3 there exists only one variable to trace, concretely e . This variable is referred to as a *unique implication point* (UIP) [MS95, MSS96a, MSS96b, MSS96c, MSS99]. UIPs exhibit a number of important properties. For the implication graph restricted to variables assigned at the current decision level, a UIP is a *dominator* of the decision variable with respect to the conflict node \perp . The same assignment to any UIP guarantees that the same conflict will be reproduced. In modern CDCL SAT solvers, clause learning stops at the first UIP [MMZ⁺01, ZMMM01]. Nevertheless, conflict analysis need not stop at the first UIP, and initial CDCL SAT solvers would learn a clause at each UIP [MS95, MSS96a, MSS99]. This capability of conflict analysis to learn multiple clauses given UIPs is not available in most modern CDCL SAT solvers, despite recent promising results [SSS12].

Example 4.3.3. Regarding Example 4.2.5, with basic conflict analysis shown in Example 4.3.1, e is a UIP. In modern CDCL SAT solvers, the conflict analysis algorithm terminates when this first UIP is reached. In this case, the algorithm learns the clause $(\bar{h} \vee \bar{e})$. The sequence of resolution steps is shown in Figure 4.5. It should be noted that, if conflict analysis were to consider more UIPs, the clause $(\bar{a} \vee \bar{b} \vee e)$ would be learned for UIP a , the decision variable.

4.3.1.1.3. Non-Chronological Backtracking. Learned clauses enable SAT solvers to perform non-chronological backtracking [MS95, MSS96c, MSS99]. A wide range of modern CDCL SAT solvers backtrack (often non-chronologically) after each conflict. This is shown in Algorithm 2. The backtracking decision level is defined as the largest decision level of the literals that remain assigned after conflict analysis. It is immediate to conclude that clause learning at the first UIP

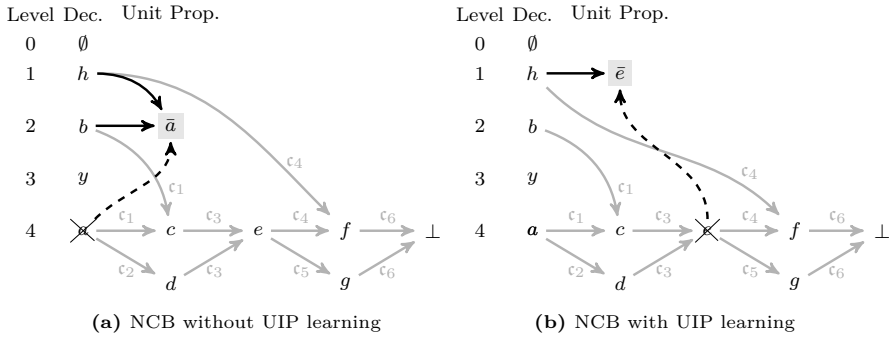

Figure 4.6. Non-chronological backtracking (NCB)

yields the most aggressive backtracking decision level [ABH⁺08]. Indeed, extending clause learning to any other UIP can only increase the number of traced literals, and so can only maintain or increase the backtracking decision level.

Starting with the SAT solver Chaff, the non-chronological backtracking step would be taken after each conflict [MMZ⁺01]. This is in contrast with the backtracking strategy used in the GRASP SAT solver [MS95, MSS96c, MSS99], where the non-chronological backtracking step would be taken *only* after the two assignments to a given decision variable had been considered. The backtracking strategy used in GRASP, improved with heuristics to decide when to apply it, has become popular in recent SAT solvers [NR18, MB19], being referred to as a *chronological backtracking* step when implementing *non-chronological backtracking*.

Example 4.3.4. For Example 4.3.1, the learned clause is $(\bar{h} \vee \bar{b} \vee \bar{a})$. After conflict analysis, at decision level 4, the clause becomes unit, due to a becoming unassigned. The largest decision level is 2, and so the CDCL algorithm backtracks to decision level 2, where the learned clause is still unit and implies the assignment $a = 0$. In case conflict analysis stops at the first UIP (see Example 4.3.3), then the learned clause is $(\bar{h} \vee \bar{e})$, the CDCL algorithm backtracks to decision level 1, and the learned clause implies the assignment $e = 0$. As can also be observed from the first UIP clause, exploiting UIPs enables more aggressive backtracking, in this case to decision level 1. Backtracking with and without UIP learning is shown in Figure 4.6.

4.3.1.1.4. Learned Clause Minimization. Although the conflict analysis procedure has remained unchanged since it was first proposed [MS95, MSS96c, MSS99], improvements have been made on how to make the learned clauses more effective in practice, concretely by filtering literals in the learned clause that can be deemed irrelevant. This section overviews two approaches for removing redundant literals from a learned clause [SB09]. One approach exploits the concept of self-subsuming resolution [SP04]. The other approach traces antecedents at decision levels lower than the current one, aiming at discovering subsets of literals in the learned clause that are implied by the other literals.

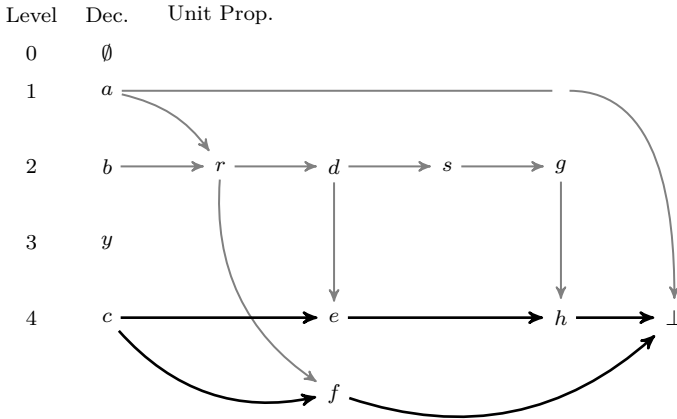

Figure 4.7. Clause minimization example

The first approach for learned clause minimization, referred to as *local minimization*, consists of applying self-subsumption resolution⁷ among the literals in the learned clause, aiming at identifying literals that can be dropped from the learned clause.

A more sophisticated (and more time-consuming) procedure, referred to as *recursive minimization*, traverses the implication graph at decision levels *smaller* than the current one:

1. Given a learned clause, pick some candidate literal, and mark all the other literals.
2. Recursively trace antecedents, starting from candidate, until marked literals or decision variables are reached.
3. If only marked literals are visited, then candidate can be declared redundant.
4. Repeat for all other literals in clause (except for decision literals).

Some practical implementations approximate exact recursive minimization [SB09]. Moreover, existing implementations ensure that the amortized run time is linear in the size of the implication graph (and so linear on the number of variables). Additional improvements to conflict clause minimization have been proposed in recent years [VG09, LLX⁺17].

The relationship of local and recursive learned clause minimization with resolution is immediate. Both clause minimization schemes identify additional resolution steps which enable the learned clause to be simpler.

Example 4.3.5. Consider the following CNF formula:

$$\begin{aligned}
 \mathcal{F} &= c_1 \wedge c_2 \wedge c_3 \wedge c_4 \wedge c_5 \wedge c_6 \wedge c_7 \wedge c_8 \\
 &= (\bar{a} \vee \bar{b} \vee r) \wedge (\bar{r} \vee d) \wedge (\bar{c} \vee \bar{d} \vee e) \wedge (\bar{c} \vee \bar{d} \vee f) \wedge (\bar{d} \vee s) \wedge \\
 &\quad (\bar{s} \vee g) \wedge (\bar{e} \vee \bar{g} \vee h) \wedge (\bar{f} \vee \bar{h} \vee \bar{a})
 \end{aligned}$$

⁷Given $(x \vee \alpha)$ and $(\bar{x} \vee \alpha \vee \beta)$, self-subsuming resolution produces the clause $(\alpha \vee \beta)$.

Table 4.3. Execution of recursive minimization

Target	Curr Var	Marked	Unmarked	Vars to Trace	Action
g	g	$\{a, d, r, c\}$	\emptyset	$[s]$	–
g	s	$\{a, d, r, c\}$	\emptyset	$[d]$	–
g	d	$\{a, d, r, c\}$	\emptyset	\square	d marked, skip
g	–	$\{a, d, r, c\}$	\emptyset	\square	no unmarked vars; \therefore drop g
d	d	$\{a, r, c\}$	\emptyset	$[r]$	–
d	r	$\{a, r, c\}$	\emptyset	\square	r marked, skip
d	–	$\{a, r, c\}$	\emptyset	\square	no unmarked vars; \therefore drop d
r	r	$\{a, c\}$	\emptyset	$[a, b]$	–
r	a	$\{a, c\}$	\emptyset	$[c]$	a marked
r	b	$\{a, c\}$	$\{b\}$	\square	b decision & unmarked
r	–	$\{a, c\}$	$\{b\}$	\square	unmarked vars; \therefore keep r
a, c	–	–	\emptyset	\square	a, c decision variables; keep both

Consider the sequence of decisions: $\langle a = 1, b = 1, y = 1, c = 1 \rangle$ and the resulting implication graph, as shown in Figure 4.7. Conflict analysis yields the (first UIP) clause: $(\bar{a} \vee \bar{g} \vee \bar{d} \vee \bar{r} \vee \bar{c})$. Local minimization exploits the fact that self-subsuming resolution between the learned clause and \mathbf{c}_2 reduces the number of literals by one, thus producing: $(\bar{a} \vee \bar{g} \vee \bar{r} \vee \bar{c})$. Recursive minimization enables one further simplification, producing the final minimized clause: $(\bar{a} \vee \bar{r} \vee \bar{c})$. Alternatively, the sole execution of recursive minimization is summarized in Table 4.3. The literal on variable g is dropped because tracing only reaches variable d , which is marked (as it is included in the learned clause). The same applies to d . The literal on variable r cannot be dropped, since tracing reaches b , which is not marked. The literals of variables a and c cannot be dropped, since these are decision variables. Moreover, Figure 4.8 summarizes clause learning and also local and recursive minimization. Figure 4.8a, Figure 4.8b and Figure 4.8c show, respectively, the resolution derivation for the original learned clause, the result with local minimization, and the result with recursive minimization.

4.3.1.2. Search Restarts

In the late 90s, researchers observed that *branching randomization* would cause DPLL-like SAT solvers to exhibit heavy-tailed behavior on satisfiable formulas [GSC97, GSK98]. Concretely, the run time of a DPLL-like SAT solver on some satisfiable formulas would be small with high probability, but also the probability mass corresponding to large run times would be non-negligible, i.e. the run time distribution on satisfiable instances exhibited a heavy tail [GSC97, GSK98, GSCK00, GS09]. Given this behavior, a natural solution for improving the run time of DPLL-like SAT solvers on satisfiable instances would be to exploit branching randomization and apply a policy to restart the search often, e.g. after a number of conflicts.

Example 4.3.6 (Search Restarts). The example sketched in Figure 4.9 illustrates the execution of restarts. After a cutoff, the search is restarted. For completeness,

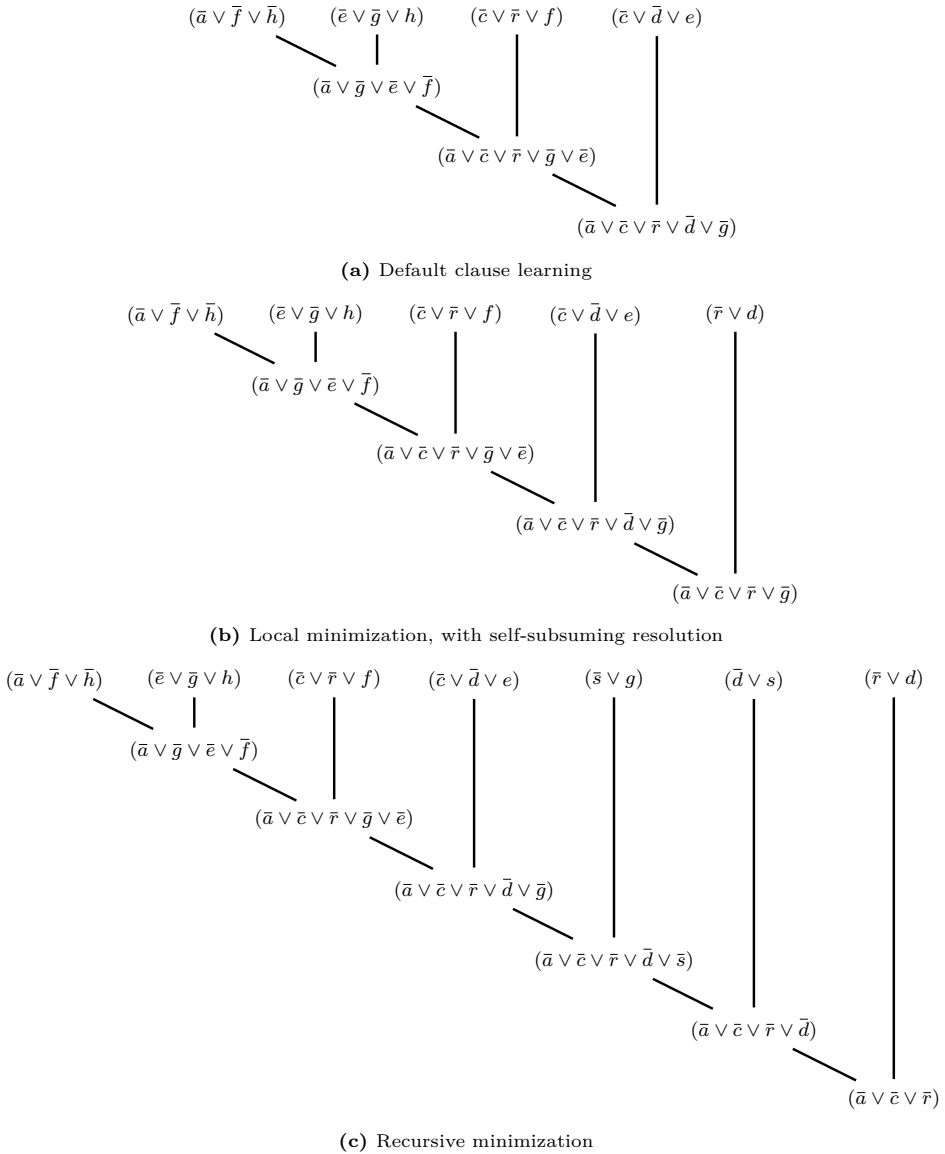

Figure 4.8. Learned clause minimization for Example 4.3.5

an increase in cutoff can be used.

The idea of search restarts was shown to work effectively with clause learning [BMS00, LBMS01], and eventually became an integral part of modern CDCL SAT solvers [MMZ⁺01, ES03, Bie08b]. More importantly, and from a theoretical perspective, it has been shown that clause learning and search restarts correspond to a proof system as powerful as general resolution, and stronger than the original

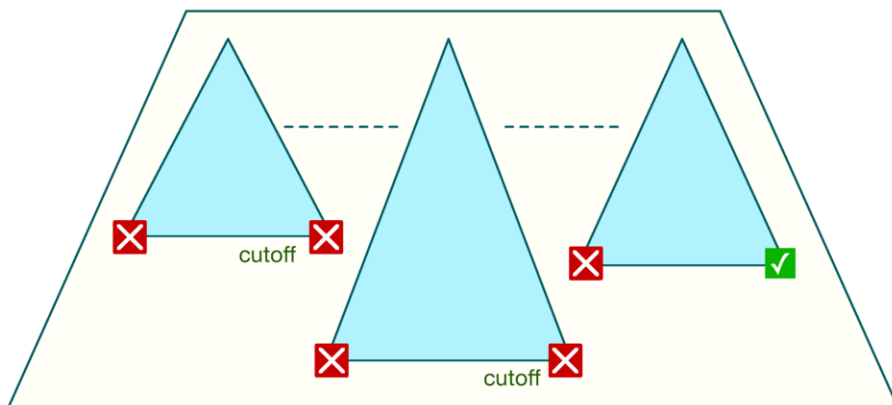

Figure 4.9. Operation of search restarts

DPLL proof system [PD09, PD11]. From a more practical perspective, branching randomization is still available in most modern CDCL SAT solvers, but mostly not used.

4.3.1.2.1. Selecting a Restart Sequence. In recent years, a number of authors proposed and evaluated different restart sequences [Hua07, Bie08b, Bie08a, SI09, BF15a]. One example are the so-called *Luby restarts* due to Luby, Sinclair and Zuckerman [LSZ93], and proposed in the CDCL SAT solver TiniSAT [Hua07]. In more recent work, different restart strategies are mixed, attempting to exploit different solver behavior between satisfiable and unsatisfiable instances [Oh15].

4.3.1.2.2. Ensuring Search Completeness. A possible limitation of search restarts is solver completeness. For example, always restarting after a fixed number of conflicts will yield an incomplete algorithm, which may be unable to solve some instances. This limitation was acknowledged in earlier work [GSK98, BMS00], and different solutions proposed. A simple solution is to increase the number of conflicts in between restarts [GSK98, BMS00]. Another solution is to ensure that enough learned clauses are kept in between restarts [LBMS01].

4.3.1.2.3. Phase Saving. A more recent technique is to keep the branching phase after the search is restarted [PD07]. Most modern CDCL SAT solvers implement the phase saving technique [Bie08a, AS09].

4.3.1.3. Deletion of Learned Clauses

From the outset [MS95, MSS96c], clause learning was proposed under the assumption that not all learned clauses would be kept, and that some of these clauses would eventually be deleted. With the improvements in performance from the early 00s [MMZ⁺01], policies for deciding which clauses to delete became paramount [GN02]. Clauses are deleted on a regular basis after some number of conflicts. The state of the art is to use the Literal Block Distance (LBD) clause quality metric to decide which clauses to delete [AS09]. Given a learned clause,

its literals are partitioned into decision levels. The number of decision levels is the LBD metric. Clauses with higher LBD metric are less likely to be relevant for future conflicts, and so can be considered for deletion. Moreover, the LBD metric has also been applied for deciding when to minimize clauses (since clauses with small LBD metric are more likely not to be deleted) [Bie13], and to decide the restart schedule [AS12, BF15a].

4.3.1.4. Conflict-Driven Branching

For a satisfiable instance, perfect branching would enable finding a satisfying assignment without conflicts, e.g. it would suffice to pick the variables and assignments from an existing model (if it were somehow known). Unfortunately, many instances are unsatisfiable and, even for the satisfiable instances, it seems fairly unlikely that a solver would be able to find the perfect way to branch.

Similarly to clause learning, which is only applied in the presence of conflicts, modern branching mechanisms aim to promote conflicts. The best known branching strategy is VSIDS (Variable State Independent Decaying Sum) [MMZ⁺01]. Over the years variants have been proposed [GN02], but all similar in spirit to VSIDS (and this is one critical contribution to the success of CDCL SAT solving). (See [BF15b] for a fairly recent account of branching heuristics.) The original VSIDS branching strategy can be summarized as follows:

1. A counter is associated with each variable.
2. After a clause is learned, the counters of the variables used for deriving the clause are incremented.
3. Branching consists of picking the unassigned variable with the highest counter, with ties broken randomly.
4. Counters are divided by a constant on a regular basis.

4.3.1.5. Lazy Data Structures

One additional ingredient for modern CDCL SAT solvers are lazy data structures. Modern CDCL SAT solvers can learn many clauses with a large number of literals. For these clauses, the classical data structure, associating a reference from each variable to each clause containing a literal in that variable, was effectively too slow to manage [MSS96c, MSS99]. An elegant solution is to consider lazy data structures, that do not maintain so many references [ZS00]. The most significant of these solutions is the watched literals data structure [MMZ⁺01].

Example 4.3.7 (Watched Literals). The example in Figure 4.10 will be used as a running example to describe the operation of watched literals. The clause c_t contains eight literals, named A, B, . . . , H, such that literal C is assigned value 0 at decision level 0, literal H is assigned value 0 at decision level 1, and literals B and D are assigned value 0 at decision level 2. (In general, shaded boxes denote assigned 0-valued literals.) After unit propagation at decision level 2, this clause c_t is unresolved with four literals still unassigned, concretely A, D, F and G.

The watched literals data structure is organized as follows [MMZ⁺01]:

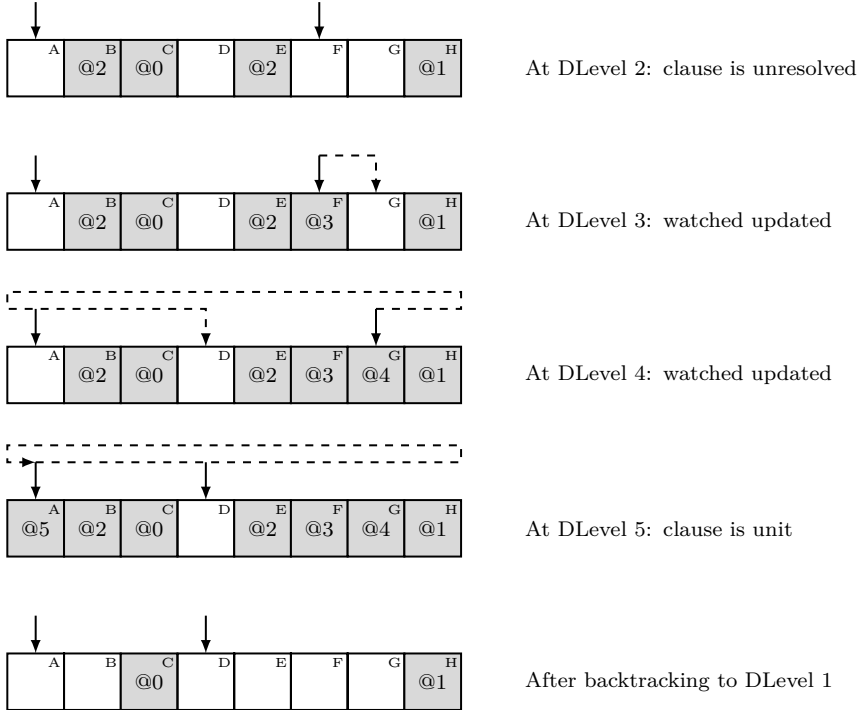

Figure 4.10. Watched literals

1. For each clause, *exactly* two unassigned literals are watched, using two *watch references*. For the running example, at decision level 2, the watch references point to the literals A and F.
2. The clause's state is only updated when one of the watched literals is assigned. If the watched literal is satisfied, nothing more is done with respect to this clause. If the literal is falsified, then the clause is traversed in search for one non-false literal that is not already being watched. For the running example, at decision level 3, since the literal in F is assigned, then the unassigned literal in G becomes watched. At decision level 4, it is necessary to traverse most of the clause's literals to conclude that the next literal to watch is D. Finally, at decision level 5, the literal in A becomes assigned. This results in all of the clause's literals to be traversed in search for another non-watched unassigned literal. In this case, there is none, and so all literals must be traversed, and the clause is declared unit.
3. When backtracking, the watched literals information is *not* updated. The ability to leave watch references unchanged when backtracking is arguably one of the most significant features of the watched literal data structure.

When a clause becomes satisfied the simplest solution is to leave the watch references untouched. It is possible to conceive mechanisms for *parking* the watch

references, such that these become unparked when the clause is no longer satisfied. Moreover, as Example 4.3.7 hints at, at each decision level, the worst-case amortized run time of updating the watched literals in a clause is linear in the clause's size. This is true if the watch references operate in circular mode (as shown in Example 4.3.7) and it is optimal [Gen13]. Some other ways of implementing watched literals (e.g. in MiniSat [ES03]) are known not to be optimal.

Some solvers implement dedicated data structures for specific types of clauses. For example, binary clauses can be represented as direct implications, which reduces not only the memory footprint, but also the overhead involved. Moreover, in many practical settings, binary clauses account for a significant percentage of the total number of clauses.

4.3.2. Additional Techniques

A number of promising techniques have been under active development in recent years, but do not yet find widespread use. An ongoing line of work, of key importance in some settings is preprocessing of CNF formulas and, more recently inprocessing [JHB12], which includes among others the blocked clause elimination technique [JBH10]. Additional recent efforts include exploiting machine learning techniques to optimize the branching heuristic [LGPC16a, LGPC16b] and more recently the restart strategy [LOM⁺18], an improved learned clause minimization procedure [LLX⁺17], and the use in some settings of GRASP's non-chronological backtracking strategy [NR18, MB19]. Finally, some solvers [SNC09, MHB12, Bie13] implement gaussian elimination [WvM98], with the purpose of more efficient handling of XOR constraints.

Additional low-level optimizations are often introduced in CDCL SAT solvers. The interested reader should read the available solver descriptions, e.g. from the SAT competitions [BBJS15, HS15, BJJ16, BJJ17a, BJJ17b, HJS18].

Given that problem representations are most often non-clausal [Stu13], one might expect that non-clausal CDCL SAT solvers would represent a promising direction for improving practical SAT solving. A number of efforts have been reported over the years [GeSSMS99, KGP01, MSGeS03, TBW04, DJN09]. However, the performance of non-clausal solvers has not kept up with that of clausal SAT solvers. Thus, the most commonly used solution is simply to clausify the problem representation. A similar situation was observed for other dedicated solvers operating over propositional domains [RM09].

A number of additional concepts have been the subject of a significant body of work, but such efforts have not materialized in their application in CDCL SAT solvers. Concrete examples include symmetry breaking [CGLR96, Sak09], backdoors and backbones [WGS03, KSTW05], but also phase transitions [MZK⁺99]. Backbones denote assignments that are fixed in any model of satisfiable formulas, and find a wide range of applications. However, in practice backbones are computed with CDCL SAT solvers, and have not served to improve the performance of CDCL SAT solvers. Backdoors represent sets of variables which, for some assignment, enable a polynomial solver to satisfy the formula in polynomial time. For unsatisfiable formulas, strong backdoors are sets of variables such that, for any assignment, unsatisfiability is decided in polynomial time. Although backdoors caused significant interest, in practice backdoors can be hard to compute.

Moreover, recent results [JJ09] cast doubts in the practical effectiveness of exploiting backdoors. To our best knowledge, CDCL SAT solvers are yet to exploit backdoors. Nevertheless, recent work exploits SAT backdoors for devising cryptographic attacks [SZO⁺18]. Finally, symmetries in SAT have been the subject of a comprehensive body of research for the last two decades. Important progress has been registered, but the performance gains of breaking symmetries can vary wildly. As a result, modern CDCL SAT solvers do not readily integrate identification of symmetry breaking predicates. Finally, phase transitions are a well-known phenomenon of combinatorial problems, denoting a transition from easy to hard problems on random instances and given some problem measure [MZK⁺99]. Insights from phase transitions are yet to be exploited by CDCL SAT solvers for improving run times of practically-oriented formulas.

4.4. Using CDCL SAT Solvers

The practical success of CDCL SAT solvers builds upon not only a highly efficient reasoning engine, but also upon a number of supporting technologies which have witnessed very significant progress, to a large extent motivated by the success of CDCL SAT solvers. These technologies include the many ways SAT solvers have been embedded in applications, but also in a wide range of reasoners, the many ways SAT solvers are used as oracles for the class NP of decision problems, and also, the many ways in which problems can be encoded into propositional domains. This section provides a glimpse of the approaches that have been devised for using SAT solvers in practical settings. The section does not aim to be exhaustive, but instead to provide a comprehensive list of pointers from which a better understanding of the range of uses of CDCL SAT solvers can be attained.

4.4.1. Practical Use of SAT Solvers

A number of practical successes of SAT solvers depend not only on the raw performance of the solvers, but also on a number of additional features that are available in most modern implementations of CDCL SAT solvers. In many settings, SAT solvers are iteratively used as (extended) oracles for the class NP of decision problems.

4.4.1.1. CDCL SAT vs. NP Oracles

The ideal model of an NP oracle provides an answer of Yes (or No) depending on whether some decision problem has (or does not have) a solution. When using SAT solvers as oracles for the class NP, there are important differences. First, SAT solvers compute a solution (i.e. the satisfying assignment) when the answer is positive. Abstracting the actual run time, (CDCL) SAT oracles can be modeled as witness-producing oracles for NP [JaMS16]. Moreover, for negative answers, SAT solvers are often capable of providing an *unsatisfiable core*, i.e. a subset of the original set of clauses, which is by itself unsatisfiable. SAT solvers offer no guarantee in terms of the quality of the computed unsatisfiable core, e.g. one possible unsatisfiable core is the formula itself. Moreover, SAT solvers provide no guarantee in terms of the quality of the resolution proof associated

with the computed unsatisfiable core. Despite this lack of guarantees in terms of the information that can be obtained given a negative outcome, and as shown in Section 4.4.3, CDCL SAT solvers find an ever increasing range of applications where both positive and negative outcomes are to be expected.

4.4.1.2. Incremental SAT with Assumptions

Most CDCL SAT solvers can be invoked given a number of assumed values on a set of variables; these are the so-called *assumptions*. In turn, this allows for incremental iterative use. Consider a clause c_i . If one needs to add or remove c_i in between calls to a SAT solver, then the clause that is actually added to the SAT solver data structures is: $(c_i \vee \bar{s}_i)$, where s_i denotes a *fresh variable* (referred to as *activation*, *selection* or *indicator* variable). As a result, a user can conditionally *program* the activation of clause c_i by setting an assumption $s_i = 1$ if the clause is to be considered, or $s_i = 0$ if the clause is not to be considered. Assumptions are passed to the SAT solver, assigned and propagated before the actual search starts. CDCL SAT solvers usually assign each one of these assumption variables per decision level, and put the reference decision level immediately after all assumptions have been handled. If the SAT solver backtracks to one of these decision levels and a conflict is identified, then the SAT solver returns unsatisfiable. A simple solution to delete clauses that can be incrementally activated/deactivated is to add a unit clause (\bar{s}_i) . Similarly, if the clause is to be declared final, meaning that it is to be used in all future calls to the SAT solver, but needs no longer to be activated/deactivated, then the solution is to add the unit clause (s_i) .

Example 4.4.1. Consider a SAT solver working with clauses taken from two sets, \mathcal{B} and \mathcal{S} :

$$\begin{aligned}\mathcal{B} &= \{(\bar{a} \vee b), (\bar{a} \vee c)\} \\ \mathcal{S} &= \{(a \vee \bar{s}_1), (\bar{b} \vee \bar{c} \vee \bar{s}_2), (a \vee \bar{c} \vee \bar{s}_3), (a \vee \bar{b} \vee \bar{s}_4)\}\end{aligned}$$

\mathcal{B} denotes background knowledge. These clauses are *final* and their activation *cannot* be controlled with indicator variables. In contrast, \mathcal{S} denotes clauses whose activation can be conditionally selected with the indicator variables $\{s_1, s_2, s_3, s_4\}$. It can also be observed that if all clauses in \mathcal{S} are activated, then the resulting formula is unsatisfiable. Nevertheless, given the set of assumptions $\{s_1 = 1, s_2 = 0, s_3 = 0, s_4 = 1\}$, the SAT solver effectively needs to decide the satisfiability of the following set of clauses:

$$\mathcal{F} = \{(\bar{a} \vee b), (\bar{a} \vee c), (a), (a \vee \bar{b})\}$$

It is immediate to conclude that \mathcal{F} is satisfiable with the satisfying assignment $\{a = 1, b = 1, c = 1\}$.

Incremental SAT solving using assumptions was first proposed in the MINISAT SAT solver [ES03], and since the mid 00s it has been applied in most applications where CDCL SAT solvers are used as (witness-producing) oracles. Incremental SAT solving with assumptions has enabled solving a growing number of problems, for which the SAT solver is used as an oracle. Section 4.4.3 provides

Figure 4.11. Finding unsatisfiable cores

a glimpse of the many applications where incremental SAT with assumption has been applied over the last decade. Moreover, a fairly recent topic of research is on improving the use of assumptions in such settings [LB13, ALS13].

Although the incremental SAT approach outlined in this section is standard, there have been recent alternative approaches to implement incremental SAT [NR12, NRS14, FBS19].

4.4.1.3. Unsatisfiable Core Extraction

In a number of practical settings one is often interested in understanding the causes of unsatisfiability. An often used representation of the causes of unsatisfiability are *unsatisfiable cores* (or unsatisfiable subsets), which denote subsets of a CNF formula which are by themselves unsatisfiable. For CDCL SAT solvers with an incremental interface, unsatisfiable cores can be computed by checking the assumptions that remain in the final learned clause.

For unsatisfiable formulas, assuming no indicator variables are in use, a SAT solver must eventually learn the empty clause, as the final confirmation that the formula is unsatisfiable. If indicator variables are in use there are a few important differences to note. Concretely, any indicator variable is necessarily transferred to a learned clause. As a result, for unsatisfiable formulas, instead of learning the empty clause, the SAT solver terminates by learning a clause that contains *all* the indicator variables of clauses used for proving (by resolution) the unsatisfiability of the formula. Clearly, it is easy to argue that the indicator variables in the final learned clause *must* be a superset of the clauses necessary to prove unsatisfiability by resolution.

Example 4.4.2. Consider again the sets of clauses \mathcal{B} and \mathcal{S} from Example 4.4.1. Moreover, given the assumptions $\{s_1 = 1, s_2 = 1, s_3 = 1, s_4 = 1\}$, an unsatisfiable core obtained by a CDCL SAT solver is represented by the indicator variables $\{s_1, s_2\}$. This signifies that the clauses associated with this set of indicator variables are inconsistent with the background knowledge. An explanation for the operation of the CDCL SAT solver is shown in Figure 4.11.

4.4.1.4. Proof Tracing

Applications of SAT solvers in safety-critical applications, or in computer-assisted proofs, motivate the need for SAT solvers to have their results validated. The val-

validation of positive (i.e. satisfiable) outcomes is straightforward. (This is a natural consequence of SAT being in the class NP, and so having succinct certificates.) Indeed, for a positive outcome, it suffices to validate the satisfying assignment against the CNF formula, which can be done in linear time on the size of the formula. In contrast, deciding unsatisfiability is in coNP, and so the existence of succinct certificates is unlikely. Interest in validating unsatisfiable outcomes can be traced at least to the early 00s [VG02], with the approaches now in common use first outlined in 2003 [ZM03, GN03]. In these approaches, CDCL SAT solvers are instrumented to output a trace of their execution, which can then be checked by validating the associated resolution proof. Existing approaches for checking proofs of unsatisfiability can rely on ad-hoc implementations (referred to as *proof checking*) or on implementations extracted from formally verified checkers (referred to as *proof certification*). A wealth of proof tracing formats have been proposed over the years for checking unsatisfiability proofs [Bie08b, Van08, Van12, HHW13, HHJW13, WHHJ14, HHJW14, CFMSSK17, CFHHJ⁺17], which evolved to enabling proof systems stronger than resolution, but also with recent formats aiming at efficient proof certification. Work on devising proof certification approaches has also witnessed remarkable progress over the last decade [Web06, WA09, DFMS10, WHHJ13, CFMSSK17, CFHHJ⁺17, HHJKW17].

The importance of checking (and of certifying) proofs of unsatisfiability cannot be overstated. For example, in recent years, solvers participating in the SAT competition are required to output traces in the case of unsatisfiable outcomes, to enable proof checking (and certification) [BHJ17a]. Furthermore, proof checking and certification has been at the core of computer-assisted mathematical proofs [KL14, KL15, HKM16, HK17, Heu18].

4.4.1.5. Warm Restarts

For iterative uses of SAT solvers, when the run time of each call to a SAT solver can be expected to be negligible, and in settings where the search tree has many levels, one technique to reduce the run time is to consider *warm restarts*⁸. The idea is to bootstrap the SAT solver with the final set of decisions from the last (positive) call to the SAT solver [JLSS14, PIMMS15, Pre15].

4.4.2. Modeling with Propositional Logic

The success of CDCL SAT solvers also motivated the quick growth of problem solving by encoding problems into propositional logic. Over the last two decades, a large number of novel propositional encodings have been proposed, which are used in an ever increasing range of applications. This section briefly overviews recent work on modeling with propositional logic.

Propositional logic is a fairly low level knowledge representation formalism. The following sections provide brief accounts of the approaches used to represent complex constraints with propositional logic. Well-known examples include cardinality constraints, pseudo-Boolean constraints, but also solutions for devising propositional encodings for more expressive domains.

⁸To our best knowledge, the term was coined by A. Biere around 2012.

For constraints defined on propositional variables, the most often used measure of quality of propositional encodings is whether arc-consistency in the original constraint can be achieved by unit propagation [Gen02, ES06, RM09]. When this is the case, the propositional encoding is said to *ensure* arc-consistency. The arc-consistency measure of quality is tightly related with the ability of unit propagation to reveal inconsistent assignment as early as possible. For constraints defined on finite domains a often used measure of quality is propagation completeness [BKN⁺09, BMS12].

4.4.2.1. Linear Inequalities

Linear inequalities over propositional variables are of the form:

$$\sum_{i=1}^n a_i x_i \bowtie b \quad (4.7)$$

where $\bowtie \in \{<, \leq, =, \geq, >\}$, and where in the general case $a_i, b \in \mathbb{R}$. A well-known encoding of linear inequalities into propositional logic was proposed by Warners [War98]. This encoding is linear on the size of the input representation (which can be exponential on the number of variables), but does not ensure arc-consistency. In SAT solving, linear inequalities are often organized into cardinality constraints and pseudo-Boolean constraints. For each, there are encodings which ensure arc-consistency, with worst-case polynomial representations on the size of the input representation. There are a few additional kinds of linear inequalities studied in recent years. The next sections briefly overview the different kinds of linear inequalities and their encodings. More detailed accounts can be found in standard references [Pre09, RM09].

4.4.2.1.1. Encoding Cardinality Constraints. One of the most often used types of constraints are cardinality constraints of the form:

$$\sum_{i=1}^n x_i \bowtie k \quad (4.8)$$

where $\bowtie \in \{<, \leq, =, \geq, >\}$. A well-known special case is $k = 1$, with specific often used constraints being referred to as *AtMost1*, *AtLeast1* and *Equals1*. Clearly, the case *AtLeast1* can be encoded with a single clause, and so the interesting case is the encoding of *AtMost1* constraints.

For the general case of cardinality constraints, some of the best known encodings include:

1. Sorting networks [Bat68, ES06].
2. Totalizers [BB03].
3. Cardinality networks [ANORC09, ANORC11b].
4. Pairwise cardinality networks [CZI10].
5. Modulo totalizer [OLH⁺13].

One can also consider a simple generalization of the pairwise encoding for *AtMost1* constraints, but the encoding size is exponential in n and k . There is also recent work on encodings that ensure arc-consistency [Kar18].

In addition to the encodings above, well-known encodings for the AtMost1 constraint include:

1. Ladder/regular [GN04, AM04].
2. Bitwise [FP01, Pre07].
3. And the straightforward pairwise encoding [Pre09].

All of the above encodings ensure arc-consistency.

4.4.2.1.2. Conditional & Soft Cardinality Constraints. In some settings cardinality constraints may be conditional, i.e. of the form:

$$y_j \rightarrow \left(\sum_i x_i \bowtie k \right) \quad (4.9)$$

depending on the value of y_j , the cardinality must (or needs not) hold. Conditional cardinality have been proposed and used in different settings, including to represent soft cardinality constraints [MDMS14] in MaxSAT, in bounded path finding [EN15], and for computing the max clique in undirected graphs [IMMS17a]. Recent work investigates mechanisms to ensure arc-consistency of conditional cardinality constraints [BJRS18].

4.4.2.1.3. Encoding Pseudo-Boolean Constraints. The most general form of linear inequalities, i.e. the so-called Pseudo-Boolean (PB) constraints can be framed as follows [RM09]:

$$\sum_{i=1}^n a_i l_i \geq b \quad (4.10)$$

where $l_i \in \{x_i, \bar{x}_i\}$, $x_i \in \{0, 1\}$, $a_i, b \in \mathbb{N}_0$.

Motivated by the applications of CDCL SAT solvers, and problem encodings into SAT, there has been recent work on finding encodings for PB constraints which ensure arc-consistency. Concrete examples include:

1. Binary decision diagrams (BDDs) [ES06], with the caveat of requiring a worst-case exponential representation on the size of the PB constraint representation.
2. Polynomial watchdog encoding [BBR09] which, to our best knowledge, was the first polynomial encoding of PB constraints that ensures arc-consistency.
3. Recent improvement to the polynomial watchdog encoding [ANORC11a, ANO+12, MPS14].

Besides the operational encoding of Warners [War98], other encodings have been proposed which do not ensure arc-consistency [ES06, MDMS14]. Similar to soft cardinality constraints, weighted boolean optimization [MMSP09] proposed the use of soft PB constraints.

4.4.2.2. Encoding More Expressive Domains

There has been extensive work on translating more expressive domains into SAT, to be solved with CDCL SAT solvers. Two well-known examples are planning

and (hardware) model checking [KS99, BCCZ99, BCC⁺99, Rin09]. Another well-known example is CSP [Wa00, Gen02], with a number of tools implementing translations of CSP into SAT. There have been efforts to encode problems in NP to SAT, e.g. NP-Spec [CS05]. Other examples include the family of relational model finders [Jac00, TJ07], but also encodings of programming languages into SAT [CKL04, Kro09].

4.4.3. SAT Solvers as Witness-Producing Oracles

The last decade has witness the quick growth of problem solving where oracles for NP are replaced with CDCL SAT oracles. As mentioned earlier, CDCL SAT solvers extend the notion of NP oracle by producing witnesses in the case of positive outcomes, and (compact) explanations (i.e. unsatisfiable cores) in the case of negative outcomes [JaMS16]. This section overviews this ongoing work. The section aims at illustrating the range of ideas being developed, but not at being exhaustive, both in the topics and in the references. The interested reader can find additional references in the references cited.

4.4.3.1. Finding Cardinality-Minimal Subsets

The identification of cardinality-minimal subsets finds many practical applications. One well-known example is Maximum Satisfiability (MaxSAT), where the goal is to compute a cardinality maximal set of constraints that is consistent. The problem is of interest when one starts from an inconsistent (i.e. unsatisfiable, often referred to as overconstrained) formula. The practical importance of MaxSAT is illustrated by recent surveys [MHL⁺13, SZGN17], covering a wide range of applications. Initial practical algorithms for MaxSAT focused on branch-and-bound search [LM09]. This state of affairs changed in 2006, with the FM core-guided algorithm for MaxSAT [FM06]. Core-guided MaxSAT algorithms are based on iteratively calling a CDCL SAT solver, finding unsatisfiable cores, and using relaxation variables and cardinality constraints for finding the least cost way of relaxing the CNF formula so as to recover consistency. Since the FM algorithm, a wealth of core-guided MaxSAT algorithms have been devised [MSP07, MMSP09, ABL09, ABL13, IMM⁺14, MJML14, MDMS14]. These include the now widely used MSU3 algorithm [MSP07] and variants [ABL13, MJML14], improvements to the based FM algorithms [MMSP09, ABL09], and the use of soft-cardinality constraints [MDMS14]. A more detailed account of earlier core-guided MaxSAT algorithms is included in a recent survey [MHL⁺13]. A different MaxSAT approach that exploits CDCL SAT solvers consists in the iterative computation of minimum hitting sets [DB11, SBJ16]. The computed minimum hitting sets identify a set of clauses to exclude. The rest is checked for satisfiability with a (CDCL) SAT solver. If the formula is satisfiable, then the result is the MaxSAT solution, otherwise a computed unsatisfiable core is added to the set of sets for which a minimum hitting set is to be computed, and the process is repeated.

Another example of computing cardinality-minimal subsets is minimal satisfiability (MinSAT) [KKM94]. As with MaxSAT, initial algorithms focused on branch-and-bound search [LMQZ10]. The use of CDCL SAT solvers, as oracles for

NP, for this problem was proposed by different researchers [ALMZ12, ZLMA12, HMPMS12, IMPMS16].

4.4.3.2. Finding Subset-Minimal Subsets

In some settings one is interested in computing subset-minimal subsets. A well-known example is the extraction and enumeration of minimal unsatisfiable subsets (MUSes) [GMP08, MS10, Nad10, MSL11, BLMS12, NRS13, MSJB13, BK15, NBMS18], or in more general terms, to find minimal explanations for over-constrained systems of constraints. Another example is the extraction and enumeration of minimal correction subsets (MCSes) and their complement: maximal satisfiable subsets (MSSes) [MSHJ⁺13, GLM14a, BDTK14, MPMS15, MIPMS16]. For both MUSes and MCSes, the state of the art algorithms are based on iterative calls to a SAT oracle, with a number of key practical optimizations developed in recent years.

There are many other examples of computing subset-minimal subsets, that exploit CDCL SAT solvers as oracles. Most of these can be cast as instantiations of the Minimal Set over Monotone Predicate (MSMP) problem [MSJB13, MSJM17]. Additional well-known examples include finding minimal models [SI10, SBTLB17], computing the autarky of an unsatisfiable CNF formula [MSIM⁺14, KMS15] and identifying the backbone (i.e. the fixed assignments) of a satisfiable formula [MSJL10, ZWM11, ZWSM11, JLMS15]. Recent examples include [GLM14b, GL15, BGL15, IMMV16], among many others. MSMP has also been exploited in settings where monotonicity does not hold [BIV18].

4.4.3.3. Solving Decision Problems Beyond NP

SAT oracles have achieved significant success in solving decision problems beyond NP. Arguably the most visible have been the stream of improvements made to QBF solvers, by exploiting different forms of abstraction refinement, and also of SAT solvers as oracles [JMS11, JKMSC12, JMS15, RT15, JKMSC16, RS16]. Moreover, the development of an exact pure SAT-based implementation of two-level logic minimization [IPMS15] resulted in an effective alternative to the Quine-McCluskey algorithm [Qui52, Qui55, McC56], the reference two-logic level minimization algorithm for more than five decades.

Abstraction refinement and SAT oracles have been applied to modal logic reasoners [CLLB⁺17, LLBdLM18], but also to propositional abduction [SWJ16, IMMS16] and quantified QBF with soft clauses (QMaxSAT) [IJMS16], among others.

4.4.3.4. Enumerating Sets & Solutions

SAT oracles have enabled observable success in the enumeration of explanations and relaxations of overconstrained systems of constraints. This is the case with the enumeration of minimal unsatisfiable subsets [LPMMS16], the enumeration of minimal correction subsets [PMJaMS18, GIL18], but also the enumeration of prime implicants and implicates [JMSS14, PIMMS15]. A related problem of practical interest is to find the union of all sets, e.g. MUSes or MCSes. One concrete approach is HuMUS [NBE12].

4.4.3.5. Approximate & Exact Solution Counting

Model counting finds a number of important applications. Early work focused on adding dedicated techniques to CDCL SAT solvers to improve exact counting. Concrete examples include connected components and component caching [BJP00, SBK05, GSS09].

More recent work focused on approximate counting, using off-the-shelf CDCL SAT solvers as oracles [EGS12, CMV13a, CMV13b, CMV16, XLE⁺16].

4.4.3.6. Portfolios

The development of portfolios of reasoners [XHHLB08, LBHHX14] has been an active area of research, finding applications for different computational problems. In the case of portfolios for SAT, CDCL SAT solvers represent an integral part of the panoply of solvers that can be used.

4.5. Impact of CDCL SAT Solvers

Over the last two decades, CDCL SAT solving technology has been truly disruptive. This section summarizes the impact of CDCL SAT solvers in terms of well-known practical applications, but also from a theoretical perspective.

4.5.1. Practical Successes

CDCL SAT solvers have been a disruptive technology since their inception, having replaced, or at least complemented, well-established alternative technologies. A number of well-known applications exist but, more importantly, CDCL SAT solvers are in a growing number of cases the engines' engine, i.e. for a number of reasoners in different settings, the most promising approach uses a CDCL SAT solver or mimics the organization of CDCL SAT solvers. This section provides a brief glimpse at the growing range of applications of CDCL SAT solvers.

A few of the best-known hallmark applications of CDCL SAT solvers include:

1. Bounded model checking [BCCZ99, BCC⁺99, Bie09].
2. Unbounded model checking [McM03, Bra11, McM18].
3. Software model checking [CKL04, Kro09].
4. Automated planning [KS99, Rin09].
5. Computer-assisted mathematical proofs [KL14, KL15, HKM16, HK17].

Recent strategic applications of CDCL SAT solvers involve applications in explainable machine learning [IPNaMS18, NIPMS18].

CDCL SAT solvers are also the main engine for a number of reasoners, or have strongly influenced their design. Concrete examples include:

1. MaxSAT (see Section 4.4.3.1)
2. QBF (see Section 4.4.3.3).
3. Modal logics(see Section 4.4.3.3).
4. Satisfiability Modulo Theories (SMT) [BSST09].
5. Answer Set Programming (ASP) [GKKS12].

6. Lazy Clause Generation (LCG) in constraint programming [OSC09].
7. Theorem proving, both with instantiation-based methods [GK03, Kor08], but more recently with superposition theorem provers [KV13, Vor14].

The general setting of model based diagnosis [Rei87], which can be viewed as the problem of explaining overconstrained systems of constraints, finds a wealth of key practical applications [Jun04, BS05, LS08, MSKC14], for which CDCL SAT solving is becoming a key instrument [MSKC14, MSJIM15, AMMS15, LPMMS16].

4.5.2. Theoretical Significance

Recent years have witnessed significant progress in understanding CDCL SAT solvers from a propositional proof complexity perspective. Among the ideas that compose CDCL SAT solvers, from a proof complexity perspective, the key aspects of CDCL SAT solvers are clause learning and search restarts. Whereas the basic backtrack search SAT algorithm (DPLL) is associated with tree-like resolution [BKS04], a proof system weaker than resolution, CDCL SAT solving corresponds instead to a proof system as strong as general resolution [PD09, PD11, AFT09, AFT11]. These recent results build on the clause learning procedure used by CDCL SAT solvers [MS95, MSS96c], namely on the fact that learned clauses are *1-empowering*, and on the use of search restarts [GSC97, GSK98]. A more recent result shows that with a suitable preprocessing technique, restarts can be simulated on a clause learning SAT solver [BS14].

Motivated by the remarkable performance achieved by CDCL SAT solvers, researchers have investigated whether efficient algorithms for stronger proof systems could be devised. This has been the case of extended resolution [Hua10, AKS10], cutting planes [LBP10, EN18, EGCNV18], a recently proposed (dual-rail) MaxSAT-based proof system [IMMS17b, BBI⁺18], but also the recently proposed proof systems related with proof tracing [HKS17, KRPH18].

Although improvements to CDCL SAT solvers continue to be reported, one would expect far more significant impact if practically effective algorithms could be devised for proof systems stronger than general resolution. Although new insights have been reported, it is unclear the success of SAT can be replicated for such stronger proof systems.

4.6. Historical Perspective

The name Conflict-Driven Clause Learning (CDCL) can be traced to L. Ryan's 2004 MSc thesis [Rya04] to designate SAT solvers implementing the DPLL algorithm, but extended with clause learning, search restarts, conflict-aware branching and lazy data structures.

From a theoretical perspective, the most significant contributions of CDCL SAT solvers are clause learning and search restarts.

The clause learning technique used in modern CDCL SAT solvers was proposed in the mid 90s [MS95, MSS96c], with a more extensive treatment in the late 90s [MSS99]. Later work also proposed and used related ideas [BJS97, Zha97].

Nevertheless, all modern CDCL SAT solvers implement the clause learning mechanism first detailed in [MS95, MSS96c], namely by exploiting decision levels and UIPs when learning clauses. The relationship between implication graphs, decision levels, and non-chronological backtracking, without clause learning, was actually described in earlier work [MSS93, MSS94].⁹ In more general settings, learning from conflicts can be traced to the 70s [SS77]. Ideas on backtracking non-chronologically can be traced to about the same time [Gas77, Gas79]. A few additional relevant later works exist [Dec90, Gin93, Pro93]. Nevertheless, and to our best knowledge, in no other area has learning had as significant an impact as in SAT.

The idea of exploiting dominators in conflict analysis is tightly related with the concept of unique sensitization points (USPs) in ATPG [FS83, SA89, MSS94]; both concepts exploit dominators, from which additional inferences can be made. USPs are (static or dynamic) dominators of a circuit with respect to the fault location. UIPs are also dominators, but related with implication sequences. From the inception of UIPs [MS95, MSS96a, MSS96b, MSS96c, MSS99], the name aimed to acknowledge the relationship with USPs.

Search restarts were first proposed in the context of SAT in 1998 [GSC97, GSK98], with the specific purpose of improving the behavior of DPLL-like SAT solvers on satisfiable instances. The practical benefits of exploiting search restarts with clause learning were first documented in 2000 [BMS00], and are now used in any CDCL SAT solver [MMZ⁺01, ES03, Bie08b, AS09]. More recent work offered a theoretical justification for the use of clause learning and search restarts [PD09, PD11, AFT11], showing that it corresponds to a proof system as powerful as general resolution. The concept of *empowering implicate* computed by clause learning SAT solvers [MS95, MSS96c] is crucial for these results.

From a practical perspective, the most significant contributions of CDCL SAT solvers include not only clause learning and search restarts, but also conflict-driven branching and lazy data structures. All these contributions are crucial for the performance of modern CDCL SAT solvers.

The idea of conflict-driven branching can be traced at least to the late 90s [MS99], where the branching heuristics DLIS and DLCS, by dynamically exploiting literal counts, would take into account the literals in already learned clauses. Both DLIS and DLCS were implemented in the GRASP SAT solver since the mid 90s [MS95, MSS96c]. The importance of conflict-driven branching was demonstrated in the Chaff SAT solver [MMZ⁺01], with the VSIDS branching heuristic, which became the de facto reference branching heuristic ever since. Indeed, and even though alternatives have been proposed over the years, VSIDS-like branching is still used in most modern CDCL SAT solvers.

The origins of exploiting lazy data structures in SAT solvers can be traced to 2000 [ZS00], concretely the idea of maintaining head and tail literals in clauses. The much more efficient alternative of watched literals was proposed in the Chaff SAT solver [MMZ⁺01]. With minor modifications, watched literals are still used in modern CDCL SAT solvers.

⁹The name *implication graph* was borrowed from [Lar89, Lar92], where it was used with a different meaning, and which is closely related to the directed graphs associated with 2CNF formulas used in the work Aspvall, Plass and Tarjan [APT79].

In recent times, CDCL is used to mean SAT solvers that implement clause learning, search restarts, conflict-driven branching and lazy data structures, but also a number of commonly used additional techniques. These include phase saving [PD07] but also literal blocks distance [AS09].

4.7. To Probe Further

The chapter provides a comprehensive list of references on the implementation but also one the practical uses of CDCL SAT solvers. Many CDCL SAT solvers have been implemented over the years. The following list summarizes those that are currently publicly available and that have impacted the organization of CDCL SAT solvers.

1. GRASP [MSS96c, MSS99]¹⁰ was the first SAT solver to implement conflict analysis as used in modern CDCL SAT solvers, including clause learning with UIP identification and non-chronological backtracking. Search restarts and its interaction with clause learning were introduced in GRASP at a later stage [BMS00, LBMS01]. GRASP has been open source since its inception.
2. Chaff [MMZ⁺01, ZMMM01]¹¹ introduced efficient lazy data structures, the VSIDS branching heuristic, and also proposed stopping conflict analysis at the first UIP. Chaff is open source, although some of its ideas have been patented [MMM08]¹².
3. MiniSat [ES03]¹³ introduced a simple architecture for the organization of CDCL SAT solvers, one that is still used by most modern CDCL SAT solvers. MiniSat also introduced learned clause minimization in a 2005 release, but this was documented only at a later stage [SB09]. MiniSat has been open source since its inception.
4. Since the mid 00s, A. Biere has developed a number of state of the art SAT solvers, including Lingeling, PicoSAT, PrecoSAT and Limmat¹⁴. These solvers are open source, and some are overviewed in [Bie08b, Bie13, BF15a, Bie16, Bie17].
5. Another CDCL SAT solver is Glucose [AS09]¹⁵, which introduced the LBD metric and proposed ways for using this metric in practice. Glucose builds on the MiniSat code base and it is also open source.
6. A more recent CDCL SAT solver is MapleSAT [LGPC16b, LGPC16a, LOM⁺18].¹⁶ MapleSAT build on the Glucose code base, and it is open source.
7. There are SAT solvers that exploit specific kinds of reasoning. One example is CryptoMiniSat¹⁷ [SNC09]. CryptoMiniSat is open source.

¹⁰GRASP is available from <https://sites.google.com/site/satgrasp/>.

¹¹Chaff is available from <https://www.princeton.edu/~chaff/software.html>.

¹²There have been a number of patents related with CDCL SAT solving and applications. One additional example is related with the work on the BerkMin SAT solver [GN08].

¹³MiniSat is available from github: <https://github.com/niklasso/minisat.git>.

¹⁴Some of A. Biere's SAT solvers are available from: <http://fmv.jku.at/software/>.

¹⁵Glucose is available from: <http://www.labri.fr/perso/lsimon/glucose/>.

¹⁶MapleSAT is available from <https://sites.google.com/a/gsd.uwaterloo.ca/maplesat/>.

¹⁷Available from <https://github.com/msoos/cryptominisat>.

Furthermore, the SAT competitions¹⁸ are an invaluable source of information about state of the art CDCL SAT solvers [BBJS15, HS15, BHJ16, BHJ17a, BHJ17b, HJS18].

A recent effort towards simplifying the implementation of SAT-based tools is the PySAT project¹⁹ [IMMS18]. PySAT offers a Python API to the low-level operation of SAT solvers, as described in previous sections. In turn, this has enabled PySAT-based tools to achieve state of the art performance in a number of settings [IMMS18]. Besides a Python API for interfacing a number of SAT solvers, PySAT offers a variety of encodings of cardinality constraints, which can be helpful for encoding problems into SAT. Furthermore a number of well-known algorithms for solving different function problems are provided as examples of use. These include MUS and MCS extraction, but also MaxSAT solving. The PySAT project is open source, with an MIT license, and should be straightforward to install on most Linux and MacOS distributions.

4.8. Conclusions & Research Directions

This chapter provides an overview of the implementation and practical uses of CDCL SAT solvers. CDCL SAT solving represents one concrete example of remarkable success at solving NP-complete decision problems in practice, and defies the often assumed worst-case characterizations of the run-time of SAT solvers. Regarding the success of practical SAT solving, one of the most striking aspects of this success is that for many years SAT was perceived as an extremely hard problem; all this changed in the mid 90s and early 00s. Similar successes have been witnessed in other areas, including integer linear programming.

As the chapter hopes to demonstrate, there has been a steady stream of improvements to what represents a CDCL SAT solver. Progress is expected to continue. Performance improvements continue to be attained. The application of machine learning has contributed to optimizing components of CDCL SAT solvers, but has also served to develop very effective portfolios of SAT solvers. New insights at the intersection of SAT solver technology and ML are to be expected. The fast pace at which CDCL SAT oracles are being used for problem solving, in different domains, suggests that one should expect that a much wider range of successes of CDCL SAT solving will be witnessed in the near future.

Acknowledgments. Armin Biere, Alexey Ignatiev, and Antonio Morgado provided comments to earlier drafts of this document. Donald Knuth provided detailed comments to the first edition of this chapter.

Chapter 5

Look-Ahead Based SAT Solvers

Marijn J.H. Heule and Hans van Maaren

5.1. Introduction

Imagine that you are for the first time in New York City (NYC). A cab just dropped you off at a crossing and now you want to see the most beautiful part of town. You consider two potential strategies to get going: A *conflict-driven* strategy and a *look-ahead* strategy.

The conflict-driven strategy consists of the following heuristics: On each crossing you look in all directions and walk towards the crossing which appears most beautiful at first sight. If at a certain crossing all new directions definitely lead to dead end situations, you write the location in a booklet to avoid the place in the future and you evaluate which was the nearest crossing where you likely chose the wrong direction. You go back to that crossing and continue with a new preferred direction.

The look-ahead strategy spends much more time to select the next crossing. First all adjacent crossings are visited. At each of them all directions are observed before returning to the current crossing. Now the next crossing is selected based on all observed directions. A schematic view of both strategies is shown in Figure 5.1.

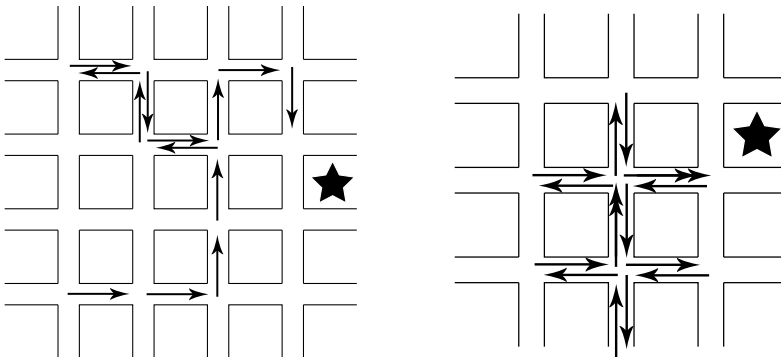

Figure 5.1. A NYC walk, conflict-driven (left) and look-ahead (right). ★ denotes the target.

As the reader has probably expected by now, the conflict-driven and look-ahead SAT solving architectures have several analogies with the conflict-driven and look-ahead NYC sightseeing strategies. Although the look-ahead NYC walk appears very costly, in practice it solves some problems quite efficiently. This chapter walks through the look-ahead architecture for SAT solvers.

5.1.1. Domain of application

Before going into the details of the look-ahead architecture, we first consider a wide range of problems and ask the question: Which architecture is the most appropriate to adequately solve a particular instance?

Traditionally, look-ahead SAT solvers are strong on random k -SAT formulae and especially on the unsatisfiable instances. Herwig [Her06] suggests that in practice, look-ahead SAT solvers are strong on benchmarks with either a low density (ratio clauses to variables) or a small diameter (longest shortest path in for instance the resolution graph¹). Figure 5.2 illustrates this. Using the structured (crafted and industrial) benchmarks from the SAT 2005 competition and SATlib, the relative performance is measured for the solvers MiniSAT (conflict-driven) and march (look-ahead). For a given combination of density and diameter of the resolution graph, the strongest solver is plotted.

Figure 5.2. Strongest architecture on structured benchmarks split by density and diameter. Architectures represented by MiniSAT (conflict-driven) and march (look-ahead).

¹The resolution graph is a clause based graph. Its vertices are the clauses and clauses are connected if they have exactly one clashing literal.

Notice that Figure 5.2 compares MiniSAT to `march` and therefore it should not be interpreted blindly as a comparison between any pair of conflict-driven and look-ahead SAT solvers in general. The solver `march` is the only look-ahead SAT solver that is optimized for large and structured benchmarks. Selecting a different look-ahead SAT solver would change the picture in favor of MiniSAT.

However, it seems that in the current state of development, both architectures have their own range of applications. The almost sharp separation shown in Figure 5.2 can be explained as follows: Density expresses the cost of unit propagation. The higher the density, the more clauses need to be reduced for each assigned variable. Therefore, look-ahead becomes very expensive for formulae with high densities, while using lazy data-structures (like MiniSAT), the cost of unit propagation does not increase heavily on these formulae.

The diameter expresses the global connectivity of clauses. If just a few variables cover all the literals of a set of clauses, such a set is referred to as a *local cluster*. The larger the diameter, the more multiple local clusters occur within the formula. Local clusters reduce the effectiveness of reasoning by look-ahead SAT solvers: Assigning decision variables to a truth value will modify the formula only locally. Therefore, expensive reasoning is only expected to learn facts within the last modified cluster. On the other hand, conflict-driven solvers benefit from local clusters: Conflict clauses will likely arise from local conflicts, yielding small clauses consisting of some covering variables. Also, they may be reused frequently.

5.2. General and Historical Overview

5.2.1. The Look-Ahead Architecture

The look-ahead architecture is based on the *DPLL* framework [DLL62]: It is a complete solving method which selects in each step a decision variable x_{decision} and recursively calls DPLL for the reduced formula where x_{decision} is assigned to false (denoted by $\mathcal{F}[x_{\text{decision}} = 0]$) and another where x_{decision} is assigned to true (denoted by $\mathcal{F}[x_{\text{decision}} = 1]$).

A formula \mathcal{F} is reduced by *unit propagation*: Given a formula \mathcal{F} , an unassigned variable x and a Boolean value \mathbf{B} , first x is assigned to \mathbf{B} . If this assignment φ results in a *unit clause* (clause of size 1), then φ is expanded by assigning the remaining literal of that clause to true. This is repeated until no unit clauses are left in φ applied to \mathcal{F} (denoted by $\varphi \circ \mathcal{F}$) - see Algorithm 5.1. The reduced formula consists of all clauses that are not satisfied. So, $\mathcal{F}[x = \mathbf{B}] := \varphi \circ \mathcal{F}$.

Algorithm 5.1 UNITPROPAGATION (formula \mathcal{F} , variable x , $\mathbf{B} \in \{0, 1\}$)

```

1:  $\varphi := \{x \leftarrow \mathbf{B}\}$ 
2: while empty clause  $\perp \notin \varphi \circ \mathcal{F}$  and unit clause  $y \in \varphi \circ \mathcal{F}$  do
3:    $\varphi := \varphi \cup \{y \leftarrow 1\}$ 
4: end while
5: return  $\varphi \circ \mathcal{F}$ 

```

The recursion has two kinds of leaf nodes: Either all clauses have been satisfied (denoted by $\mathcal{F} = \emptyset$), meaning that a satisfying assignment has been found, or \mathcal{F} contains an *empty clause* \perp (a clause of which all literals have been falsified), meaning a dead end. In the latter case the algorithm backtracks.

The decision variable is selected by the LOOKAHEAD procedure. Besides selecting x_{decision} it also attempts to reduce the formula in each step by assigning *forced* variables and to further constrain it by adding clauses. Algorithm 5.2 shows the top level structure. Notice that the LOOKAHEAD procedure returns both a simplified formula and x_{decision} .

In addition, the presented algorithm uses direction heuristics to select which of the reduced formulae $\mathcal{F}[x_{\text{decision}} = 0]$ or $\mathcal{F}[x_{\text{decision}} = 1]$ should be visited first - see Section 5.3.2. Effective direction heuristics improve the performance on satisfiable instances². Although direction heuristics can be applied to all DPLL based solvers, look-ahead SAT solvers are particularly the ones that use them.

Algorithm 5.2 DPLL (formula \mathcal{F})

```

1: if  $\mathcal{F} = \emptyset$  then
2:   return satisfiable
3: end if
4:  $\langle \mathcal{F}; x_{\text{decision}} \rangle := \text{LOOKAHEAD}(\mathcal{F})$ 
5: if empty clause  $\perp \in \mathcal{F}$  then
6:   return unsatisfiable
7: else if no  $x_{\text{decision}}$  is selected then
8:   return DPLL( $\mathcal{F}$ )
9: end if
10:  $\mathbf{B} := \text{DIRECTIONHEURISTIC}(x_{\text{decision}}, \mathcal{F})$ 
11: if DPLL( $\mathcal{F}[x_{\text{decision}} = \mathbf{B}]$ ) = satisfiable then
12:   return satisfiable
13: end if
14: return DPLL( $\mathcal{F}[x_{\text{decision}} = \neg \mathbf{B}]$ )

```

The LOOKAHEAD procedure, as the name suggests, performs *look-aheads*. A look-ahead on x starts by assigning x to true followed by unit propagation. The importance of x is measured *and* possible reductions of the formula are detected. After this analysis, it backtracks, ending the look-ahead. The rationale of a look-ahead operation is that evaluating the effect of actually assigning variables to truth values and performing unit propagation is more adequate compared to taking a cheap guess using some statistical data on \mathcal{F} .

This brings us to the two main features of the LOOKAHEAD procedure. The first is the *decision heuristic* which measures the importance of a variable. This heuristic consists of a *difference* or *distance heuristic* (in short DIFF) and a heuristic that combines two DIFF values (in short MIXDIFF).

A DIFF heuristic measures the reduction of the formulae caused by a look-ahead. The larger the reduction, the higher the heuristic value. This reduction can be measured with all kinds of statistics. Effective statistics are the reduction of free variables and the number of newly created (reduced, but not satisfied) clauses. The final judgment of a variable is obtained by combining $\text{DIFF}(\mathcal{F}, \mathcal{F}[x = 0])$ and $\text{DIFF}(\mathcal{F}, \mathcal{F}[x = 1])$ using a MIXDIFF heuristic. The product of these numbers is generally considered to be an effective heuristic. It aims to create a balanced search-tree. Notice that this is not a goal in its own: The trivial 2^n tree is perfectly balanced, but huge. See Chapter 8 for more details and theory.

²Direction heuristics applied in a conflict-driven setting may heavily influence performance on unsatisfiable formulae.

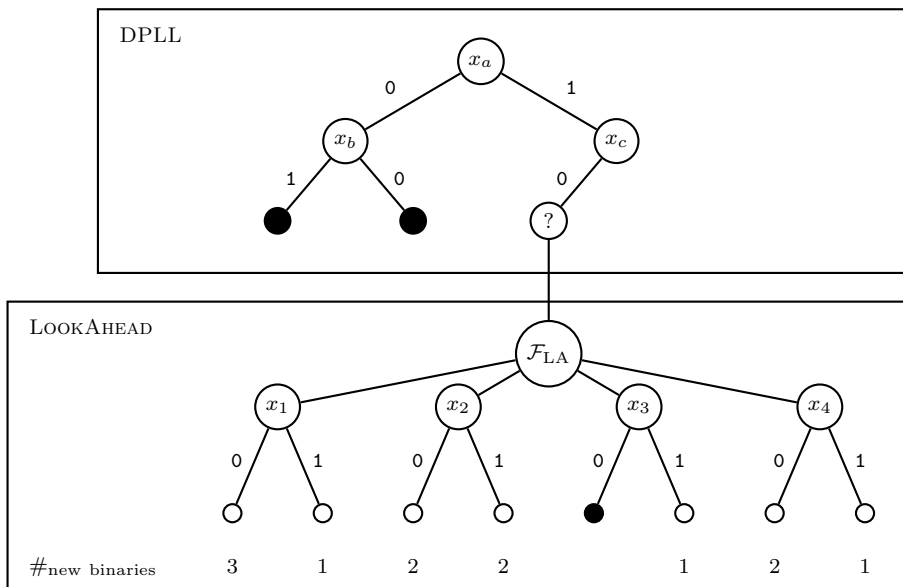

Figure 5.3. A graphical representation of the look-ahead architecture. Above, the DPLL super-structure (a binary tree) is shown. In each node of the DPLL-tree, the LOOKAHEAD procedure is called to select the decision variable and to compute implied variables by additional reasoning. Black nodes refer to leaf nodes and variables shown in the vertices refer to the decision variables and look-ahead variables, respectively.

The second main feature of the look-ahead architecture is the detection of *failed literals*: If a look-ahead on x results in a conflict, then x is forced to be assigned to false. Detection of failed literals reduces the formula because of these “free” assignments. The LOOKAHEAD procedure terminates in case both x_i and $\neg x_i$ are detected as failed literals.

Figure 5.3 shows a graphical representation of the look-ahead architecture. On the top level, the DPLL framework is used. The selection of the decision variable, reduction of the formula, and addition of learned clauses are performed by the LOOKAHEAD procedure. Black nodes refer to a dead end situation, either an unsatisfiable leaf node (DPLL) or a failed literal (LOOKAHEAD procedure).

Example 5.2.1. Consider the following example formula:

$$\mathcal{F}_{LA} = (\neg x_1 \vee x_3) \wedge (x_1 \vee x_2 \vee x_3) \wedge (x_1 \vee \neg x_2 \vee x_4) \wedge (x_1 \vee \neg x_2 \vee \neg x_4) \wedge (x_2 \vee \neg x_3 \vee x_4)$$

Since the largest clauses in \mathcal{F}_{LA} have size three, only new binary clauses can be created. For instance, during the look-ahead on $\neg x_1$, three new binary clauses are created (all clauses in which literal x_1 occurs). The look-ahead on x_1 will force x_3 to be assigned to true by unit propagation. This will reduce the last clause to a binary clause, while all other clauses become satisfied. Similarly, we can compute the number of new binary clauses (denoted by #_{new binaries}) for all look-aheads - see Figure 5.3.

Notice that the look-ahead on $\neg x_3$ results in a conflict. So $\neg x_3$ is a *failed literal* and forces x_3 to be assigned to true. Due to this forced assignment the formula changes. To improve the accuracy of the look-ahead heuristics (in this case the reduction measurement), the look-aheads should be performed again. However, by assigning forced variables, more failed literals might be detected. So, for accuracy, first iteratively perform the look-aheads until no new failed literals are detected.

Finally, the selection of the decision variable is based on the reduction measurements of both the look-ahead on $\neg x_i$ and x_i . Generally, the product is used to combine the numbers. In this example, x_2 would be selected as decision variable, because the product of the reduction measured while performing look-ahead on $\neg x_2$ and x_2 is the highest (i.e. 4). Section 8.6 discusses the preference for the product in more detail.

Several enhancements of the look-ahead architecture have been developed. To reduce the cost of the LOOKAHEAD procedure, look-aheads could be restricted to a subset of the free variables. The subset (denoted by \mathcal{P}) is selected by the PRESELECT procedure - see Section 5.3.3. However, if $|\mathcal{P}|$ is too small, this could decrease overall performance, since less failed literals will be detected and possibly a less effective decision variable is selected.

Various forms of additional look-ahead reasoning can be applied to \mathcal{F} to either reduce its size by assigning forced literals or to further constrain it by adding learned clauses. Four kinds of additional reasoning are discussed in Section 5.4.

Algorithm 5.3 LOOKAHEAD (\mathcal{F})

```

1:  $\mathcal{P} := \text{PRESELECT}(\mathcal{F})$ 
2: repeat
3:   for all variables  $x_i \in \mathcal{P}$  do
4:      $\mathcal{F} := \text{LOOKAHEADREASONING}(\mathcal{F}, x)$ 
5:     if empty clause  $\perp \in \mathcal{F}[x = 0]$  and empty clause  $\perp \in \mathcal{F}[x = 1]$  then
6:       return  $\langle \perp; * \rangle$ 
7:     else if empty clause  $\perp \in \mathcal{F}[x = 0]$  then
8:        $\mathcal{F} := \mathcal{F}[x = 1]$ 
9:     else if empty clause  $\perp \in \mathcal{F}[x = 1]$  then
10:       $\mathcal{F} := \mathcal{F}[x = 0]$ 
11:    else
12:       $H(x_i) = \text{DECISIONHEURISTIC}(\mathcal{F}, \mathcal{F}[x = 0], \mathcal{F}[x = 1])$ 
13:    end if
14:  end for
15: until nothing (important) has been learned
16: return  $\langle \mathcal{F}; x_i \text{ with greatest } H(x_i) \rangle$ 

```

Algorithm 5.3 shows the LOOKAHEAD procedure with these enhancements. Mostly the procedure will return a simplified formula \mathcal{F} and a decision variable x_{decision} . Except in two cases this procedure returns no decision variable: First, if the procedure detects that the formula is unsatisfiable by failed literals. Second, if all (pre-selected) variables are assigned. In the latter case, we either detected a satisfying assignment or we need to restart the LOOKAHEAD procedure with a new set of pre-selected variables.

Detection of failed literals or other look-ahead reasoning that change \mathcal{F} , can influence the DIFF values. Also the propagation of a forced literal could result

in the failure of the look-head on other literals. Therefore, to improve both the accuracy of the decision heuristic and to increase the number of detected failed literals, the LOOKAHEAD procedure can be iterated until no (important) facts are learned (in the last iteration).

The unit propagation part within the LOOKAHEAD procedure is relatively the most costly aspect of this architecture. Heuristics aside, performance could be improved by reduction of these costs. Section 5.5 discusses three optimization techniques.

5.2.2. History of Look-Ahead SAT Solvers

The Böhm solver [BS96] could be considered as the first look-ahead SAT solver. In each node it selects the variable that occurs most frequently in the shortest active (not satisfied) clauses. Although no look-aheads are performed, it uses *eager data-structures* which are common in look-ahead SAT solvers: Two dimensional linked lists are used to cheaply compute the occurrences in active clauses. This data-structure is also used in the OKsolver. The Böhm solver won the first SAT competition in 1991/1992 [BK92].

The first SAT solvers with a LOOKAHEAD procedure were developed in the mid 1990s: *csat* by Dubois et al. [DABC93] and *posit* by Freeman [Fre95, Fre96]. They already contained aspects of the important heuristics used in the “modern” look-ahead SAT solvers:

- Decision variables are selected by a DIFF heuristic that measures the reduction of free variables. The MIXDIFF heuristic used in *posit*, is still used in most look-ahead SAT solvers. Let $L := \text{DIFF}(\mathcal{F}, \mathcal{F}[x = 0])$ and $R := \text{DIFF}(\mathcal{F}, \mathcal{F}[x = 1])$ then MIXDIFF is computed by $1024 \cdot LR + L + R$. The product is selected to create a balanced search-tree. The addition is for tie-breaking purposes. The factor 1024, although seemingly arbitrary, gives priority to the product (balancedness of the emerging search-tree).
- A direction heuristic is used to improve the performance on satisfiable instances: Using a simple heuristic, it estimates the relative costs of solving $\mathcal{F}[x = 0]$ and $\mathcal{F}[x = 1]$. The smallest one is preferred as first branch.
- Variables in *posit* are pre-selected for the LOOKAHEAD procedure using three principles: First, important variables (ones with a high estimated MIXDIFF) are selected to get an effective decision variable. Second, literals that occur frequently negated in binary clauses are selected (so possibly not their complement) as candidate failed literals. Third, many variables are selected near the root of the tree, because here, accurate heuristics and failed literals have more impact on the size of the tree.

Results on hard random 3-SAT formulae were boosted by *satz*. This solver was developed by Li and Anbulagan in 1997. All heuristics were optimized for these benchmarks:

- The DIFF heuristic measures the newly created binary clauses in a weighted manner based on the literals in these binary clauses. This heuristic is called *weighted binarities heuristic* and is discussed in Section 5.3.1.2. The same MIXDIFF heuristic is used as in *posit*.

- No direction heuristics are used. $\mathcal{F}[x_{\text{decision}} = 1]$ is always preferred.
- Variables are pre-selected using the prop_z heuristic [LA97a] - see Section 5.3.3.1. On random 3-SAT formulae, it pre-selects most free variables near the root of the search-tree. As the tree deepens, the number of selected variables decreases.

In 1999, Li added a `DOUBLELOOK` procedure to `satz` and further reduced the size of the search-tree to solve random formulae [Li99]. This procedure - see Section 5.4.3 - attempts to detect more failed literals by also performing some look-aheads on a second level of propagation: If during the look-ahead on x more than a certain number of new binary clauses are created, then additional look-aheads are performed on the reduced formula $\mathcal{F}[x = 1]$ to check whether it is unsatisfiable. The parameter (called Δ_{trigger}) which expresses the number of new binary clauses to trigger the `DOUBLELOOK` procedure is fixed to 65 based on experiments on hard random 3-SAT formulae. Performance clearly improves using this setting, while on many structured benchmarks it results in a slowdown: The procedure is executed too frequently.

To exploit the presence of so-called equivalence clauses in many benchmarks, Li [Li00] created a special version of `satz`, called `eqsatz`, which uses equivalence reasoning. During the look-ahead phase, it searches binary equivalences $x_i \leftrightarrow x_j$ in the reduced formulae $\mathcal{F}[x = 0]$ and $\mathcal{F}[x = 1]$. Using five inference rules, it reasons about the detected equivalences. Due to this equivalence reasoning, `eqsatz` was the first SAT solver to solve the hard `parity32` benchmarks [CKS95] without performing Gaussian elimination on the detected equivalence clauses.

Starting from 1998, Oliver Kullmann developed the `OKsolver`, motivation by the idea to create a “pure” look-ahead SAT solver [Kul02]. The heuristics are kept clean. They are not stuffed with magic constants:

- The `DIFF` heuristic in `OKsolver` measures the newly created clauses in a weighted manner - based on the size on the new clauses. For each of the used weights a separate experiment has been performed. This *clause reduction heuristic* is discussed in Section 5.3.1.1. The `MIXDIFF` uses the product $\text{DIFF}(\mathcal{F}, \mathcal{F}[x = 0]) \cdot \text{DIFF}(\mathcal{F}, \mathcal{F}[x = 1])$ which is based on the τ -function [KL99].
- The direction heuristics prefer $\mathcal{F}[x_{\text{decision}} = 0]$ or $\mathcal{F}[x_{\text{decision}} = 1]$ which is probabilistically the most satisfiable. Details are shown in Section 5.3.2.
- No pre-selection heuristics are used.

Besides the clean heuristics, `OKsolver` also adds some reasoning to the look-ahead architecture:

- **Local Learning**³: If the look-ahead on x assigns y to true, then we learn $x \rightarrow y$. This can be stored as binary clause $\neg x \vee y$. These learned binary clauses are valid under the partial assignment. This means that they should be removed while backtracking.
- **Autarky Reasoning**: If during the look-ahead on x no new clauses are created then an autarky is detected. This means that $\mathcal{F}[x = 1]$ is satisfi-

³Local learning is an optimal feature in the `OKsolver` which was turned off in the version submitted to SAT 2002.

ability equivalent with \mathcal{F} . Therefore, x can be freely assigned to true. If only one new clause is created, then an 1-autarky is detected. In this case, two local learned binary clauses can be added. Details are presented in Section 5.4.2.

- **Backjumping:** While backtracking, the OKsolver maintains a list of the variables that were responsible for detected conflicts. If a decision variable does not occur in the list, the second branch can be skipped. This technique has the same effect as the ones used in conflict-driven solvers.

To maximize the number of learned facts, the LOOKAHEAD procedure is iterated until in the last iteration no new forced literals have been detected and no new binary clauses have been added. During the first SAT competition⁴ (2002), OKsolver won both divisions of random k -SAT benchmarks.

The first version of `march`, developed by Heule et al. [HDvZvM04] in 2002 was inspired by `satz` and applied most of its features. The most significant difference was a pre-processing technique which translated any formula to 3-SAT. The updated version of 2003, `march_eq`, was modified to become a look-ahead SAT solver for general purposes. New techniques were added to increase performance on structured instances, while still being competitive on random formulae. Three techniques have been added to improve efficiency. Due to some overhead these techniques are cost neutral on random formulae, but generate significant speed-ups on many structured instances:

- The binary and non-binary clauses of the formula are stored in separate data-structures. This reduces the required memory (especially on structured benchmarks) and facilitates a more efficient unit propagation - see Section 5.5.1.
- Before entering the LOOKAHEAD procedure, all redundant (satisfied) clauses are removed from the active data-structures. This boosts the unit propagation during this procedure - see Section 5.5.2.
- By building implication trees of the binary clauses containing two pre-selected variables, a lot of redundancy in the LOOKAHEAD procedure can be tackled - see Section 5.5.3.

Also equivalence reasoning was added. Instead of searching for equivalence clauses in all reduced formulae, `march_eq` only extracts them from the input formula. They are stored in a separate data-structure to implement a specialized unit propagation procedure. The solver won two divisions of crafted benchmarks during SAT 2004.

The `kcfnfs` solver by Dubois and Dequen, developed in 2004, is in many aspects similar to `satz`. However, it features some important improvements with respect to hard random k -SAT formulae:

- The most effective modification is a minor one. Like `satz`, the DIFF heuristic measures the newly created binary clauses in a weighted manner - based on occurrences of the variables in these clauses. However, instead of adding the weighted literals, they are multiplied per binary clause - see Section 5.3.1.3. This *backbone search heuristic* (BSH) significantly improves

⁴see www.satcompetition.org

the performance on random k -SAT formulae.

- The implementation is optimized for efficiency on random k -SAT formulae.
- Normalization has been developed for *BSH*, such that it can measure newly created clauses of any size. This is required for fast performance on random k -SAT formulae with $k > 3$.

The *kcfnfs* solver performs very strong on random formulae on the SAT competitions. It won one random division during both SAT 2003 and SAT 2004, and even two random divisions during SAT 2005.

In 2005 two adaptive heuristics were added to *march_eq*, resulting in *march_dl*:

- It was observed [HvM06a] that there is some correlation between the number of failed literals and the optimal number of pre-selected free variables. Based on this observation, an adaptive heuristic was added which aims to converge to the optimal value.
- An adaptive algorithm for the *DOUBLELOOK* procedure [HvM07] has been added to *march_eq*. It modifies Δ_{trigger} after each look-ahead. In contrast to earlier implementations of the *DOUBLELOOK* procedure, it now reduces the computational costs on almost all formulae.

5.3. Heuristics

As the previous section showed, the look-ahead architecture enables one to invoke many heuristic features. Research tends to focus on three main categories of heuristics, which we recall here:

- **Difference heuristics:** To measure the difference between the formulae before and after a look-ahead. The quality of the used difference heuristic influences the actual impact of the decision variable.
- **Direction heuristics:** Given a decision variable x_{decision} , one can choose whether to examine first the positive branch $\mathcal{F}[x_{\text{decision}} = 1]$ or the negative branch $\mathcal{F}[x_{\text{decision}} = 0]$. Effective direction heuristics improve the performance on satisfiable formulae.
- **Pre-selection heuristics:** To reduce the computational costs, look-ahead can be restricted to a subset of the variables. As a possible negative consequence, however, a smaller pre-selected set of variables may result in fewer detected failed literals and a less effective decision variable.

5.3.1. Difference heuristics

This section covers the branching heuristics used in look-ahead SAT solvers. A general description of these heuristics is offered in Chapter 8. To measure the difference between a formula and its reduction after a look-ahead (in short *DIFF*), various kinds of statistics can be applied. For example: The reduction of free variables, the reduction of the number of clauses, the reduced size of clauses, or any combination. *Posit* uses the reduced number of free variables as *DIFF* [Fre95]. All look-ahead SAT solvers which participated in the SAT competitions use a *DIFF* based on newly created (reduced, but not satisfied) clauses. The set of new

clauses created during the look-ahead on x is denoted by $\mathcal{F}[x = 1] \setminus \mathcal{F}$. All these heuristics use weights to quantify the relative importance of clauses of a certain size. The importance of a clause of size k is denoted by γ_k and the subformula of \mathcal{F} which contains only the clauses of size k is denoted by \mathcal{F}_k . This section discusses and compares three main DIFF heuristics.

5.3.1.1. Clause reduction heuristic

The DIFF implemented by Kullmann in OKsolver [Kul02] uses only the γ_k weights and is called *clause reduction heuristic*⁵ (*CRH*):

$$CRH(x_i) := \sum_{k \geq 2} \gamma_k \cdot |\mathcal{F}[x_i = 1]_k \setminus \mathcal{F}| \quad \text{with}$$

$$\gamma_2 := 1, \gamma_3 := 0.2, \gamma_4 := 0.05, \gamma_5 := 0.01, \gamma_6 := 0.003$$

$$\gamma_k := 20.4514 \cdot 0.218673^k \text{ for } k \geq 7$$

These constants γ_k for $k = 3, 4, 5, 6$ are the result of performance optimization of the OKsolver on random k -SAT formulae, while the formula for $k \geq 7$ is the result of linear regression [Kul02].

5.3.1.2. Weighted binaries heuristic

Weighted binaries heuristic (*WBH*) is developed by Li and Anbulagan [LA97b] and applied in the solver **satz**. Each variable is weighted (both positive and negative) based on its occurrences in the formula. Each new binary clause $x \vee y$ is weighted using the sum of the weights of their complementary literals. The sum $\#(\neg x) + \#(\neg y)$ expresses the number of clauses on which resolution can be done with $x \vee y$.

Occurrences in a clause of size k is valued 5^{k-3} . This weighting function followed from performance optimization of **satz** over random formulae. Notice that as in the OKsolver (i.e. γ_k in *CRH*) clauses of size $k + 1$ are about $\frac{1}{5}$ of the importance of clauses of size k - although a different heuristic is used on a different solver.

$$w_{WBH}(x_i) := \sum_{k \geq 2} \gamma_k \cdot \#_k(x_i) \quad \text{with } \gamma_k := 5^{3-k}$$

$$WBH(x_i) := \sum_{(x \vee y) \in \{\mathcal{F}[x_i = 1]_2 \setminus \mathcal{F}_2\}} (w_{WBH}(\neg x) + w_{WBH}(\neg y))$$

5.3.1.3. Backbone search heuristic

Backbone search heuristic (*BSH*) was developed by Dubois and Dequen [DD01]. This heuristic is inspired by the concept of the *backbone* of a formula - the set of

⁵This heuristic is also known as *MNC* and is further discussed in Section 8.7.4.1.

variables that has a fixed truth value in all assignments satisfying the maximum number of clauses [MZK⁺99]. Like *WBH*, the variables are weighted based on their occurrences in clauses of various sizes. Clauses of size $k + 1$ are considered only half⁶ as important as clauses of size k .

The most influential difference between *WBH* and *BSH* is that the latter multiplies the weights of the literals in the newly created binary clauses - while the former adds them. For every new clause $x \vee y$, the product $\#(\neg x) \cdot \#(\neg y)$ expresses the number of resolvents that can be created due to the new clause.

$$w_{BSH}(x_i) := \sum_{k \geq 2} \gamma_k \cdot \#_k(x_i) \quad \text{with } \gamma_k := 2^{3-k}$$

$$BSH(x_i) := \sum_{(x \vee y) \in \mathcal{F}[x_i=1]_2 \setminus \mathcal{F}} (w_{BSH}(\neg x) \cdot w_{BSH}(\neg y))$$

Notice that both $w_{BSH}(x_i)$ and $BSH(x_i)$ express the importance of literal x_i . Since $BSH(x_i)$ is far more costly to compute than $w_{BSH}(x_i)$, *BSH* could only improve performance if it proves to be a better heuristic than w_{BSH} . So far, this claim only holds for random formulae.

Based on the assumption that $BSH(x_i)$ is better than $w_{BSH}(x_i)$, Dubois and Dequen [DD01] propose to iterate the above by using $BSH(x_i)$ instead of $w_{BSH}(x_i)$ for the second iteration to improve the accuracy of the heuristic. This can be repeated by using the $BSH(x_i)$ values of iteration i (with $i > 2$) to compute $BSH(x_i)$ of iteration $i + 1$. However, iterating *BSH* makes it much more costly. In general, performing only a single iteration is optimal in terms of solving time.

In [DD03] Dubois and Dequen offer a normalization procedure for *BSH* such that it weighs *all* newly created clauses - instead of only the binary ones. The normalization is required for fast performances on random k -SAT formula with $k > 3$. Backbone Search Renormalized Heuristic (in short *BSRH*) consists of two additional aspects: 1) Smaller clauses are more heavier using the γ_k weights, and 2) the w_{BSH} values to compute $BSH(x_i)$ are renormalized, by dividing them by the average weight of all literals in $\mathcal{F}[x_i = 1] \setminus \mathcal{F}$ - denoted by $\mu_{BSH}(x_i)$.

$$\mu_{BSH} := \frac{\sum_{C \in \mathcal{F}[x_i=1] \setminus \mathcal{F}} \sum_{x \in C} w_{BSH}(\neg x)}{\sum_{C \in \mathcal{F}[x_i=1] \setminus \mathcal{F}} |C|}$$

$$BSRH(x_i) := \sum_{C \in \mathcal{F}[x_i=1] \setminus \mathcal{F}} \left(\gamma_{|C|} \cdot \prod_{x \in C} \frac{w_{BSH}(\neg x)}{\mu_{BSH}(x_i)} \right)$$

Similar as *BSH*, *BSRH* can be iterated to improve accuracy.

5.3.1.4. Comparison of DIFF heuristics

Example 5.3.1. Consider the unsatisfiable 3-SAT formula $\mathcal{F}_{\text{heuristic}}$ below:

⁶Although the various descriptions of the heuristic [DD01, DD03] use a factor 2, the actual implementation of the heuristic in *knfs* (see <http://www.laria.u-picardie.fr/~dequen/sat/>) also uses factor 5.

$$\begin{aligned} \mathcal{F}_{\text{heuristic}} = & (\neg x_1 \vee x_2 \vee \neg x_6) \wedge (\neg x_2 \vee \neg x_3 \vee \neg x_4) \wedge (\neg x_1 \vee \neg x_2 \vee \neg x_7) \wedge \\ & (\neg x_1 \vee \neg x_3 \vee x_4) \wedge (x_1 \vee \neg x_3 \vee x_4) \wedge (x_1 \vee \neg x_3 \vee \neg x_4) \wedge \\ & (x_2 \vee x_3 \vee \neg x_4) \wedge (\neg x_2 \vee x_3 \vee x_5) \wedge (\neg x_2 \vee x_3 \vee \neg x_5) \wedge \\ & (x_1 \vee x_2 \vee x_6) \wedge (x_1 \vee x_2 \vee x_7) \wedge (x_2 \vee x_4 \vee \neg x_5) \wedge (x_2 \vee x_4 \vee x_5) \end{aligned}$$

Table 5.1 compares the heuristic values of look-aheads on $\mathcal{F}_{\text{heuristic}}$ using the three heuristics *CRW*, *WBH*, and *BSH*. Notice that *CRH* prefers x_2 as decision variable, while *WBH* and *BSH* prefer x_3 . The latter choice will result in a smaller search-tree. Between *WBH* and *BSH* the preferred ordering differs as well. For *BSH*, variables x_4 and x_5 are relatively more important than for *WBH*.

BSH is the most effective heuristic on random k -SAT formulae. The relative effectiveness of these heuristics on structured instances is not well studied yet.

Table 5.1. Comparison between the heuristic values of the look-ahead on the variables in $\mathcal{F}_{\text{heuristic}}$ using *CRH*, *WBH* and *BSH*. The product is used as MIXDIFF.

	$\#(x_i)$	$\#(\neg x_i)$	MIXDIFF(<i>CRH</i>)	MIXDIFF(<i>WBH</i>)	MIXDIFF(<i>BSH</i>)
x_1	4	4	$4 \cdot 4 = 16$	$24 \cdot 21 = 504$	$30 \cdot 27 = 810$
x_2	6	3	$3 \cdot 6 = 18$	$17 \cdot 33 = 516$	$20 \cdot 40 = 800$
x_3	3	4	$4 \cdot 3 = 12$	$30 \cdot 23 = 690$	$56 \cdot 36 = 2016$
x_4	4	3	$3 \cdot 4 = 12$	$21 \cdot 24 = 504$	$36 \cdot 36 = 1296$
x_5	2	2	$2 \cdot 2 = 4$	$15 \cdot 15 = 225$	$27 \cdot 27 = 729$
x_6	1	1	$1 \cdot 1 = 1$	$7 \cdot 7 = 49$	$12 \cdot 12 = 144$
x_7	1	1	$1 \cdot 1 = 1$	$10 \cdot 7 = 70$	$24 \cdot 12 = 288$

5.3.2. Direction heuristics

Various state-of-the-art satisfiability (SAT) solvers use *direction heuristics* to predict the sign of the decision variables: These heuristics choose, after the selection of the decision variable, which Boolean value is examined first. Direction heuristics are in theory very powerful: If always the correct Boolean value is chosen, satisfiable formulae would be solved without backtracking. Moreover, existence of perfect direction heuristics (computable in polynomial time) would prove that $\mathcal{P} = \mathcal{NP}$. These heuristics are also discussed in Section 8.9.

Although very powerful in theory, it is difficult to formulate effective direction heuristics in practice. Look-ahead SAT solvers even use complementary strategies to select the first branch - see Section 5.3.2.1.

Direction heuristics may bias the distribution of solutions in the search-tree. For instance, while using *march* or *kcdfs*, such a biased distribution is observed on hard random 3-SAT formulae. A biased distribution can be used to replace the DPLL *depth-first* search by a search that visits subtrees in order of increasing likelihood of containing a solution - see Section 5.3.2.2.

Figure 5.4. Complete binary search-tree (DPLL) for a formula with nine variables (x_1, \dots, x_9) . The decision variables are shown inside the internal nodes. A node is colored black if all child nodes are unsatisfiable, and white otherwise. The type of edge shows whether it is visited first (left branch), visited last (right branch), its decision variable is assigned to true (positive branch), or its decision variable is assigned to false (negative branch).

The search-tree of a DPLL-based SAT solver can be visualized as a binary search-tree, see Figure 5.4. This figure shows such a tree with decision variables drawn in the internal nodes. Edges show the type of each branch. We will refer to the *left branch* as the subformula that is visited first. Consequently, the *right branch* refers to the one examined later. A black leaf refers to an unsatisfiable dead end, while a white leaf indicates that a satisfying assignment has been found. An internal node is colored black in case both its children are black, and white otherwise. For instance, at depth 4 of this search-tree, 3 nodes are colored white. This means that at depth 4, 3 subtrees contain a solution.

5.3.2.1. Complementary strategies

A wide range of direction heuristics is used in look-ahead SAT solvers:

- **kcdfs**⁷ selects $\mathcal{F}[x_{\text{decision}} = 1]$ if x_{decision} occurs more frequently in \mathcal{F} than $\neg x_{\text{decision}}$. Otherwise it selects $\mathcal{F}[x_{\text{decision}} = 0]$.
- **march** selects $\mathcal{F}[x_{\text{decision}} = 1]$ if $\text{DIFF}(\mathcal{F}, \mathcal{F}[x_{\text{decision}} = 1])$ is smaller than $\text{DIFF}(\mathcal{F}, \mathcal{F}[x_{\text{decision}} = 0])$, and $\mathcal{F}[x_{\text{decision}} = 0]$ otherwise [HDvZvM04].
- **OKsolver** selects the subformula with the smallest probability that a random assignment will falsify a random formula of the same size [Kul02]. It prefers the minimum sum of

$$\sum_{k \geq 2} -|\mathcal{F}_k| \cdot \ln(1 - 2^{-k}) \quad (5.1)$$

- **posit** selects $\mathcal{F}[x_{\text{decision}} = 0]$ if x_{decision} occurs more often than $\neg x_{\text{decision}}$ in the shortest clauses of \mathcal{F} . Otherwise it selects $\mathcal{F}[x_{\text{decision}} = 1]$ [Fre95].
- **satz**⁸ does not use direction heuristics and starts with $\mathcal{F}[x_{\text{decision}} = 1]$.

These heuristics can be divided into two strategies:

A) *Estimate which subformula will require the least computational time.*

This strategy assumes that it is too hard to predict whether a subformula is satisfiable. Therefore, if both subformulae have the same expectation of containing a solution, you will find a solution faster by starting with the one that requires less computational time. From the above solvers, **posit** uses this strategy.

Notice that conflict-driven SAT solvers may prefer this strategy to focus on the most unsatisfiable subformula. This may result in an early conflict, and possibly a short conflict clause. However, since the current look-ahead SAT solvers do not add conflict clauses, this argument is not applicable for these solvers.

B) *Estimate which subformula has the highest probability of being satisfiable.*

If a formula is satisfiable, then it is expected that the subformula which is heuristically the most satisfiable will be your best bet. The other subformula may be unsatisfiable and - more importantly - a waste of time. The solvers **kcdfs**, **march**, and **OKsolver** use this strategy.

Generally these two strategies are complementary: The subformula which can be solved with relatively less computational effort is probably the one which is more

⁷version 2006

⁸version 2.15.2

constraint and therefore has a smaller probability being satisfiable. In practice, for example, satisfiable hard random k -SAT formulae are solved faster by using a direction heuristic based on strategy B , while on various structured satisfiable instances strategy A is more successful.

The *balancedness* of the DPLL search-tree could hint which is the best strategy to use: In a balanced search-tree, solving $\mathcal{F}[x_{\text{decision}} = 0]$ requires almost as much effort as solving $\mathcal{F}[x_{\text{decision}} = 1]$ for each decision variable x_{decision} . In this case, strategy A seems less appealing. Since look-ahead solvers produce a balanced search tree on hard random k -SAT formulae, strategy B would be preferred.

On the other hand, in an unbalanced search-tree one could get lucky using strategy A which would be therefore preferred. On many structured instances look-ahead SAT solvers produce an unbalanced search-tree - although the MIX-DIFF heuristic attempts to achieve a balanced search-tree.

Based on this explanation, `march_ks` uses both strategies: Strategy B is used (as implemented in `march_dl`) in case $\text{DIFF}(\mathcal{F}, \mathcal{F}[x = 0])$ and $\text{DIFF}(\mathcal{F}, \mathcal{F}[x = 1])$ are *comparable*. Otherwise, strategy A is used by preferring the complementary branch which would have been selected by `march_dl`. In `march_ks`, “comparable” is implemented as $0.1 \leq \frac{\text{DIFF}(\mathcal{F}, \mathcal{F}[x=0])}{\text{DIFF}(\mathcal{F}, \mathcal{F}[x=1])} \leq 10$.

5.3.2.2. Distribution of solutions

Given a family of benchmark instances, we can observe the effectiveness of the direction heuristic used in a certain solver on that particular family. The observation can be illustrated as follows: Consider the subtrees at depth d of the DPLL search-tree. These subtrees are denoted by T_i with $i = \{1, \dots, 2^d\}$ and are numbered in depth-first order. The histogram showing the number of formulae in the given family containing at least one solution in T_i is called a *solution distribution plot*.

Figures 5.5 and 5.6 show solution distribution plots at depth 12 for `march_dl` and `kcfnfs` respectively on 3000 random 3-SAT formulae with 350 variables and 1491 clauses (at phase transition density). The observed distribution is clearly biased for both solvers. The distribution observed using `march_dl` is more biased than the one using `kcfnfs`. Based on these plots, one could conclude that the direction heuristics used in `march_dl` are more effective for the instances at hand.

For both solvers, the number of formulae with at least one solution in T_i is highly related to the number of left branches that is required to reach T_i . With this in mind, the DPLL depth first search can be replaced [HvM06b] by a search strategy that, given a *jump depth*, visits the subtrees at that depth in the order of required left branches. Using jump depth 12, first subtree T_1 is visit (twelve left branches, zero right branches), followed by subtrees $T_2, T_3, T_5, T_9, \dots, T_{2049}$ (eleven left branches, one right branch), etc. Random satisfiable formulae of the same size are on average solved much faster using modified DPLL search.

Notice that for conflict-driven solvers this kind of solution distribution plots could not be made. The most important reason is that there is no clear left and right branch, because conflict clauses assign former decision variables to the complement of the preferred truth value. Another difficulty to construct these plots is the use of restarts in conflict-driven solvers. Finally, the use of lazy data-structures makes it very expensive to apply a direction heuristic that requires

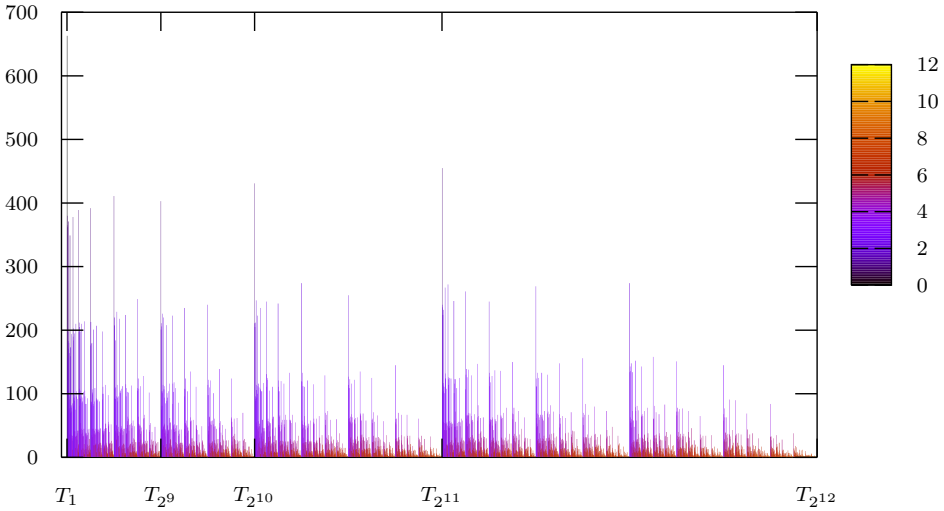

Figure 5.5. Solution distribution plot with `march_dl` showing for each subtree T_i at depth 12 the number of formulae that have at least one solution in that subtree. The experiments are based on 3000 random 3-SAT formulae with 350 variables and 1491 clauses. The colors show the number of right branches.

much statistical data.

5.3.3. Pre-selection heuristics

Overall performance can be gained or lost by performing look-ahead on a subset of the free variables in each node of the DPLL-tree: Gains are achieved by the reduction of computational costs, while losses are the result of either the inability of the *pre-selection heuristics* (heuristics that determine the set of variables to enter the look-ahead phase) to select effective decision variables or to predict candidate failed literals. When look-ahead is performed on a subset of the variables, only a subset of the failed literals is most likely detected. Depending on the formula, this could increase the size of the DPLL-tree. This section describes the two most commonly used pre-selection heuristics in look-ahead SAT solvers: *prop_z* and *clause reduction approximation*.

5.3.3.1. *prop_z*

Li [LA97a] developed the *prop_z* heuristic for his solver `satz`, which is also used in `kcdfs`. It pre-selects variables based on their occurrences in binary clauses. The *prop_z* heuristic is developed to perform faster on hard random k -SAT formulae. Near the root of the search-tree it pre-selects all free variables. From a certain depth on, it pre-selects only variables that occur both positive and negative in binary clauses. It always pre-selects a lower bound of 10 variables.

Although this heuristic is effective on hard random k -SAT formulae, its behavior on structured instances is not clear. On some benchmarks it will pre-select all

Figure 5.6. Solution distribution plot with `knfs` showing for each subtree T_i at depth 12 the number of formulae that have at least one solution in that subtree. The experiments are based on 3000 random 3-SAT formulae with 350 variables and 1491 clauses. The colors show the number of right branches.

free variables in all nodes of the search-tree, while on others it always pre-selects slightly more variables than the lower bound used.

Table 5.2. Average number of variables selected for the LOOKAHEAD procedure by $\text{RANK}_{10\%}$ and prop_z for 300 variables and 1275 clauses random 3-SAT problems.

depth	#freeVars	prop_z	depth	#freeVars	prop_z
1	298.24	298.24	11	264.55	26.81
2	296.52	296.52	12	260.53	21.55
3	294.92	293.89	13	256.79	19.80
4	292.44	292.21	14	253.28	19.24
5	288.60	280.04	15	249.96	19.16
6	285.36	252.14	16	246.77	19.28
7	281.68	192.82	17	243.68	19.57
8	277.54	125.13	18	240.68	19.97
9	273.17	71.51	19	237.73	20.46
10	268.76	40.65	20	234.82	20.97

5.3.3.2. Clause reduction approximation

In march the pre-selection heuristics are based on an approximation of a decision heuristic that counts the number of newly created clauses, called *clause reduction approximation (CRA)*. It uses the sizes of all clauses in the formula and is therefore more costly than prop_z . First, the set of variables to be assigned during look-ahead on x is approximated. All variables that occur with $\neg x$ in

binary clauses are used as approximated set. Second, if y_i occurs in this set, then all n -ary clauses in which $\neg y_i$ occurs will be reduced. This is an approximation of the number of newly created clauses, because some of the reduced ones will be satisfied. Third, the product is used as MIXDIFF. Let $\#_{>2}(x_i)$ denotes the number of occurrences of literal x_i in clauses with size > 2 . For all free variables CRA is computed as:

$$CRA(x) := \left(\sum_{x \vee y_i \in \mathcal{F}} \#_{>2}(\neg y_i) \right) \cdot \left(\sum_{\neg x \vee y_i \in \mathcal{F}} \#_{>2}(\neg y_i) \right) \quad (5.2)$$

Variables with the highest CRA scores are pre-selected for the LOOKAHEAD procedure. Once the CRA scores are computed, one has to determine how many variables should be pre-selected. The optimal number varies heavily from benchmark to benchmark and from node to node in the search-tree. Early march versions used a fraction of the original number of variables. Most versions used 10% of the number of variables, which is referred to as RANK_{10%}. Later versions use an adaptive heuristic discussed in the next paragraph.

5.3.3.3. Adaptive Ranking

As observed in [HDvZvM04], the optimal number of pre-selected variables is closely related to the number of detected failed literals: When relatively many failed literals were detected, a larger pre-selected set appeared optimal. Let $\#\text{failed}_i$ be the number of detected failed literals in node i . To exploit this correlation, the average number of detected failed literals is used as an indicator for the (maximum) size of the pre-selected set in node n (denoted by RANKADAPT _{n}):

$$\text{RANKADAPT}_n := L + \frac{S}{n} \sum_{i=1}^n \#\text{failed}_i \quad (5.3)$$

In the above, parameter L refers to the lower bound of RANKADAPT _{n} (namely when the average tends to zero) and S is a parameter modeling the importance of failed literals. `March_eq` uses $L := 5$ and $S := 7$ based on experiments on structured and random benchmarks. Notice that the above adaptive pre-selection heuristics are heavily influenced by the decision heuristics - which in turn are also affected by these heuristics.

Generally RANKADAPT select a subset of the free variables, but in some cases—due to many detected failed literals—all free variables are selected. It may occur that, during the LOOKAHEAD procedure, all selected variables are forced. In that case a new set of variables is pre-selected.

5.4. Additional Reasoning

Selection of decision variables by performing many look-aheads is very expensive compared to alternative decision heuristics. As such, this could hardly be considered as an advantage. However, since the decision heuristics are already costly, some additional reasoning is relatively cheap. This section presents various

techniques that can be added to the LOOKAHEAD procedure in order to improve overall performance.

Look-ahead on variables which will not result in a conflict appears only useful to determine which variable has the highest decision heuristic value. However, by applying some additional reasoning, look-ahead on some variables can also be used to reduce the formula (like failed literals). Look-ahead on the other variables can be used to add *resolvents* (learned clauses) to further constrain the formula. Three kinds of additional reasoning are used in look-ahead SAT solvers for these purposes: *Local learning* (Section 5.4.1), *autarky detection* (Section 5.4.2), and *double look-ahead* (Section 5.4.3).

5.4.1. Local learning

During the look-ahead on x , other variables y_i can be assigned by unit propagation. Some due to the presence of binary clauses $\neg x \vee (\neg)y_i$, called *direct implications*. Variables assigned by other clauses are called *indirect implications*. For those variables y_i that are assigned to true (or false) by a look-ahead on x though indirect implications, a binary clause $\neg x \vee y_i$ (or $\neg x \vee \neg y_i$, respectively) can be added to the formula. This is referred to as *local learning*. As the name suggests, these clauses are not globally valid and should therefore be removed while backtracking.

Example 5.4.1. Consider the formula $\mathcal{F}_{\text{learning}}$ below:

$$\mathcal{F}_{\text{learning}} := (\neg x_1 \vee x_2) \wedge (\neg x_1 \vee \neg x_2 \vee x_3) \wedge (\neg x_1 \vee \neg x_3 \vee x_4) \wedge (x_1 \vee x_3 \vee x_6) \wedge (x_1 \vee x_4 \vee \neg x_5) \wedge (x_1 \vee \neg x_6) \wedge (x_4 \vee x_5 \vee x_6) \wedge (x_5 \vee \neg x_6)$$

Some look-aheads on literals $(\neg)x_i$ will result in unit clauses, thereby assigning other variables. These assignments are listed below:

$$\begin{array}{ll} [x_1 := 0] \rightarrow \{x_3=1, x_6=0\} & [x_4 := 0] \rightarrow \{\} \\ [x_1 := 1] \rightarrow \{x_2=1, x_3=1, x_4=1\} & [x_4 := 1] \rightarrow \{\} \\ [x_2 := 0] \rightarrow \{x_1=0, x_3=1, x_6=0\} & [x_5 := 0] \rightarrow \{x_4=1, x_6=0\} \\ [x_2 := 1] \rightarrow \{\} & [x_5 := 1] \rightarrow \{\} \\ [x_3 := 0] \rightarrow \{\} & [x_6 := 0] \rightarrow \{\} \\ [x_3 := 1] \rightarrow \{\} & [x_6 := 1] \rightarrow \{x_1=1, x_2=1, x_3=1, x_4=1, x_5=1\} \end{array}$$

Eight of the above assignments follow from indirect implications. Therefore, these can be added to $\mathcal{F}_{\text{learning}}$:

$$\begin{array}{llll} x_1 \vee x_3 & \neg x_1 \vee x_4 & x_2 \vee \neg x_6 & x_4 \vee x_5 \\ \neg x_1 \vee x_3 & x_2 \vee \neg x_3 & x_3 \vee \neg x_6 & x_4 \vee \neg x_6 \end{array}$$

In the example above, the number of binary clauses that could be added by local learning is equal to the number of original clauses in $\mathcal{F}_{\text{learning}}$. In most real world examples, the number of local learned clauses is significantly larger than the number of original clauses. Therefore, adding all these binary clauses is generally not useful because it slows down propagation.

5.4.1.1. Necessary assignments

A cheap technique to reduce the size of the formula is detection of *necessary assignments*: If the look-ahead on x_i assigns x_j to true *and* the look-ahead on $\neg x_i$ assigns x_j to true then the assignment x_j to true is referred to as necessary. This technique requires only the short storage of implications. First, store all implications while performing look-ahead on x_i . Then continue with look-ahead on $\neg x_i$ and check for each implication whether it is in the stored list. All matches are necessary assignments. After look-ahead on $\neg x_i$ the stored implications can be removed.

In Example 5.4.1, variable x_3 is necessarily assigned to true because it is implied by both x_1 and $\neg x_1$. Necessary assignments can also be detected by adding local learned clauses: When these clauses are added, look-ahead on the complement of the necessary assignment will fail. Notice that by searching for necessary assignments, variables which are not in the pre-selected set can be forced to an assignment.

Searching for necessary assignments is a simplified technique of learning in the Stålmarck proof procedure [SS98]. This patented procedure learns the intersection of the new clauses in the reduced formulae (after look-ahead on x_i and $\neg x_i$). Necessary assignments are only the new unit clauses in this intersection. One could learn even more by adding clauses of size 2 and larger, but none of the current look-ahead SAT solvers adds these clauses because computing them is quite expensive. However, the HeerHugo SAT solver [GW00], inspired by the Stålmarck proof procedure, performs the “full” learning. The theory regarding these and other strengthenings of unit clause propagation are discussed in [Kul99a, Kul04].

5.4.1.2. Constraint resolvents

The concept of necessary assignments is not sufficient to detect all forced literals by using local learning. For example, after adding the learned clauses $\neg x_1 \vee x_4$ and $x_4 \vee x_5$ to $\mathcal{F}_{\text{learning}}$, look-ahead on $\neg x_4$ will fail, forcing x_4 to be assigned to true. Now, the question arises: Which local learned clauses should be added to detect all forced literals?

Local learned clauses are useful when the number of assigned variables is increased during look-ahead on the complement of one of its literals. For instance, given a formula with clauses $x_1 \vee x_2$ and $\neg x_2 \vee x_3$. The local learned clause $x_1 \vee x_3$ is not useful because look-ahead on $\neg x_1$ would already assign x_3 to true and look-ahead on $\neg x_3$ would already assign x_1 to true.

However, given a formula with clauses $x_1 \vee x_2$ and $x_1 \vee \neg x_2 \vee x_3$ then local learned clause $x_1 \vee x_3$ is useful: Only after adding this clause, look-ahead on $\neg x_3$ will assign x_1 to true. These useful local learned clauses are referred to as *constraint resolvents* [HDvZvM04].

In Example 5.4.1, all local learned clauses except $x_2 \vee \neg x_6$ are constraint resolvents. Yet, in practice, only a small subset of the local learned clauses are constraint resolvents. In Section 5.5.1 a technique is explained to efficiently detect constraint resolvents.

Constraint resolvents and heuristics. Pre-selection heuristics rank variables based on their occurrences in binary clauses - see Section 5.3.3. Addition of constraint resolvents (or local learned clauses in general) will increase the occurrences in binary clauses of variables in the pre-selected set in particular. So, once variables are pre-selected, their rank will rise, increasing the chances of being pre-selected again in a next node. Therefore, it becomes harder for “new” variables to enter the look-ahead phase.

5.4.2. Autarky Reasoning

An *autarky* (or autark assignment) is a partial assignment φ that satisfies all clauses that are “touched” by φ . So, all satisfying assignments are autark assignments. Autarkies that do not satisfy all clauses can be used to reduce the size of the formula: Let $\mathcal{F}_{\text{touched}}$ be the clauses in \mathcal{F} that are satisfied by an autarky. The remaining clauses $\mathcal{F}^* := \mathcal{F} \setminus \mathcal{F}_{\text{touched}}$ are satisfiability equivalent with \mathcal{F} - see Chapter 14. So, if we detect an autark assignment, we can reduce \mathcal{F} by removing all clauses in $\mathcal{F}_{\text{touched}}$.

5.4.2.1. Pure literals

The smallest example of an autarky is a *pure literal*: A literal whose negation does not occur in the formula. Consider the example formula:

$$\mathcal{F}_{\text{pure literal}} := (x_1 \vee \neg x_2) \wedge (\neg x_1 \vee x_3) \wedge (\neg x_2 \vee \neg x_3)$$

Variable x_2 occurs only negated in this formula - making $\neg x_2$ a pure literal. Assigning x_2 to false will therefore only satisfy clauses. Under this assignment the only clause left is $(\neg x_1 \vee x_3)$. Now both $\neg x_1$ and x_3 are pure literals. So by assigning a pure literal to true could make other literals pure.

5.4.2.2. Autarky detection by look-ahead

Look-aheads can also be used to detect autarkies. Whether a look-ahead resulted in an autark assignment requires a check that all reduced clauses became satisfied. Recall that the *CRH* and the *BSH* look-ahead evaluation heuristics count (and weight, respectively) the newly created clauses. While using these heuristics, an autarky detection check can be computed efficiently: All reduced clauses are satisfied if and only if their heuristic value is 0.

Example 5.4.2. Consider the formula $\mathcal{F}_{\text{autarky}}$ below.

$$\mathcal{F}_{\text{autarky}} := (x_1 \vee \neg x_2) \wedge (\neg x_1 \vee x_5) \wedge (\neg x_1 \vee x_2 \vee \neg x_3) \wedge (x_3 \vee x_4) \wedge (\neg x_2 \vee \neg x_3 \vee \neg x_4) \wedge (x_2 \vee x_4 \vee \neg x_5)$$

The heuristic values of the *CRH* look-ahead evaluation heuristic (in this case the number of newly created binary clauses) of all possible look-aheads on $\mathcal{F}_{\text{autarky}}$ are shown in Table 5.3. Both the look-aheads on $\neg x_3$ and $\neg x_5$ result in a heuristic value of 0. The first represents the autark assignment $\varphi = \{x_3 = 0, x_4 = 1\}$, and the second represents the autarky assignment $\varphi = \{x_1 = x_2 = x_5 = 0\}$.

Table 5.3. Number of new binary clauses after a look-ahead on x_i on $\mathcal{F}_{\text{autarky}}$. For this formula these values equal $CRH(x_i)$ because the largest clause has length 3.

	x_1	$\neg x_1$	x_2	$\neg x_2$	x_3	$\neg x_3$	x_4	$\neg x_4$	x_5	$\neg x_5$
$CRH(x_i)$	2	2	1	2	2	0	1	2	1	0

In general, look-ahead SAT solvers do not check whether a look-ahead satisfies all remaining clauses - thereby detecting a satisfying assignment. By detecting autarkies, satisfying assignments will also be detected as soon as they appear.

5.4.2.3. Look-ahead autarky resolvents

In case a look-ahead satisfies all but one of the reduced clauses, we have almost detected an autarky. In Example 5.4.2 the look-ahead on x_2 , x_4 , and x_5 created only one clause that was not satisfied: $\neg x_3 \vee \neg x_4$, $\neg x_2 \vee \neg x_3$, and $x_2 \vee x_4$ respectively. Due to these binary clauses, none of the variables is forced to a value.

However, we know that if such a particular clause were satisfied, we would have detected an autarky. This knowledge can be added to the formula: In case of the look-ahead on x_2 , if $\neg x_3 \vee \neg x_4$ is satisfied x_2 is true. So $\neg x_3 \rightarrow x_2$ and $\neg x_4 \rightarrow x_2$. The binary clauses of these implications, $x_3 \vee x_2$ and $x_4 \vee x_2$, are referred to as *look-ahead autarky resolvents*. Recall that the look-ahead on $\neg x_3$ in the autarky $\varphi = \{x_3 = 0, x_4 = 1\}$. After the addition of $x_3 \vee x_2$, the same look-ahead will result in the autarky $\varphi = \{x_1 = 1, x_2 = 1, x_3 = 0, x_4 = 1, x_5 = 1\}$.

Look-ahead autarky resolvents can be added to the formula to further constrain it. Generally, let C be the only reduced clause which is not satisfied after the look-ahead on x . For all literals l_i in C we can add to the formula a look-ahead autarky resolvent $x \vee \neg l_i$. More details about look-ahead autarky resolvents are described in Section 14.13.2 and [Kul99c, Kul99b].

Look-ahead autarky resolvents and heuristics. Although look-ahead autarky resolvents further constrain a formula, their addition could contribute to a significant drop in performance of a solver. The reason for this paradox can be found in the effect of look-ahead autarky resolvents on the heuristics: According to difference heuristics, variables are important if they create many new clauses. Therefore, variables on which look-ahead results in only a single new clause should be considered unimportant. However, the heuristic values of *WBH*, *BSH*, and *CRA* increases after adding these look-ahead autarky resolvents. This makes it more likely that unimportant variables are chosen as decision variable. Therefore, it is useful to neglect these clauses while computing the heuristics.

5.4.3. Double look-ahead

Due to the design of MIXDIFF heuristics in look-ahead SAT solvers, unbalanced variables are rarely selected as decision variables. To compensate for this, Li developed the DOUBLELOOK procedure [Li99]. This procedure performs look-aheads on a second level of propagation (on the reduced formula after a look-ahead) to increase the number of detected forced literals.

We refer to the *double look-ahead* on x as calling the DOUBLELOOK procedure on the reduced formula $\mathcal{F}[x = 1]$. A double look-ahead on x is called successful if the DOUBLELOOK procedure detects that $\mathcal{F}[x = 1]$ is unsatisfiable. Otherwise it is called unsuccessful. Similar to a failed look-ahead on x , a successful double look-ahead on x detects a conflict in $\mathcal{F}[x = 1]$ and thereby forces x to be assigned to false.

Although double look-aheads are expensive, they can be a relatively efficient method to detect some forced literals in practice. In order to reduce the solving time, many double look-aheads must be successful. Prediction of the success of a double look-ahead is therefore essential.

Double look-ahead heuristics. The heuristics regarding double look-aheads focus on the success predictor. Li suggests to use the number of newly created binary clauses as an effective predictor [Li99]. If the number of newly created binary clauses during look-ahead on x (denoted by $|\mathcal{F}[x = 1]_2 \setminus \mathcal{F}|$) is larger than a certain parameter (called Δ_{trigger}), then the DOUBLELOOK procedure should be triggered. All double look-ahead heuristics are concerned with the optimal value for Δ_{trigger} .

The first implementation of the DOUBLELOOK procedure used a static value for Δ_{trigger} . Li implemented $\Delta_{\text{trigger}} := 65$ in his solver *satz*. This magic constant is based on experiments on hard random 3-SAT formulae. Although these instances can be solved much faster using this setting, on structured instances it frequently results in the call of too many double look-aheads, which will reduce overall performance.

Another static implementation for Δ_{trigger} is found in *kcncfs* by Dubois and Dequen. They use $\Delta_{\text{trigger}} := 0.17 \cdot n$, with n referring to the original number of variables. This setting also arises from experiments on random 3-SAT formulae. Especially on random and structured instances with large n , better results are obtained compared to $\Delta_{\text{trigger}} := 65$.

A first dynamic heuristic was developed by Li for a later version of *satz*. It initializes $\Delta_{\text{trigger}} := 0.17 \cdot n$. If a double look-ahead on x is unsuccessful, Δ_{trigger} is updated to $\Delta_{\text{trigger}} := |\mathcal{F}[x = 1]_2 \setminus \mathcal{F}|$. The motivation for the update is as follows: Assuming the number of newly created binary clauses is an effective predictor for success of a double look-ahead, and because the double look-ahead on x was unsuccessful, Δ_{trigger} should be at least $|\mathcal{F}[x = 1]_2 \setminus \mathcal{F}|$. After a successful DoubleLook call, Δ_{trigger} is reset to $\Delta_{\text{trigger}} = 0.17 \cdot n$. In practice, this dynamic heuristic "turns off" the DOUBLELOOK procedure on most structured instances. The procedure is only rarely triggered due to the first update rule. The performance on these instances is improved to back to normal (i.e. not calling the DOUBLELOOK at all).

A second dynamic heuristic was developed by Heule and Van Maaren for their solver *march_dl* [HvM07]. It initializes $\Delta_{\text{trigger}} := 0$. Like the dynamic heuristic in *satz*, it updates $\Delta_{\text{trigger}} = |\mathcal{F}[x = 1]_2 \setminus \mathcal{F}|$ after an unsuccessful double look-ahead on x . The important difference is that Δ_{trigger} is not decreased after a successful doublelook, but Δ_{trigger} is slightly reduced after each look-ahead. Therefore, double look-aheads are performed once in a while. On random instances this dynamic heuristic yields comparable performances on random formulae. However, the use

of the DOUBLELOOK procedure with this heuristic improves the performance on many structured instances as well.

5.4.3.1. Double look-ahead resolvents

An unsuccessful double look-ahead is generally not a total waste of time. For example, the look-ahead on x_i triggers the DOUBLELOOK procedure. On the second level of propagation three failed literals are detected: x_r , $\neg x_s$, and x_t . Thus we learn $x_i \rightarrow \neg x_r$, $x_i \rightarrow x_s$, and $x_i \rightarrow \neg x_t$ - equivalent to the binary clauses $\neg x_i \vee \neg x_r$, $\neg x_i \vee x_s$, $\neg x_i \vee \neg x_t$. Since the DOUBLELOOK procedure performs additional look-aheads on free variables in $\mathcal{F}[x_i = 1]$, we know that \mathcal{F} does not contain these binary clauses - otherwise they would have been assigned already.

We refer to these binary clauses as *double look-ahead resolvents*. In case a double look-ahead is unsuccessful, double look-ahead resolvents can be added to \mathcal{F} to further constrain the formula. On the other hand, a successful double look-ahead on x_i will force x_i to false, thereby satisfying all these resolvents.

Adding double look-ahead resolvents can be useful to reduce overall costs caused by the DOUBLELOOK procedure. If a look-ahead on x_i triggers this procedure and appears to be unsuccessful, it is likely that it will trigger it again in the next node of the search-tree. By storing the failed literals at the second level of propagation as resolvents, the DOUBLELOOK procedure does not have to perform costly look-aheads to detect them again.

Double look-ahead resolvents and heuristics. Since the DOUBLELOOK procedure is triggered when a look-ahead on literal $(\neg)x_i$ creates many new binary clauses, the DIFF values for those literals is relatively high. Adding double look-ahead resolvents will further boost these DIFF values. This increases the chance that variables are selected as decision variable because the DIFF of either its positive or negative literal is very large. Concluding: By adding double look-ahead resolvents, decision heuristics may select decision variables yielding a more unbalanced search-tree.

5.5. Eager Data-Structures

Unit propagation is the most costly part of state-of-the-art complete SAT solvers. Within conflict-driven solvers, the computational costs of unit propagation is reduced by using lazy data-structures such as 2-literal watch pointers. Yet, for look-ahead SAT solvers these data-structures are not useful: The costs of unit propagation in these solvers is concentrated in the LOOKAHEAD procedure due to the numerous look-aheads. To compute the difference heuristics (as presented in Section 5.3.1), one requires the sizes of the reduced clauses. By using lazy data-structures, these sizes cannot be computed cheaply. However, by using *eager data-structures* the unit propagation costs can be reduced. The use of eager data-structures originates from the Böhm SAT solver [BS96]. This section offers three techniques to reduce the costs of unit propagation:

- **Efficient storage of binary clauses:** Binary clauses can be stored such that they require only half the memory compared to conventional storage.

In general, structured instances consists mostly of binary clauses. This significantly reduces the storage of the formula. Such a way of storage reduces the cost of unit propagation and makes it possible to cheaply detect constraint resolvents - see Section 5.5.1

- **Removal of inactive clauses:** Many of the original clauses become inactive (satisfied) down in the search-tree. Look-ahead can be performed faster if these clauses are removed from the data-structures - see Section 5.5.2
- **Tree based look-ahead:** Many propagations made during the look-ahead phase are redundant. A technique called tree-based look-ahead reduces this redundancy using implication trees - see Section 5.5.3.

5.5.1. Binary implication arrays

Generally, clauses are stored in a clause database together with a look-up table for each literal in which clauses it occurs. Such a storage is relatively cheap for binary clauses: Instead of storing the clauses, one could add the implications of assigning a literal to true directly in the “look-up table” [PH02]. We refer to such a storage as *binary implication arrays*. Notice that the latter data-structure requires only half the space compared to the former one. Figure 5.7 shows a graphical example of both data-structures for four binary clauses. Storing clauses in separate binary and n-ary data-structures reduced the computational costs of unit propagation: 1) Cache performance is improved because of the cheaper storage, and 2) No look-up is required for binary clauses when they are stored in binary implication arrays.

Figure 5.7. (a) A structure with binary clauses stored in a clause database, and literal look-up arrays containing the indices that point to the clauses in which they occur. (b) Binary clauses stored in implication arrays.

Besides the cheaper storage, splitting a formula in binary clauses (\mathcal{F}_2) and n -ary clauses ($\mathcal{F}_{>2}$) is also useful to efficiently detect constraint resolvents: Recall that constraint resolvents consist of the complement of the look-ahead literal and a literal that only occurs in a unit clause that originates from an n -ary clause. By performing unit propagation in such a way that unit clauses resulting from clauses in \mathcal{F}_2 are always preferred above those in $\mathcal{F}_{>2}$, the latter can be used to construct constraint resolvents. Algorithm 5.4 shows this *binary clause preferred (BCP) unit propagation* including the addition of constraint resolvents. Notice that this procedure returns both an expanded formula with learned constraint resolvents ($\mathcal{F}_2 \cup \mathcal{F}_{>2}$) and a reduced formula by the look-ahead ($\mathcal{F}[x = 1]$).

Algorithm 5.4 BCPUNITPROPAGATION (formula \mathcal{F} , variable x)

```

1:  $\varphi := \{x \leftarrow 1\}$ 
2: while empty clause  $\perp \notin \varphi \circ \mathcal{F}_2$  and a unit clause  $\in \varphi \circ \mathcal{F}_2$  do
3:   while empty clause  $\perp \notin \varphi \circ \mathcal{F}_2$  and unit clause  $\{y\} \in \varphi \circ \mathcal{F}_2$  do
4:      $\varphi := \varphi \cup \{y \leftarrow 1\}$ 
5:   end while
6:   if empty clause  $\perp \notin \varphi \circ \mathcal{F}_{>2}$  and unit clause  $\{y\} \in \varphi \circ \mathcal{F}_{>2}$  then
7:      $\mathcal{F}_2 := \mathcal{F}_2 \cup \{\neg x \vee y\}$ 
8:   end if
9: end while
10: return  $\mathcal{F}_2 \cup \mathcal{F}_{>2}, \varphi \circ \mathcal{F}$ 

```

5.5.2. Removal of inactive clauses

The presence of inactive clauses increases the computational costs of unit propagation during the LOOKAHEAD procedure. Two important causes can be observed: First, the larger the number of clauses considered during a look-ahead, the poorer the performance of the cache. Second, if both active and inactive clauses occur in the active data-structure during the look-ahead, a check is required to determine the status of every clause. Removal of inactive clauses from the active data-structure prevents these unfavorable effects from taking place.

All satisfied clauses are clearly inactive clauses. In case clauses are stored in separate binary and n -ary data-structures (see Section 5.5.1), then also clauses become inactive if they are represented in both data-structures: If an n -ary clause becomes a binary one and is added to the binary clause data-structure, it can be removed from the n -ary data-structure.

5.5.3. Tree-based look-ahead

Suppose the LOOKAHEAD procedure is about to perform look-ahead on the free variables x_1 , x_2 , and x_3 on a formula that contains the binary clauses $x_1 \vee \neg x_2$ and $x_1 \vee \neg x_3$. Obviously, the look-ahead on x_1 will assign all variables that are forced by $x_1 = 1$. Also, due to the binary clauses, the look-ahead on x_2 and x_3 will assign these variables (amongst others). Using the result of the look-ahead on x_1 , the look-aheads on x_2 and x_3 can be performed more efficiently.

Generally, suppose that two look-ahead literals share a certain implication. In this simple case, we could propagate the shared implication first, followed by a propagation of one of the look-ahead literals, backtracking the latter, then propagating the other look-ahead literal and finally backtracking to the initial state. This way, the shared implication has been propagated only once.

Figure 5.8 shows this example graphically. The implications (from the binary clauses) among x_1 , x_2 and x_3 form a small tree. Some thought reveals that this process, when applied recursively, could work for arbitrary trees. Based on this idea - at the start of each look-ahead phase - trees can be constructed from the implications between the literals selected for look-ahead, in such a way that each literal occurs in exactly one tree. By recursively visiting these trees, the LOOKAHEAD procedure is more efficient. Of course, the more dense the implication graph which arises from the binary clauses, the more possibilities are available to form trees. Adding all sorts of resolvents will in many cases be an important catalyst for the effectiveness of this method.

Chapter 6

Incomplete Algorithms

Henry Kautz, Ashish Sabharwal, and Bart Selman

An *incomplete* method for solving the propositional satisfiability problem (or a general constraint satisfaction problem) is one that does not provide the guarantee that it will eventually either report a satisfying assignment or declare that the given formula is unsatisfiable. In practice, most such methods are biased towards the satisfiable side: they are typically run with a pre-set resource limit, after which they either produce a valid solution or report failure; they never declare the formula to be unsatisfiable. These are the kind of algorithms we will discuss in this chapter. In complexity theory terms, such algorithms are referred to as having one-sided error. In principle, an incomplete algorithm could instead be biased towards the unsatisfiable side, always providing proofs of unsatisfiability but failing to find solutions to some satisfiable instances, or be incomplete with respect to both satisfiable and unsatisfiable instances (and thus have two-sided error).

Unlike systematic solvers often based on an exhaustive branching and backtracking search, incomplete methods are generally based on *stochastic local search*, sometimes referred to as SLS. On problems from a variety of domains, such incomplete methods for SAT can significantly outperform DPLL-based methods. Since the early 1990's, there has been a tremendous amount of research on designing, understanding, and improving local search methods for SAT.¹ There have also been attempts at hybrid approaches that explore combining ideas from DPLL methods and local search techniques [e.g. HLDV02, MSG96, Pre01, RD96]. We cannot do justice to all recent research in local search solvers for SAT, and will instead try to provide a brief overview and touch upon some interesting details. The interested reader is encouraged to further explore the area through some of the nearly a hundred publications we cite along the way.

We begin the chapter by discussing two methods that played a key role in the success of local search for satisfiability, namely **GSAT** [SLM92] and **Walksat** [SKC93]. We will then discuss some extensions of these ideas, in particular clause weighting schemes which have made local search solvers highly competitive [CI96,

¹Various works [APSS05, CI96, FCS97, GW93, GM94, Gu92, GPFW97, HK05, Hoo99, Hoo02, HS04, KS94, Kon94, LWZ07, LSB03, MSK97, Mor93, PW96, PTS07, RF93, SS01, Spe93, TPBF04, WW00], and others.

Fra97, HTH02, ITA⁺06, Mor93, SLM92, TPBF04], and explore alternative techniques based on the discrete Lagrangian method [SSH01, SW98, WW99, WW00]. We will close this chapter with a discussion of the phase transition phenomenon in random k -SAT [CA93, KS94, MSL92] which played a critical role in the development of incomplete methods for SAT in the 1990s, and mention a relatively new incomplete technique for SAT called Survey Propagation [MPZ02].

These ideas lie at the core of most of the local search based competitive incomplete SAT solvers out there today, and have been refined and implemented in a number of very successful prototypes including `adaptg2wsat+`, `AdaptNovelty`, `gNovelty+`, `R+AdaptNovelty+`, `SAPS`, `UBCSAT`, `UnitWalk`, and `Walksat`. Rather than going into the details of each individual solver, we hope to present the broader computer science concepts that form the backbone of these solvers and to provide the reader with enough background and references to further explore the intricacies if desired.

We note that there are other exciting incomplete solution methodologies, such as those based on translation to Integer Programming [Hoo88, KKRR90], Evolutionary and Genetic Algorithms [DJW02, ES03, GMR02, LSH06], and Finite Learning Automata [GB07], that we will not discuss here. There has also been work on formally analyzing local search methods, yielding some of the best $o(2^n)$ time algorithms for SAT. For instance, the expected running time, ignoring polynomial factors, of a simple local search method with restarts after every $3n$ “flips” has been shown to be $(2 \cdot (k - 1)/k)^n$ for k -SAT [Sch99, Sch02], which yields a complexity of $(4/3)^n$ for 3-SAT. This result has been derandomized to yield a deterministic algorithm with complexity 1.481^n up to polynomial factors [DGH⁺02]. We refer the reader to Part 1, Chapter 12 of this Handbook for a detailed discussion of worst-case upper bounds for k -SAT.

For the discussion in the rest of this chapter, it will be illustrative to think of a propositional formula F with n variables and m clauses as creating a discrete manifold or *landscape* in the space $\{0, 1\}^n \times \{0, 1, \dots, m\}$. The 2^n truth assignments to the variables of F correspond to the points in $\{0, 1\}^n$, and the “height” of each such point, a number in $\{0, 1, \dots, m\}$, corresponds to the number of clauses of F that are violated by this truth assignment. The solutions or satisfying assignments for F are precisely the points in this landscape with height zero, and thus correspond to the global minima of this landscape, or, equivalently, the global minima of the function that maps each point in $\{0, 1\}^n$ to its height. The search problem for SAT is then a search for a global minimum in this implicitly defined exponential-size landscape. Clearly, if the landscape did not have any local minima, a greedy descent would provide an effective search method. All interesting formulas, however, do have local minima—the main challenge and opportunity for the designers of local search methods.

This landscape view also leads one naturally to the problem of *maximum satisfiability* or MAX-SAT: Given a formula F , find a truth assignment that satisfies the most number of clauses possible. Solutions to the MAX-SAT problem are, again, precisely the global minima of the corresponding landscape, only that these global minima may not have height zero. Most of the incomplete methods we will discuss in this chapter, especially those based on local search, can also work as a solution approach for the MAX-SAT problem, by providing the “best found”

truth assignment (i.e., one with the lowest observed height) upon termination. Of course, while it is easy to test whether the best found truth assignment is a solution to a SAT instance, it is NP-hard to perform the same test for a MAX-SAT instance. Thus, this approach only provides a heuristic algorithm for MAX-SAT, with a two-sided error. For further details on this problem, we refer the reader to Part 2, Chapter 19 of this Handbook.

6.1. Greedy Search and Focused Random Walk

The original impetus for trying a local search method on the satisfiability problem was the successful application of such methods for finding solutions to large N -queens instances, first using a connectionist system by Adorf and Johnston [AJ90], and then using greedy local search by Minton et al. [MJPL90]. It was originally assumed that this success simply indicated that N -queens was an easy problem, and researchers felt that such techniques would fail in practice for SAT and other more intricate problems. In particular, it was believed that local search methods would easily get stuck in local minima, with a few clauses remaining unsatisfied. Experiments with the solver **GSAT** showed, however, that certain local search strategies often do reach global minima, in many cases much faster than systematic search methods.

GSAT is based on a randomized local search technique proposed for combinatorial optimization by Lin and Kernighan [LK73] and Papadimitriou and Steiglitz [PS82]. The basic **GSAT** procedure, introduced by Selman et al. [SLM92] and described here as Algorithm 6.1, starts with a randomly generated truth assignment for all variables. It then greedily changes (‘flips’) the truth assignment of the variable that leads to the greatest decrease in the total number of unsatisfied clauses. The *neighborhood* of the current truth assignment, thus, is the set of n truth assignments each of which differs from the current one in the value of exactly one variable. Such flips are repeated until either a satisfying assignment is found or a pre-set maximum number of flips (**MAX-FLIPS**) is reached. This process is repeated as needed, up to a maximum of **MAX-TRIES** times.

Selman et al. showed that **GSAT** substantially outperformed even the best backtracking search procedures of the time on various classes of formulas, including randomly generated formulas and SAT encodings of graph coloring instances [JAMS91]. The search of **GSAT** typically begins with a rapid greedy descent towards a better truth assignment (i.e., one with a lower height), followed by long sequences of “sideways” moves. Sideways moves are moves that do not increase or decrease the total number of unsatisfied clauses. In the landscape corresponding to the formula, each collection of truth assignments that are connected together by a sequence of possible sideways moves is referred to as a *plateau*. Experiments indicate that on many formulas, **GSAT** spends most of its time on plateaus, transitioning from one plateau to another every so often. Interestingly, Frank et al. [FCS97] observed that in practice, almost all plateaus do have so-called “exits” that lead to another plateau with a lower number of unsatisfied clauses. Intuitively, in a very high dimensional search space such as the space of a 10,000 variable formula, it is very rare to encounter local minima, which are plateaus from where there is no local move that decreases the number

Algorithm 6.1: GSAT (F)

```

Input      : A CNF formula  $F$ 
Parameters : Integers MAX-FLIPS, MAX-TRIES
Output    : A satisfying assignment for  $F$ , or FAIL
begin
  for  $i \leftarrow 1$  to MAX-TRIES do
     $\sigma \leftarrow$  a randomly generated truth assignment for  $F$ 
    for  $j \leftarrow 1$  to MAX-FLIPS do
      if  $\sigma$  satisfies  $F$  then return  $\sigma$  // success
       $v \leftarrow$  a variable flipping which results in the greatest decrease
        (possibly negative) in the number of unsatisfied clauses
      Flip  $v$  in  $\sigma$ 
    return FAIL // no satisfying assignment found
end

```

of unsatisfied clauses. In practice, this means that **GSAT** most often does not get stuck in local minima, although it may take a substantial amount of time on each plateau before moving on to the next one. This motivates studying various modifications in order to speed up this process [SK93, SKC94]. One of the most successful strategies is to introduce noise into the search in the form of uphill moves, which forms the basis of the now well-known local search method for SAT called **Walksat** [SKC93].

Walksat interleaves the greedy moves of **GSAT** with random walk moves of a standard Metropolis search. It further *focuses the search* by always selecting the variable to flip from an unsatisfied clause C (chosen at random). This seemingly simple idea of focusing the search turns out to be *crucial for scaling such techniques* to formulas beyond a few hundred variables. If there is a variable in C flipping which does not turn any currently satisfied clauses to unsatisfied, it flips this variable (a “freebie” move). Otherwise, with a certain probability, it flips a random literal of C (a “random walk” move), and with the remaining probability, it flips a variable in C that minimizes the *break-count*, i.e., the number of currently satisfied clauses that become unsatisfied (a “greedy” move). **Walksat** is presented in detail as Algorithm 6.2. One of its parameters, in addition to the maximum number of tries and flips, is the *noise* $p \in [0, 1]$, which controls how often are non-greedy moves considered during the stochastic search. It has been found empirically that for various instances from a single domain, a single value of p is optimal. For random 3-SAT formulas, the optimal noise is seen to be 0.57, and at this setting, **Walksat** is empirically observed to scale linearly for clause-to-variable ratios α up to (and even slightly beyond) 4.2 [SAO05], though not all the way up to the conjectured satisfiability threshold of nearly 4.26.²

The focusing strategy of **Walksat** based on selecting variables solely from unsatisfied clauses was inspired by the $O(n^2)$ randomized algorithm for 2-SAT by Papadimitriou [Pap91]. It can be readily shown that for any satisfiable formula

²Aurell et al. [AGK04] had observed earlier that **Walksat** scales linearly for random 3-SAT at least till clause-to-variable ratio 4.15.

Algorithm 6.2: Walksat (F)

```

Input      : A CNF formula  $F$ 
Parameters : Integers MAX-FLIPS, MAX-TRIES; noise parameter  $p \in [0, 1]$ 
Output     : A satisfying assignment for  $F$ , or FAIL
begin
  for  $i \leftarrow 1$  to MAX-TRIES do
     $\sigma \leftarrow$  a randomly generated truth assignment for  $F$ 
    for  $j \leftarrow 1$  to MAX-FLIPS do
      if  $\sigma$  satisfies  $F$  then return  $\sigma$  // success
       $C \leftarrow$  an unsatisfied clause of  $F$  chosen at random
      if  $\exists$  variable  $x \in C$  with break-count = 0 then
         $v \leftarrow x$  // freebie move
      else
        With probability  $p$ : // random walk move
           $v \leftarrow$  a variable in  $C$  chosen at random
        With probability  $1 - p$ : // greedy move
           $v \leftarrow$  a variable in  $C$  with the smallest break-count
        Flip  $v$  in  $\sigma$ 
    return FAIL // no satisfying assignment found
end

```

and starting from any truth assignment, there exists a sequence of flips using only variables from *unsatisfied* clauses such that one obtains a satisfying assignment. To see this, fix a particular satisfying assignment $\bar{\sigma}$. Let σ be any truth assignment. Every clause not satisfied by σ must contain a variable whose truth value is different in σ and $\bar{\sigma}$. Flipping such a variable in σ brings it one step closer to $\bar{\sigma}$. Repeating this at most n times makes σ identical to $\bar{\sigma}$, thereby turning σ into a satisfying assignment.

Knuth [Knu12] raised the question as to whether the rather innocuous looking *freebie rule* in *walksat* could make the search incomplete. (See also Hoos [Hoo98].) Cohen [Coh12] resolved this question by showing that one can construct a satisfiable set of clauses on which the freebie rule can result in a cycle through a set of unsatisfying assignments. This phenomenon requires a very careful construction and, in practice, such a cycle appears to be extremely rare.

Remark 6.1.1. We take a small detour to explain the elegant and insightful $O(n^2)$ time randomized local search algorithm for 2-SAT by Papadimitriou [Pap91]. The algorithm itself is very simple: while the current truth assignment does not satisfy all clauses, select an unsatisfied clause arbitrarily, select one of its variables uniformly at random, and flip this variable. Why does this take $O(n^2)$ flips in expectation before finding a solution? Assume without loss of generality that the all-zeros string (i.e., all variables set to FALSE) is a satisfying assignment for the formula at hand. Let $\bar{\sigma}$ denote this particular solution. Consider the Hamming distance $d(\sigma, \bar{\sigma})$ between the current truth assignment, σ , and the (unknown) solution $\bar{\sigma}$. Note that $d(\sigma, \bar{\sigma})$ equals the number of TRUE variables in σ . We claim that in each step of the algorithm, we reduce $d(\sigma, \bar{\sigma})$ by 1 with probability at least

a half, and increase it by one with probability at most a half. To see this, note that since $\bar{\sigma}$ is a solution, all clauses of the formula have at least one negative literal so that any unsatisfied clause selected by the algorithm must involve at least one variable that is currently set to TRUE, and selecting this variable to flip will result in decreasing $d(\sigma, \bar{\sigma})$ by 1. Given this claim, the algorithm is equivalent to a one-dimensional Markov chain of length $n + 1$ with the target node—the all-zeros string—on one extreme and the all-ones string at the other extreme, and that at every point we walk towards the target node with probability at least a half. It follows from standard Markov chain hitting time analysis that we will hit $\bar{\sigma}$ after $O(n^2)$ steps. (The algorithm could, of course, hit another solution before hitting $\bar{\sigma}$, which will reduce the runtime even further.)

When one compares the biased random walk strategy of `Walksat` on hard, random 3-CNF formulas against basic `GSAT`, the simulated annealing process of Kirkpatrick et al. [KGV83], and a pure random walk strategy, the biased random walk process significantly outperforms the other methods [SKC94]. In the years following the development of `Walksat`, many similar methods have been shown to be highly effective on not only random formulas but on several classes of structured instances, such as encodings of circuit design problems, Steiner tree problems, problems in finite algebra, and AI planning [cf. HS04].

6.2. Extensions of the Basic Local Search Method

Various extensions of the basic process discussed above have been explored, such as dynamic noise adaptation as in the solver `adapt-novelty` [Hoo02], incorporating unit clause elimination as in the solver `UnitWalk` [HK05], incorporating resolution-based reasoning [APSS05], and exploiting problem structure for increased efficiency [PTS07]. Recently, it was shown that the performance of stochastic solvers on many structured problems can be further enhanced by using new SAT encodings that are designed to be effective for local search [Pre07].

While adding random walk moves as discussed above turned out to be a successful method of guiding the search away from local basins of attraction and toward other parts of the search space, a different line of research considered techniques that relied on the idea of *clause re-weighting* as an extension of basic greedy search [CI96, Fra97, HTH02, ITA⁺06, Mor93, SLM92, TPBF04]. Here one assigns a positive weight to each clause and attempts to minimize the sum of the weights of the unsatisfied clauses. The clause weights are dynamically modified as the search progresses, increasing the weight of the clauses that are currently unsatisfied. (In some implementations, increasing the weight of a clause is done by simply adding identical copies of the clause.) In this way, if one waits sufficiently long, any unsatisfied clause gathers enough weight so as to sway the truth assignment in its favor. This is thought of as “flooding” the current local minimum by re-weighting unsatisfied clauses to create a new descent direction for local search. Variants of this approach differ in the re-weighting strategy used, e.g., how often and by how much the weights of unsatisfied clauses are increased, and how are all weights periodically decreased in order to prevent certain weights from becoming disproportionately high. The work on DLM or Discrete Lagrangian Method

grounded these techniques in a solid theoretical framework, whose details we defer to Section 6.3. The SDF or “smoothed descent and flood” system of Schuurmans and Southey [SS01] achieved significantly improved results by using multiplicative (rather than additive) re-weighting, by making local moves based on how strongly are the clauses currently satisfied in terms of the number of satisfied literals (rather than simply how many are satisfied), and by periodically shrinking all weights towards their common mean. Overall, two of the most well-known clause-reweighting schemes that have been proposed are SAPS (*scaling and probabilistic smoothing*, along with its *reactive* variant RSAPS) [HTH02] and PAWS (*pure additive weighting scheme*) [TPBF04].

Other approaches for improving the performance of GSAT were also explored in the early years. These include TSAT by Mazure et al. [MSG97], who maintain a tabu list in order to prevent GSAT from repeating earlier moves, and HSAT by Gent and Walsh [GW93], who consider breaking ties in favor of least recently flipped variables. These strategies provide improvement, but to a lesser extent than the basic random walk component added by Walksat.

In an attempt towards better understanding the pros and cons of many of these techniques, Schuurmans and Southey [SS01] proposed three simple, intuitive measures of the effectiveness of local search: *depth*, *mobility*, and *coverage*. (A) Depth measures how many clauses remain unsatisfied as the search proceeds. Typically, good local search strategies quickly descend to low depth and stay there for a long time; this corresponds to spending as much time as possible near the bottom of the search landscape. (B) Mobility measures how rapidly the process moves to new regions in the search space (while simultaneously trying to stay deep in the objective). Clearly, the larger the mobility, the better the chance that a local search strategy has of achieving success. (C) Coverage measures how systematically the process explores the entire space, in terms of the largest “gap”, i.e., the maximum Hamming distance between any unexplored assignment and the nearest evaluated assignment. Schuurmans and Southey [SS01] hypothesized that, in general, successful local search procedures work well not because they possess any special ability to predict whether a local basin of attraction contains a solution or not—rather they simply descend to promising regions and explore near the bottom of the objective as rapidly, broadly, and systematically as possible, until they stumble across a solution.

6.3. Discrete Lagrangian Methods

Shang and Wah [SW98] introduced a local search system for SAT based on the theory of Lagrange multipliers. They extended the standard Lagrange method, traditionally used for continuous optimization, to the discrete case of propositional satisfiability, in a system called DLM (Discrete Lagrangian Method). Although the final algorithm that comes out of this process can be viewed as a clause weighted version of local search as discussed in Section 6.2, this approach provided a theoretical foundation for many design choices that had appeared somewhat ad-hoc in the past. The change in the weights of clauses that are unsatisfied translates in this system to a change in the corresponding Lagrange multipliers, as one searches for a (local) optimum of the associated Lagrange function.

The basic idea behind DLM is the following. Consider an n -variable CNF formula F with clauses C_1, C_2, \dots, C_m . For $x \in \{0, 1\}^n$ and $i \in \{1, 2, \dots, m\}$, let $U_i(x)$ be a function that is 0 if C_i is satisfied by x , and 1 otherwise. Then the SAT problem for F can be written as the following optimization problem over $x \in \{0, 1\}^n$:

$$\begin{aligned} & \text{minimize} && N(x) = \sum_{i=1}^m U_i(x) && (6.1) \\ & \text{subject to} && U_i(x) = 0 && \forall i \in \{1, 2, \dots, m\} \end{aligned}$$

Notice that $N(x) \geq 0$ and equals 0 if and only if all clauses of F are satisfied. Thus, the objective function $N(x)$ is minimized if and only if x is a satisfying assignment for F . This formulation, somewhat strangely, also has each clause as an explicit constraint $U_i(x)$, so that any feasible solution is automatically also locally as well as globally optimal. This redundancy, however, is argued to be the strength of the system: the dynamic shift in emphasis between the objective and the constraints, depending on the relative values of the Lagrange multipliers, is the key feature of Lagrangian methods.

The theory of discrete Lagrange multipliers provides a recipe for converting the above constrained optimization problem into an unconstrained optimization problem, by introducing a Lagrange multiplier for each of the constraints and adding the constraints, appropriately multiplied, to the objective function. The resulting discrete Lagrangian function, which provides the new objective function to be optimized, is similar to what one would obtain in the traditional continuous optimization case:

$$L_d(x, \lambda) = N(x) + \sum_{i=1}^m \lambda_i U_i(x) \quad (6.2)$$

where $x \in \{0, 1\}^n$ are points in the variable space and $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_m) \in \mathbb{R}^m$ is a vector of Lagrange multipliers, one for each constraint in (i.e., clause of) F . A point $(x^*, \lambda^*) \in \{0, 1\}^n \times \mathbb{R}^m$ is called a *saddle point* of the Lagrange function $L_d(x, \lambda)$ if it is a local minimum w.r.t. x^* and a local maximum w.r.t. λ^* . Formally, (x^*, λ^*) is a saddle point for L_d if

$$L_d(x^*, \lambda) \leq L_d(x^*, \lambda^*) \leq L_d(x, \lambda^*)$$

for all λ sufficiently close to λ^* and for all x that differ from x^* only in one dimension. It can be proven that x^* is a local minimum solution to the discrete constrained optimization formulation of SAT (6.1) if there exists a λ^* such that (x^*, λ^*) is a saddle point of the associated Lagrangian function $L_d(x, \lambda)$. Therefore, local search methods based on the Lagrangian system look for saddle points in the extended space of variables and Lagrange multipliers. By doing descents in the original variable space and ascents in the Lagrange-multiplier space, a saddle point equilibrium is reached when (locally) optimal solutions are found.

For SAT, this is done through a *difference gradient* $\Delta_x L_d(x, \lambda)$, defined to be a vector in $\{-1, 0, 1\}^n$ with the properties that it has at most one non-zero entry and $y = x \oplus \Delta_x L_d(x, \lambda)$ minimizes $L_d(y, \lambda)$ over all neighboring points y of x , including x itself. Here \oplus denotes vector addition; $x \oplus z = (x_1 + z_1, \dots, x_n + z_n)$.

The neighbors are “user-defined” and are usually taken to be all points that differ from x only in one dimension (i.e., are one variable flip away). Intuitively, the difference gradient $\Delta_x L_d(x, \lambda)$ “points in the direction” of the neighboring value in the variable space that minimizes the Lagrangian function for the current λ .

This yields an algorithmic approach for minimizing the discrete Lagrangian function $L_d(x, \lambda)$ associated with SAT (and hence minimizing the objective function $N(x)$ in the discrete constrained optimization formulation of SAT (6.1)). The algorithm proceeds iteratively in stages, updating $x \in \{0, 1\}^n$ and $\lambda \in \mathbb{R}^m$ in each stage using the difference gradient and the current status of each constraint in terms of whether or not it is satisfied, until a fixed point is found. Let $x(k)$ and $\lambda(k)$ denote the values of x and λ after the k^{th} iteration of the algorithm. Then the updates are as follows:

$$\begin{aligned}x(k+1) &= x(k) \oplus \Delta_x L_d(x(k), \lambda(k)) \\ \lambda(k+1) &= \lambda(k) + cU(x(k))\end{aligned}$$

where $c \in \mathbb{R}^+$ is a parameter that controls how fast the Lagrange multipliers are increased over iterations and U denotes the vector of the m constraint functions U_i defined earlier. The difference gradient $\Delta_x L_d$ determines which variable, if any, to flip in order to lower $L_d(x, \lambda)$ for the current λ . When a fixed point for these iterations is reached, i.e., when $x(k+1) = x(k)$ and $\lambda(k+1) = \lambda(k)$, it must be that all constraints U_i are satisfied. To see this, observe that if the i^{th} clause is unsatisfied after the k^{th} iteration, then $U_i(x(k)) = 1$, which implies $\lambda_i(k+1) = \lambda_i(k) + c$; thus, λ_i will keep increasing until U_i is satisfied. This provides *dynamic clause re-weighting* in this system, placing more and more emphasis on clauses that are unsatisfied until they become satisfied. Note that changing the Lagrange multipliers λ_i in turn affects x by changing the direction in which the difference gradient $\Delta_x L_d(x, \lambda)$ points, eventually leading to a point at which all constraints are satisfied. This is the essence of the DLM system for SAT.

The basic implementation of DLM [SW98] uses a simple controlled update rule for λ : increase λ_i by 1 for all unsatisfied clauses C_i after a pre-set number θ_1 of *up-hill* or *flat* moves (i.e., changes in x that do not decrease $L_d(x, \lambda)$) have been performed. In order to avoid letting some Lagrange multipliers become disproportionately large during the search, all λ_i 's are periodically decreased after a pre-set number θ_2 of increases in λ have been performed. Finally, the implementation uses *tabu lists* to store recently flipped variables, so as to avoid flipping them repeatedly.

Wu and Wah [WW99] observed that in many difficult to solve instances, such as from the **parity** and **hanoi** domains, basic DLM frequently gets stuck in *traps*, i.e., pairs (x, λ) such that there are one or more unsatisfied clauses but the associated L_d increases by changing x in any one dimension. They found that on these instances, some clauses are significantly more likely than others to be amongst the unsatisfied clauses in such a trap. (Note that this is different from counting how often is a clause unsatisfied; here we only consider the clause status inside a trap situation, ignoring how the search arrived at the trap.) Keeping track of such clauses and periodically performing a special increase in their associated Lagrange multipliers, guides the search away from traps and results in better performance.

[WW00] later generalized this strategy by recording not only information about traps but a history of all recently visited points in the variable space. Instead of performing a special increase periodically, this history information is now added directly as a *distance penalty* term to the Lagrangian function L_d . The penalty is larger for points that are in Hamming distance closer to the current value of x , thereby guiding the search away from recently visited points (in particular, points inside a trap that would be visited repeatedly).

6.4. The Phase Transition Phenomenon in Random k -SAT

One of the key motivations in the early 1990's for studying incomplete, stochastic methods for solving SAT instances was the observation that DPLL-based systematic solvers perform quite poorly on certain randomly generated formulas. For completeness, we provide a brief overview of these issues here; for a detailed discussion, refer to Part 1, Chapter 8 of this Handbook.

Consider a random k -CNF formula F on n variables generated by independently creating m clauses as follows: for each clause, select k distinct variables uniformly at random out of the n variables and negate each selected variable independently with probability $1/2$. When F is chosen from this distribution, Mitchell, Selman, and Levesque [MSL92] observed that the median hardness of the instances is very nicely characterized by a single parameter: the *clause-to-variable ratio*, m/n , typically denoted by α . They observed that instance hardness peaks in a critically constrained region determined by α alone. The top pane of Figure 6.1 depicts the now well-known “easy-hard-easy” pattern of SAT and other combinatorial problems, as the key parameter (in this case α) is varied. For random 3-SAT, this region has been experimentally shown to be around $\alpha \approx 4.26$ (for early results see Crawford and Auton [CA93] and Kirkpatrick and Selman [KS94]; new findings by Mertens et al. [MMZ06]), and has provided challenging benchmarks as a test-bed for SAT solvers. Cheeseman et al. [CKT91] observed a similar easy-hard-easy pattern in the random graph coloring problem. For random formulas, interestingly, a slight natural variant of the above “fixed-clause-length” model, called the variable-clause-length model, does *not* have a clear set of parameters that leads to a hard set of instances [FP83, Gol79, PB87]. This apparent difficulty in generating computationally hard instances for SAT solvers provided the impetus for much of the early work on local search methods for SAT. We refer the reader to Cook and Mitchell [CM97] for a detailed survey.

The critically constrained region marks a stark transition not only in the computational hardness of random SAT instances but also in their satisfiability itself. The bottom pane of Figure 6.1 shows the fraction of random formulas that are unsatisfiable, as a function of α . We see that nearly all formulas with α below the critical region (the under-constrained instances) are satisfiable. As α approaches and passes the critical region, there is a sudden change and nearly all formulas in this over-constrained region are unsatisfiable. Further, as n grows, this phase transition phenomenon becomes sharper and sharper, and coincides with the region in which the computational hardness peaks. The relative hardness of the instances in the unsatisfiable region to the right of the phase transition is consistent with the formal result of Chvátal and Szemerédi [CS88] who,

Figure 6.1. The phase transition phenomenon in random 3-SAT. Top: Computational hardness peaks at $\alpha \approx 4.26$. Bottom: Formulas change from being mostly satisfiable to mostly unsatisfiable. The transitions sharpen as the number of variables grows.

building upon the work of Haken [Hak85], proved that large unsatisfiable random k -CNF formulas almost surely require exponential size resolution refutations, and thus exponential length runs of any DPLL-based algorithm proving unsatisfiability. This formal result was subsequently refined and strengthened by others [cf. BKPS98, BP96, CEI96].

Relating the phase transition phenomenon for 3-SAT to statistical physics, Kirkpatrick and Selman [KS94] showed that the threshold has characteristics typical of phase transitions in the statistical mechanics of disordered materials (see also Monasson et al. [MZK⁺99] and Part 2, Chapter 18 of this Handbook). Physicists have studied phase transition phenomena in great detail because of the many interesting changes in a system's macroscopic behavior that occur at phase boundaries. One useful tool for the analysis of phase transition phenomena is called *finite-size scaling* analysis [SK96]. This approach is based on rescaling the horizontal axis by a factor that is a function of n . The function is such that the horizontal axis is stretched out for larger n . In effect, rescaling “slows down” the phase-transition for higher values of n , and thus gives us a better look inside

the transition. From the resulting universal curve, applying the scaling function backwards, the actual transition curve for each value of n can be obtained. In principle, this approach also localizes the 50%-satisfiable-point for any value of n , which allows one to generate very hard, random 3-SAT instances.

Interestingly, it is still not formally known whether there even exists a critical constant α_c such that as n grows, almost all 3-SAT formulas with $\alpha < \alpha_c$ are satisfiable and almost all 3-SAT formulas with $\alpha > \alpha_c$ are unsatisfiable. In this respect, Friedgut [Fri99] provided the first positive result, showing that there exists a *function* $\alpha_c(n)$ depending on n such that the above threshold property holds. (It is quite likely that the threshold in fact does not depend on n , and is a fixed constant.) In a series of papers, researchers have narrowed down the gap between upper bounds on the threshold for 3-SAT [e.g. BFU93, DBM03, FP83, JSV00, KKK96], the best so far being 4.51 [DBM03], and lower bounds [e.g. Ach00, AS00, BFU93, Fra83, FS96, HS03, KKL06], the best so far being 3.52 [HS03, KKL06]. On the other hand, for random 2-SAT, we do have a full rigorous understanding of the phase transition, which occurs at the clause-to-variable ratio of 1 [BBC⁺01, CR92]. Also, for general k , the threshold for random k -SAT is known to be in the range $2^k \ln 2 - O(k)$ [ANP05, AP04, GS05].

6.5. A New Technique for Random k -SAT: Survey Propagation

We end this chapter with a brief discussion of Survey Propagation (SP), an exciting new incomplete algorithm for solving hard combinatorial problems. The reader is referred to Part 2, Chapter 18 of this Handbook for a detailed treatment of work in this direction. Survey propagation was discovered in 2002 by Mézard, Parisi, and Zecchina [MPZ02], and is so far the only known method successful at solving random 3-SAT instances with one million variables and beyond in near-linear time in the most critically constrained region.³

The SP method is quite radical in that it tries to approximate, using an iterative process of local “message” updates, certain marginal probabilities related to the set of satisfying assignments. It then assigns values to variables with the most extreme probabilities, simplifies the formula, and repeats the process. This strategy is referred to as SP-inspired decimation. In effect, the algorithm behaves like the usual DPLL-based methods, which also assign variable values incrementally in an attempt to find a satisfying assignment. However, quite surprisingly, SP almost never has to backtrack. In other words, the “heuristic guidance” from SP is almost always correct. Note that, interestingly, computing marginals on satisfying assignments is strongly believed to be much harder than finding a single satisfying assignment (#P-complete vs. NP-complete). Nonetheless, SP is able to efficiently approximate certain marginals on random SAT instances and uses this information to successfully find a satisfying assignment.

SP was derived from rather complex statistical physics methods, specifically, the so-called *cavity method* developed for the study of spin glasses. The origin

³As mentioned earlier, it has been recently shown that by finely tuning its noise parameter, `Walksat` can also be made to scale well on hard, random 3-SAT instances with clause-to-variable ratios α slightly exceeding 4.2 [SAO05].

of SP in statistical physics and its remarkable and unparalleled success on extremely challenging random 3-SAT instances has sparked a lot of interest in the computer science research community, and has led to a series of papers in the last five years exploring various aspects of SP [e.g. ART06, AGK04, BZ04, KSS07, KSS08, KMRT⁺07, Man06, MS07, MMW07, MMZ05, MZ02, ZK07]. Many of these aspects still remain somewhat mysterious, making SP an active and promising research area for statistical physicists, theoretical computer scientists, and artificial intelligence practitioners alike.

While the method is still far from well-understood, close connections to belief propagation (BP) methods [Pea88] more familiar to computer scientists have been subsequently discovered. In particular, it was shown by Braunstein and Zecchina [BZ04] (later extended by Maneva, Mossel, and Wainwright [MMW07]) that SP equations are equivalent to BP equations for obtaining marginals over a special class of combinatorial objects called covers. In this respect, SP is the first successful example of the use of a probabilistic reasoning technique to solve a purely combinatorial search problem. The recent work of Kroc et al. [KSS07] empirically established that SP, despite the very loopy nature of random formulas which violate the standard tree-structure assumptions underlying the BP algorithm, is remarkably good at computing marginals over these covers objects on large random 3-SAT instances. Kroc et al. [KSS08] also demonstrated that information obtained from BP-style algorithms can be effectively used to enhance the performance of algorithms for the model counting problem, a generalization of the SAT problem where one is interested in counting the number of satisfying assignments.

Unfortunately, the success of SP is currently limited to random SAT instances. It is an exciting research challenge to further understand SP and apply it successfully to more structured, real-world problem instances.

6.6. Conclusion

Incomplete algorithms for satisfiability testing provide a complementary approach to complete methods, using an essentially disjoint set of techniques and being often well-suited to problem domains in which complete methods do not scale well. While a mixture of greedy descent and random walk provide the basis for most local search SAT solvers in use today, much work has gone into finding the right balance and in developing techniques to focus the search and efficiently bring it out of local minima and traps. Formalisms like the discrete Lagrangian method and ideas like clause weighting or flooding have played a crucial role in pushing the understanding and scalability of local search methods for SAT. An important role has also been played by the random k -SAT problem, particularly in providing hard benchmarks and a connection to the statistical physics community, leading to the survey propagation algorithm. Can we bring together ideas and techniques from systematic solvers and incomplete solvers to create a solver that has the best of both worlds? While some progress has been made in this direction, much remains to be done.

Chapter 7

Proof Complexity and SAT Solving

Sam Buss and Jakob Nordström

7.1. Introduction

The satisfiability problem (SAT) — i.e., to determine whether a given formula in propositional logic has a satisfying assignment or not — is of central importance to both the theory of computer science and the practice of automatic theorem proving and proof search. Proof complexity — i.e., the study of the complexity of proofs and the difficulty of searching for proofs — joins the theoretical and practical aspects of satisfiability.

For theoretical computer science, SAT is the canonical NP-complete problem, even for conjunctive normal form (CNF) formulas [Coo71, Lev73]. In fact, SAT is very efficient at expressing problems in NP in that many of the standard NP-complete problems, including the question of whether a (nondeterministic) Turing machine halts within n steps, have very efficient, almost linear time, reductions to the satisfiability of CNF formulas.¹ A popular hypothesis in the computational complexity community is the *Strong Exponential Time Hypothesis (SETH)*, which says that any algorithm for solving CNF SAT must have worst-case running time (roughly) 2^n on instances with n variables [IP01, CIP09]. This hypothesis has been widely studied in recent years, and has served as a basis for proving conditional hardness results for many other problems. In other words, CNF SAT serves as the canonical hard decision problem, and is frequently conjectured to require exponential time to solve.

In contrast, for practical theorem proving, CNF SAT is the core method for encoding and solving problems. On one hand, the expressiveness of CNF formulas means that a large variety of problems can be faithfully and straightforwardly translated into CNF SAT problems. On the other hand, the message that SAT is supposed to be hard to solve does not seem to have reached practitioners of SAT solving; instead, there has been enormous improvements in performance in SAT algorithms over the last decades. Amazingly, state-of-the-art algorithms for

¹Formally, these reductions run in *quasilinear* time, i.e. time at most $n(\log n)^k$ for some constant k . For these quasilinear time reductions of the Turing machine halting problem to CNF SAT, see [Sch78, PF79, Rob79, Rob91, Coo88].

deciding satisfiability — so-called *SAT solvers* — can routinely handle real-world instances involving hundreds of thousands or even millions of variables. It is a dramatic development that SAT solvers can often run in (close to) linear time!

Thus, theoreticians view SAT as being infeasible, while practitioners view it as being (often) feasible. There is no contradiction here. First, it is possible to construct tiny formulas with just a few hundred variables that are totally beyond reach for even the best of today’s solvers. Conversely, the large instances which are solved by SAT solvers are based on problems that seem to be “easy” in some sense, although they are very large. However, we currently lack a good theoretical explanation for what makes these problems “easy”. Most SAT solvers are general-purpose and written in a very generic way that does not seem to exploit special properties of the underlying problem. Nonetheless, although SAT solvers will sometimes fail miserably, they succeed much more frequently than might be expected. This raises the questions of how practical SAT solvers can perform so well on many large problems and of what distinguishes problems that can be solved by SAT solvers from problems that cannot.

The best current SAT solvers are based on *conflict-driven clause learning (CDCL)* [MSS99, MMZ⁺01].² Some solvers also incorporate elements of algebraic reasoning (e.g., Gaussian elimination) and/or geometric reasoning (e.g., linear inequalities), or use algebraic or geometric methods as the foundation rather than CDCL. Another augmentation of CDCL that has attracted much interest is *extended resolution (ER)*. How can we analyze the power of such algorithms? Our best approach is to study the underlying methods of reasoning and what they are able or unable to do in principle. This leads to the study of proof systems such as resolution, extended resolution, Nullstellensatz, polynomial calculus, cutting planes, et cetera. *Proof complexity*, as initiated in modern form by [CR79, Rec75], studies these systems mostly from the viewpoint of the complexity of static, completed proofs. With a few exceptions (perhaps most notably *automatability*³ as defined in [BPR00]), research in proof complexity ignores the constructive, algorithmic aspects of SAT solvers. Nonetheless, proof complexity has turned out to be a very useful tool for studying practical SAT solvers, in particular, because it is a way to obtain mathematically rigorous bounds on solver performance. Lower bounds on the complexity of proofs in a proof system show fundamental limitations on what one can hope to achieve using SAT solvers based on the corresponding method of reasoning. Conversely, upper bounds can be viewed as indications of what should be possible to achieve using a method of reasoning, if only proof search using this method could be implemented efficiently enough.

We want to stress, though, that the tight connections to proof complexity come with a price. Since proof complexity studies what reasoning can be achieved by a method in principle, ignoring the algorithmic challenge of actually implementing such reasoning, it becomes very hard to say anything meaningful about satisfiable formulas. In principle, it is very hard to rule out that a solver could simply zoom in on a satisfying assignment right away, and this will of course only take linear time. For unsatisfiable formulas, however, a (complete) solver

²A similar technique for constraint satisfaction problems (CSPs) was independently developed in [BS97].

³Automatability is sometimes also called *automatizability*.

will have to certify that there is no satisfying assignment, and for many SAT solving methods used in practice this is a computational task that is amenable to mathematical analysis. This article, therefore, will focus almost exclusively on unsatisfiable formulas. This is, admittedly, a severe limitation, but it is dictated by the limitations of our current mathematical knowledge. There has been some work on proof complexity of satisfiable formulas by reducing this to problems about unsatisfiable subformulas (e.g., in [AHI05]), but the literature here is very limited. Having said this, we want to point out that the setting of unsatisfiable formulas is nevertheless very interesting, since in many real-world applications proving unsatisfiability is the objective, and conventional wisdom is that such instances are often the hardest ones.

This chapter is intended as an overview of the connection between SAT solving and proof complexity aimed at readers who wish to become more familiar with either (or both) of these areas. We focus on the proof systems underlying current approaches to SAT solving. Our goal is first to explain how SAT solvers correspond to proof systems and second to review some of the complexity results known for these proof systems. We will discuss *resolution* (corresponding to basic CDCL proof search), *Nullstellensatz* and *polynomial calculus* (corresponding to algebraic approaches such as *Gröbner basis* computations), *cutting planes* (corresponding to *pseudo-Boolean solving*), *extended resolution* (corresponding to the *DRAT* proof logging system used for CDCL solvers with pre-/inprocessing), and will also briefly touch on *Frege systems* and *bounded-depth Frege systems*.

We want to emphasize that we do not have space to cover more than a small part of the research being done in proof complexity. Some useful material for further reading are the survey articles [BP98a, Seg07] and the recent book [Kra19]. Additionally, we would like to mention the authors' own surveys [Bus99, Bus12, Nor13]. The present chapter is adapted from and partially overlaps with the second author's survey [Nor15], but has been thoroughly rewritten and substantially expanded with new material.

7.1.1. Outline of This Survey Chapter

The rest of this chapter is organized as follows. Section 7.2 presents a quick review of preliminaries. We discuss the resolution proof system and describe the connection to CDCL SAT solvers in Section 7.3, and then give an overview of some of the proof complexity results known for resolution in Section 7.4. In Section 7.5 we consider the algebraic proof systems Nullstellensatz and polynomial calculus, and also briefly touch on algebraic SAT solving. In Section 7.6 we move on to the geometric proof system cutting planes and the connections to conflict-driven pseudo-Boolean solving, after which we give an overview of what is known in proof complexity about different flavours of the cutting planes proof system in Section 7.7. We review extended resolution and DRAT in Section 7.8, and then continue to Frege and extended Frege proof systems and bounded-depth Frege systems in Sections 7.9 and 7.10. Section 7.11 gives some concluding remarks.

7.2. Preliminaries

We use the notation $[n] = \{1, 2, \dots, n\}$ for n a positive integer. We write $\mathbb{N} = \{0, 1, 2, 3, \dots\}$ to denote the set of all natural numbers and $\mathbb{N}^+ = \mathbb{N} \setminus \{0\}$ for the set of positive integers.

7.2.1. Propositional Logic

A *Boolean variable* x ranges over values *true* and *false*; unless otherwise stated, we identify 1 with true and 0 with false. A *literal* a over a Boolean variable x is either the variable x itself (a *positive literal*) or its negation \bar{x} (a *negative literal*). We define $\bar{\bar{x}} = x$. It will sometimes be convenient to use the alternative notation x^σ , $\sigma \in \{0, 1\}$, for literals, where $x^1 = x$ and $x^0 = \bar{x}$. (In other words, x^σ is the literal that evaluates to true under the assignment $x = \sigma$.)

A *clause* $C = a_1 \vee \dots \vee a_k$ is a disjunction of literals over distinct variables. The empty clause, with $k = 0$, is denoted \perp . By convention, clauses are not *tautological*; i.e., do not contain any variable and its negation. A clause C' *subsumes* another clause C if every literal from C' also appears in C . In this case, C' is at least as strong as clause C . A *k-clause* is a clause that contains at most k literals. A *CNF formula* $F = C_1 \wedge \dots \wedge C_m$ is a conjunction of clauses. F is a *k-CNF formula* if it consists of k -clauses. We think of clauses and CNF formulas as sets: the order of elements is irrelevant and there are no repetitions.⁴

The *width* of a clause is the number of literals in it. Thus, a *k-clause* has width at most k . In the rest of this chapter, k is assumed to be some arbitrary but fixed constant unless stated otherwise. There is a standard way to turn any CNF formula F into 3-CNF by converting every clause

$$a_1 \vee a_2 \vee \dots \vee a_w \tag{7.1a}$$

of width $w > 3$ into the set of $w-2$ many 3-clauses

$$\{a_1 \vee a_2 \vee y_2\} \cup \{\bar{y}_{j-1} \vee a_j \vee y_j \mid 3 \leq j < w-1\} \cup \{\bar{y}_{w-2} \vee a_{w-1} \vee a_w\}, \tag{7.1b}$$

where the y_j 's denote new variables. This conversion to 3-CNF often does not change much from a theoretical point of view (however, there are some exceptions to this rule, which we will discuss in the relevant context).

We typically use N to denote the *size* of a formula F , namely the total number of occurrences of literals in F . (For a k -CNF formula with $k = O(1)$, N may instead denote the number of clauses in F ; this differs from the size of F by at most a constant factor.)

A *truth assignment* is any mapping from variables to truth values 0 or 1. We allow truth assignments to be *partial*, i.e., with some variables left unassigned. A truth assignment is *total* if it assigns values to all variables under consideration. We represent a (partial) truth assignment ρ as the set of literals set to true by ρ . We write $\rho(x^\sigma) = 1$ if $x^\sigma \in \rho$, and $\rho(x^\sigma) = 0$ if $x^{1-\sigma} \in \rho$. If ρ does not assign any truth value to x , we write $\rho(x^\sigma) = *$. The assignment ρ *satisfies* a clause C

⁴It can be noted, though, that some SAT solvers implement formulas as *multisets* of clauses.

provided it sets at least one literal of C true; it *falsifies* C provided it sets every literal in C false. It *satisfies* a formula F provided it satisfies every clause in F .

A formula F is *satisfiable* provided some assignment satisfies it; otherwise it is *unsatisfiable*. We say that a formula F *logically implies* a clause C if every total truth assignment ρ which satisfies F also satisfies C . In this case, we write $F \models C$. Since \perp is unsatisfiable, $F \models \perp$ is equivalent to F being unsatisfiable.

7.2.2. Proof Systems

The principal task of a SAT solver is to determine whether a given formula F is satisfiable or unsatisfiable. When F is satisfiable, there is always a short proof of its satisfiability; namely, a satisfying truth assignment. Establishing that F is unsatisfiable is generally done using some kind of proof system; *proof complexity* studies the complexity of the possible proofs in different proof systems.

In what follows, we give a high-level mathematical description of what a formal proof system is. Later sections will focus in more detail on concrete proof systems that are relevant in the context of SAT solving, and these sections can be read independently without appreciating all of the finer details below.

In the most general setting of proof complexity, one focuses on some *language* L , i.e., an (infinite) set of strings over some (finite) alphabet of symbols, and studies the complexity of proving that a given string x is in the set L . In this abstract setting, a *proof system for* L is a binary predicate $\mathcal{P}(x, \pi)$ that takes as input two strings x and π , is computable (deterministically) in time polynomial in the sizes $|x|$ and $|\pi|$ of the inputs, and has two key properties:

Completeness: for all $x \in L$ there is a string π (a *proof*) for which $\mathcal{P}(x, \pi)$ evaluates to true;

Soundness: for all $x \notin L$ it holds for all strings π that $\mathcal{P}(x, \pi)$ evaluates to false.

Intuitively, completeness means that all valid statements are provable, whereas soundness means that no fake proofs of invalid claims are accepted.

Informally, the strength of a proof system is measured by how small proofs it can produce. The *size* of a formula or proof is equal to the number of symbols it contains. The ideal scenario would be to have a proof system where all theorems can be proven with at most a polynomial blow-up in size of the proof compared to the size of the input. Formally, a proof system is said to be *polynomially bounded* if for every $x \in L$ there is a proof π_x for x that has size at most polynomial in $|x|$.

It is common to measure the relative strengths of proof systems in terms of the lengths of their proofs. Suppose \mathcal{P} and \mathcal{P}' are proof systems. We say that \mathcal{P}' *polynomially simulates* \mathcal{P} if, for all $x \in L$, the size of the shortest \mathcal{P}' -proof of x is polynomially bounded by the size of the shortest \mathcal{P} -proof of x .⁵

In the context of this survey, we will mostly focus on proving unsatisfiability of CNF formulas. This means that we will deal with proof systems for the formal language L consisting of all unsatisfiable CNF formulas. In this context, a proof

⁵In the literature, the terms “simulate”, “p-simulate” and “polynomially simulate” are used more or less interchangeably, but sometimes coupled with the proviso that there is a polynomial time algorithm which can produce a \mathcal{P}' -proof given a \mathcal{P} -proof as input.

system is a polynomial-time algorithm for verifying the unsatisfiability of a given formula F with the aid of a given proof π . Most of the proof systems relevant for SAT solvers (such as resolution, Nullstellensatz, polynomial calculus, cutting planes, et cetera) are such *refutation systems* designed for refuting unsatisfiable formulas F . However, some proof systems in propositional logic (such as Frege systems) instead produce proofs of valid formulas. For such proof system, the language L under study consists of all tautological formulas. There is a duality between refutations and proofs in that the CNF formula F is unsatisfiable if and only if its negation, the DNF formula $\neg F$, is valid (i.e., is a tautology). We will use the term *proof system* to refer to both kinds of systems above. When discussing refutation systems, we will frequently use the term *proof (of unsatisfiability) for F* to refer to a refutation of F .

7.2.3. Complexity and Asymptotic Notation

One of the central tasks of proof complexity is to prove upper or lower bounds on the complexity of proofs. That is, for a fixed proof system \mathcal{P} and a class \mathcal{F} of unsatisfiable formulas, we may let $f(N)$ denote the worst-case size that might be needed for a \mathcal{P} -refutation of any formula $F \in \mathcal{F}$ of size N ; then we wish to provide sharp bounds on the growth rate of $f(N)$. Small upper bounds on $f(N)$ indicate that \mathcal{P} is an efficient proof system for \mathcal{F} -formulas. Small upper bounds also suggest the possibility of efficient search procedures for finding refutations of formulas $F \in \mathcal{F}$. Large lower bounds on $f(N)$ indicate that \mathcal{P} cannot be efficient for all \mathcal{F} -formulas.

Proof complexity often deals with asymptotic upper and lower bounds, generally expressed by using “big-O” notation. The commonly used notations include $f(n) = O(g(n))$, $f(n) = o(g(n))$, $f(n) = \Omega(g(n))$, $f(n) = \omega(g(n))$, and $f(n) = \Theta(g(n))$, where $f(n)$ and $g(n)$ are always nonnegative. We write $f(n) = O(g(n))$ to express that $\exists c > 0 \exists n_0 \forall n \geq n_0 f(n) \leq c \cdot g(n)$, i.e., that f grows at most as quickly as g asymptotically. We write $f(n) = o(g(n))$ to express that $\forall \epsilon > 0 \exists n_0 \forall n \geq n_0 f(n) \leq \epsilon \cdot g(n)$, i.e., that f grows strictly more slowly than g . When $g(n) > 0$ always holds, $f(n) = o(g(n))$ is equivalent to $\lim_{n \rightarrow \infty} f(n)/g(n) = 0$. The notations $f(n) = \Omega(g(n))$ and $f(n) = \omega(g(n))$, mean that $g(n) = O(f(n))$ and $g(n) = o(f(n))$, respectively, or, in words, that f grows at least as fast or strictly faster than g . We write $f(n) = \Theta(g(n))$ to denote that both $f(n) = O(g(n))$ and $g(n) = O(f(n))$ hold, i.e., that asymptotically speaking f and g are essentially the same function up to a constant factor. Big-O notation is often used in subexpressions. For example, we write $f(n) = 2^{(1-o(1))n}$ to mean that for any fixed $\epsilon > 0$, we have $f(n) > 2^{(1-\epsilon)n}$ for all sufficiently large n .

7.3. Resolution and CDCL SAT solvers

We start our survey by discussing the *resolution proof system* [Bla37, DP60, DLL62, Rob65], which is the most important proof system from the point of view of SAT solving. Resolution is a refutation system that works directly with clauses. A resolution derivation π of a clause D from a CNF formula F is a sequence of clauses $\pi = (D_1, D_2, \dots, D_{L-1}, D_L)$ such that $D = D_L$ and each clause D_i is either

1. $x \vee y$ Axiom
2. $x \vee \bar{y} \vee z$ Axiom
3. $\bar{x} \vee z$ Axiom
4. $y \vee \bar{z}$ Axiom
5. $\bar{y} \vee \bar{z}$ Axiom
6. \bar{z} Res(4, 5)
7. \bar{x} Res(3, 6)
8. $x \vee \bar{y}$ Res(2, 6)
9. x Res(1, 8)
10. \perp Res(7, 9)

(a) Refutation as annotated list.

(b) Refutation as directed acyclic graph (DAG).

Figure 7.1. Resolution refutation of the CNF formula (7.3).

1. an *axiom clause* $D_i \in F$, or
2. a clause of the form $D_i = B \vee C$ derived from clauses $D_j = B \vee x$ and $D_k = C \vee \bar{x}$ for $j, k < i$ by the *resolution rule*

$$\frac{B \vee x \quad C \vee \bar{x}}{B \vee C} . \tag{7.2}$$

We call $B \vee C$ the *resolvent over x* of $B \vee x$ and $C \vee \bar{x}$.

We write $\pi : F \vdash D$ to denote that π is a derivation of D from F ; we write $F \vdash D$ to denote that some such π exists. When D is the empty clause \perp , we call π a *resolution refutation* of F , and write $\pi : F \vdash \perp$. The *length*, or *size*, of a resolution derivation/refutation is the number of clauses in it.

A resolution derivation π can be represented as a list of clauses annotated with explanations for each clause how it was obtained. This is illustrated in Figure 7.1a for a resolution refutation of the CNF formula

$$(x \vee y) \wedge (x \vee \bar{y} \vee z) \wedge (\bar{x} \vee z) \wedge (y \vee \bar{z}) \wedge (\bar{y} \vee \bar{z}) . \tag{7.3}$$

A derivation $\pi = (D_1, D_2, \dots, D_L)$ from F can alternatively be represented by a directed acyclic graph (DAG) G_π , also referred to as a *proof DAG*, in the following way. The vertices of G_π are $\{v_1, v_2, \dots, v_L\}$, with vertex v_i labelled by the clause D_i . The sources (also called *leaves*) of the DAG are vertices labelled with the axiom clauses in F . Without loss of generality there is a unique sink and it is labelled with D_L .⁶ If π is a refutation, the sink is labelled with \perp . Every vertex that is not a source has indegree two and is the resolvent of its two predecessors. See Figure 7.1b for the refutation in Figure 7.1a represented as a DAG instead.

A resolution refutation π is *tree-like* if G_π is a tree, or equivalently, if every clause D_i in the refutation is used at most once as a hypothesis in an application

⁶Any other sinks are parts of superfluous subderivations that can be removed.

of the resolution rule. Note that it is permitted that clauses are repeated in the sequence $\pi = (D_1, D_2, \dots, D_L)$, so different vertices in G_π can be labelled by the same clause if need be (though every repetition counts towards the size of the refutation). The refutation in Figure 7.1b is not tree-like since the clause \bar{z} is used twice, but it could be made tree-like if we added a second derivation of \bar{z} from $y \vee \bar{z}$ and $\bar{y} \vee \bar{z}$. More generally, any derivation can be converted into a tree-like derivation by repeating subderivations, but possibly at the cost of an exponential increase in the size of the proof [Tse68, BSIW04].

As discussed in Section 7.2.2, *completeness* and *soundness* are fundamental properties of proof systems. For resolution, they are as follows.

Theorem 7.3.1. *Let F be a CNF formula and C be a clause.*

Completeness: *If $F \models C$, then there is a clause $C' \subseteq C$ such that $F \vdash C'$. In particular, if F is unsatisfiable, then F has a resolution refutation.*

Soundness: *If $F \vdash C$, then $F \models C$. In particular, if F has a resolution refutation, then F is unsatisfiable.*

For technical reasons it is sometimes convenient to allow also the *weakening rule*

$$\frac{B}{B \vee C}, \quad (7.4)$$

which makes it possible to infer a subsumed clause (i.e., a strictly weaker clause) from an already derived clause. Resolution with weakening is also sound and complete; in fact, completeness holds in the stronger sense that if $F \models C$, then C has a resolution-plus-weakening derivation from F .

It is not hard to show that weakening inferences in a resolution refutation can be eliminated without increasing the complexity of the proof. This also holds for all the notions of complexity that we will discuss later, including length, width, and space.

An important restricted form of resolution is *regular resolution*. A resolution refutation π is *regular* provided that no variable is resolved over more than once along any path in the DAG G_π . For example, the refutation of Figure 7.1 is not regular, since the inferences introducing the clauses \bar{z} and x lie on a common path, and both resolve on y . The soundness of regular resolution is immediate from the soundness of resolution. Regular resolution is also complete [DP60]. However, it was shown in [Urq11, AJPU07] that there is a family of CNF formulas F_n that have polynomial size resolution refutations, but are such that, letting $c = c(n)$ be the length of F_n (i.e., the number of clauses in F_n), the shortest regular resolution refutation of F_n has size $2^{c^{1-o(1)}}$. This gives an exponential separation between regular resolution and (general) resolution. In particular, regular resolution does not efficiently simulate resolution in the sense discussed in Section 7.2.2.

As already mentioned, resolution without weakening can polynomially simulate resolution. On the other hand, tree-like resolution cannot polynomially simulate resolution, or even regular resolution [Tse68].

Another interesting restriction on resolution which is relevant for CDCL SAT solvers is *trivial resolution*. A resolution derivation π is a trivial derivation of D from F if it can be written as a sequence of clauses $\pi = (D_1, \dots, D_L = D)$ such that

1. π is *input*; i.e., $D_1 \in F$, and for all $i \geq 1$ it holds that $D_{2i} \in F$ and that D_{2i+1} is the resolvent of the latest derived clause D_{2i-1} with the axiom D_{2i} .
2. π is regular, i.e., no variable is used more than once as the resolution variable.

The sequence π is a trivial resolution refutation provided D_L is \perp . Trivial resolution is sound but *not* complete. For example (and jumping ahead a bit), the formula (7.3) is not refutable by *unit propagation* (which will be described later), and thus does not have a trivial resolution refutation.

A *unit clause* is a clause of width 1. A *unit resolution* refutation is a resolution refutation in which each resolution inference has at least one unit clause as a hypothesis. Unit resolution is sound but not complete. Indeed, it is very closely connected to trivial resolution [BKS04]. For F a CNF formula and $C = a_1 \vee \dots \vee a_k$ a clause, there is a trivial resolution derivation of C from F if and only if there is a unit resolution refutation of $F \cup \{\bar{a}_1, \bar{a}_2, \dots, \bar{a}_k\}$, i.e., of F plus k many unit clauses. In particular, F has a trivial resolution refutation exactly when F has a unit resolution refutation.

7.3.1. DPLL and Conflict-Driven Clause Learning

The most successful present-day SAT solvers are based on *conflict-driven clause learning (CDCL)* [MSS99, MMZ⁺01], which, when run on unsatisfiable CNF formulas, is a search procedure for resolution proofs. CDCL algorithms have been highly refined and augmented with both practical optimizations and sophisticated inference techniques; however, they are based on four main conceptual ingredients:

1. *DPLL*, a depth-first, backtracking search procedure for satisfying assignments.⁷
2. *Unit propagation*, a method for making obvious inferences during search.
3. A *clause learning* algorithm that attempts to prune the search space by inferring (“learning”) clauses whenever the search procedure falsifies a clause (finds a “conflict”) and has to backtrack.
4. A *restart policy* for stopping a depth-first search and starting a new one.

We will discuss these four ingredients one at a time. Our treatment will be informal, without including all necessary details, as we presume that most readers are familiar with the concepts, and as our focus is on discussing connections between SAT solving and proof complexity. For a more detailed treatment, see Chapter 3 on complete algorithms and Chapter 4 on CDCL solvers.

7.3.1.1. Depth-First Search Using the DPLL Method

The first ingredient, *DPLL*, is named after the four collective authors, Davis, Putnam, Logemann and Loveland, of two of the primary sources for resolution

⁷Often unit propagation is included as part of DPLL; however, we adopt the convention that DPLL means a backtracking search, and does not need to include unit propagation. The original definition of the DPLL algorithm in [DLL62], following [DP60], included both unit propagation and the pure literal rule.

```

if the partial assignment  $\rho$  falsifies some clause of  $F$  then
  | return false;
end
if  $\rho$  satisfies  $F$  then
  | Output  $\rho$  as a satisfying assignment and terminate.
end
Pick some unassigned literal,  $a$ , called the decision literal;
Extend  $\rho$  to set  $a$  true;
Call this DPLL procedure recursively;
Update  $\rho$  to set  $a$  false;
Call this DPLL procedure recursively (again);
Update  $\rho$  to make  $a$  unassigned;
return false;

```

Figure 7.2. DPLL recursive procedure (without unit propagation).

and automated solvers, namely [DP60] and [DLL62]. The DPLL procedure is given as input a CNF formula F , i.e., a set of clauses. Its task is to determine whether F is satisfiable, and if so to find a satisfying assignment. The DPLL algorithm maintains a partial truth assignment ρ and runs the algorithm shown in Figure 7.2 recursively. Initially, ρ is the empty assignment with all variables unassigned. Each time the recursive procedure is called it chooses a *decision literal* a , and tries setting it first true and then false, using recursive calls to explore the two assignments to a . It either halts with a satisfying assignment, or eventually returns *false* from the top level if F is unsatisfiable.

There is an exact correspondence between the DPLL search procedure (without unit propagation) and tree-like, regular resolution refutations.⁸ In one direction, any tree-like regular resolution refutation π containing S occurrences of clauses corresponds to a DPLL search tree with S nodes (each node an invocation of the recursive procedure). Such a search tree can be generated by letting the DPLL search procedure traverse the proof tree G_π starting at \perp in a depth-first fashion. When the traversal of G_π is at a node labelled with a clause C , the partial assignment ρ falsifies C . Conversely, any DPLL search with S calls to the recursive procedure gives rise to a tree-like, regular resolution refutation with $\leq S$ clauses. Such a refutation can be formed from the leaves starting with clauses falsified by the deepest recursive calls. Pairs of recursive calls are joined by resolution inferences as needed (possibly with parts of the DPLL search tree being pruned away).

7.3.1.2. Unit Propagation

The second ingredient is *unit propagation*. Unit propagation can be viewed as a way to guide the DPLL search procedure, but it becomes much more important when used with clause learning, as will be discussed momentarily. Suppose that the CNF formula F contains a clause $C = a_1 \vee \dots \vee a_k$ and that the current partial assignment ρ has set all but one of the literals in C false, and that the remaining literal a_i is unassigned. Then *unit propagation* is the operation of setting a_i true

⁸Any tree-like resolution refutation can be converted to be regular by pruning away parts of the proof where variables are resolved on more than once.

```

 $\rho_0 \leftarrow \rho$ ;
Extend  $\rho$  by unit propagation for as long as possible;
if  $\rho$  falsifies some clause of  $F$  then
  |  $\rho \leftarrow \rho_0$ ;
  | return false;
end
if  $\rho$  satisfies  $F$  then
  | Output  $\rho$  as a satisfying assignment and terminate.
end
Pick some literal  $a$  not set by  $\rho$  (the decision literal);
Extend  $\rho$  to set  $a$  true;
Call this DPLL procedure recursively;
Update  $\rho$  to set  $a$  false;
Call this DPLL procedure recursively (again);
 $\rho \leftarrow \rho_0$ ;
return false;

```

Figure 7.3. The recursive procedure for DPLL with unit propagation.

and adding it to ρ . This can be done without loss of generality, since setting a_i false would falsify C .

Unit propagation is directly related to the unit resolution proof system discussed earlier. Let F' be the CNF formula consisting of F plus the unit clauses \bar{a} for all literals a such that $\rho(a) = 0$. Then repeatedly applying unit propagation starting with F and the partial assignment ρ will falsify some clause of F if and only if F' has a unit resolution refutation.

With unit propagation, the recursive procedure for the DPLL algorithm is shown in Figure 7.3. This runs similar to the algorithm of Figure 7.2, but now does unit propagation whenever possible. Values of ρ can be set either as decision literals or by unit propagation (with ρ_0 used to restore the state of ρ when returning). Each set literal is assigned a *decision level*. Literals propagated even before any decision literal has been set are assigned decision level 0. The decision level is incremented when setting a decision literal, and unit propagated literals are given the decision level of the last decision literal. Each call to the procedure either halts with a satisfying assignment extending ρ , or returns false if no such satisfying assignment exists.

7.3.1.3. Clause Learning and Nonchronological Backtracking

The third ingredient in the recipe for state-of-the-art SAT solvers is a crucial one: the use of *clause learning* to infer new clauses. This modifies the first step of DPLL algorithm to also add clauses to the formula; namely, when ρ falsifies some clause of F , i.e., reaches a *conflict*, then clause learning is used to derive one or more clauses and add them to F . The intent is that the learned clauses will be used in the future to prune the search space and avoid repeatedly exploring the same impossible assignments to literals. Essentially all clause learning methods used in practice will infer only clauses C that can be derived from F (together with previously learned clauses) by trivial resolution. This is due to the equivalence between trivial resolution refutations and unit resolution refutations and the fact

that DPLL/CDCL uses unit propagation to find contradictions.

The most popular methods for learning clauses in modern CDCL SAT solvers are based on the *first unique implication point (UIP)* learning scheme, as illustrated in Figure 7.4. But for purposes of the connection between clause learning and trivial resolution, the key point is that the learned clause is chosen to be a clause $C = a_1 \vee \dots \vee a_k$ with the following two properties:

1. C is falsified by ρ , i.e., $\rho(a_i) = 0$ for each a_i in C , and
2. there is a unit resolution refutation of F plus the k unit clauses $\{\bar{a}_i \mid i \in [k]\}$.

When C is chosen in this way, C is called a *reverse unit propagation (RUP)* clause or an *asymmetric tautology (AT)* for F .⁹ By the correspondence between trivial resolution and unit resolution, this is equivalent to the existence of a trivial resolution derivation of C from F .

A third property that typically holds for a learned clause C is the *UIP* or *assertive property*:

3. C contains exactly one literal a_i set to false at the last decision level; the rest of the literals in C were set false at earlier decision levels. The literal a_i is called the *UIP literal* or *asserting literal*.

When C is chosen so that a_i is as “close as possible to the contradiction,” then this is called 1UIP learning, and C is called the *first unique implication point (UIP) clause* with a_i being the *UIP literal*. There is always at least one UIP clause, since the decision literal at the last level is a UIP literal (because this decision led to a conflict).

In order to visualize conflict analysis, it is helpful to construct a *conflict graph* that shows how assignments to different literals causes propagations of other literals. Figure 7.4 illustrates 1UIP clause learning in the conflict graph formed from the clauses

$$\{\bar{x} \vee \bar{a} \vee z, \bar{x} \vee \bar{z} \vee y, \bar{y} \vee t, \bar{y} \vee \bar{a} \vee u, \bar{y} \vee \bar{u} \vee v, \bar{y} \vee \bar{t} \vee s, \bar{u} \vee \bar{b} \vee \bar{c} \vee w, \bar{t} \vee \bar{v} \vee \bar{w}, \bar{a} \vee \bar{b} \vee c\}. \quad (7.5)$$

Arrows indicate which literals are involved in causing which unit propagations. The three literals a, b, c have been set true at earlier decision levels, and the decision literal at the last level is x . The 1UIP learned clause is $\bar{a} \vee \bar{b} \vee \bar{c} \vee \bar{y}$, with the 1UIP literal being y . The dashed line shows the portion of the conflict graph with propagations that depend on y , and the predecessors vertices of all edges crossing this cut are the literals a, b, c , and y that form the learned clause.

For an alternative view of the same conflict analysis, Figure 7.5a shows the unit propagations caused by setting x to 1, where $x \stackrel{\text{DEC}}{\leftarrow} 1$ denotes that x is set true as a decision literal and $\ell \stackrel{C}{\leftarrow} \sigma$ denotes the literal ℓ being set to the truth value σ by unit propagation using clause C . The 1UIP clause $\bar{a} \vee \bar{b} \vee \bar{c} \vee \bar{y}$ is derived as depicted in Figure 7.5b by traversing backwards through the list of unit propagated literals starting with the clause $\bar{t} \vee \bar{v} \vee \bar{w}$ that was falsified. Each time a literal is reached that is set false in the current clause, a resolution inference

⁹See [GN03, Van08] for the original definitions of RUP; the modern terminology AT is discussed in [HJB10, JHB12].

Figure 7.4. Example of a conflict graph and 1UIP learning with learned clause $\bar{a} \vee \bar{b} \vee \bar{c} \vee \bar{y}$. This conflict graph is generated using the clauses in Equation (7.5), also shown on the right in the figure.

is applied to update the current clause. (Note how s is skipped as it does not appear negated in $\bar{b} \vee \bar{c} \vee \bar{t} \vee \bar{u} \vee \bar{y}$.) When we reach for the first time a clause (in this example, $\bar{a} \vee \bar{b} \vee \bar{c} \vee \bar{y}$) that contains only a single literal at the last decision level (in this example, y), we have obtained the 1UIP clause.

A nice feature of the 1UIP clause learning scheme, and the reason that the learned clause is called *asserting*, is that this clause contains exactly one literal a_i that has not been set false at an earlier decision level. This means that after the solver has backtracked and undone the last decision, the literal a_i will unit propagate to true, flipping the value it had before. For example, the clause learned in Figure 7.4 is asserting: a, b and c have been set at earlier levels, and so \bar{y} can be inferred from the learned clause by unit propagation. Conflict analysis algorithms with this property are sometimes referred to as *asserting clause learning schemes*, and learning schemes used in modern CDCL solvers tend to be of this type.

Perhaps the most direct way to incorporate both unit propagation and clause learning (but not backjumping or restarts) in DPLL is as in the algorithm shown in Figure 7.6, which we will call *DPLL with clause learning (DPLL-CL)*. We want to emphasize that DPLL-CL is not an algorithm that would be used in practice; we instead introduce it as a didactic tool to illustrate how there is a natural algorithmic development from DPLL to CDCL.

The DPLL-CL algorithm has been formulated to be faithful to the idea of DPLL as a depth-first search procedure, but has been updated with clause learning. Like the basic DPLL algorithm, it acts to set a literal a first true and then false. The first recursive call to DPLL-CL has the decision literal a set true. If that call returns, the newly learned clauses may already be enough to set a false by unit propagation. But if not, a can be set false as a decision literal anyway. For example, in the 1UIP learning in Figures 7.4 and 7.5 the learned clause allows y to be set false by unit propagation, but it does not allow \bar{x} to be derived by unit propagation. Nonetheless \bar{x} is a consequence of the literals set in ρ .¹⁰

¹⁰This will not generally be true in the CDCL algorithm described next, since CDCL allows

(a) The unit propagations triggered by setting x true.

(b) The trivial resolution derivation of $\bar{a} \vee \bar{b} \vee \bar{c} \vee \bar{y}$ (written bottom-up).

Figure 7.5. Unit propagation derivation of the contradiction shown in Figure 7.4 and trivial resolution derivation of the learned clause (from the clauses in (7.5)).

The DPLL-CL algorithm in Figure 7.6 still lacks an important component of the CDCL algorithm, namely *backjumping* (also called *nonchronological backtracking*). What this means is that the solver backtracks not just one decision level but potentially multiple decision levels at once.¹¹ For an example of a common way to use backjumping, refer to the conflict graph and 1UIP learned clause of Figures 7.4 and 7.5. There, x has been set as a decision literal with decision level $lev(x)$. The literals a , b and c were set with strictly lower decision levels $lev(a)$, $lev(b)$ and $lev(c)$; let $L \leq lev(x) - 1$ denote the maximum of these three levels. Once the 1UIP clause $\bar{a} \vee \bar{b} \vee \bar{c} \vee \bar{y}$ has been learned, the literal y can be propagated to true already at decision level L , which is called the *assertion level*. To readily take advantage of this, the CDCL algorithm uses backjumping (nonchronological backtracking) to backtrack to decision level L , which could be much smaller than $lev(x) - 1$. Another reason for backjumping is that it can be viewed a miniature version of restarting, which we will discuss next, in that a restart consists of backtracking to decision level 0.

backjumping to backtrack multiple decision levels.

¹¹It can be noted, though, that a CDCL algorithm with chronological backtracking, somewhat similar in spirit to the DPLL-CL algorithm in Figure 7.6, was recently proposed in [NR18] and has been shown to perform very well on certain types of benchmarks.

```

 $\rho_0 \leftarrow \rho;$ 
loop
  Extend  $\rho$  by unit propagation for as long as possible;
  if  $\rho$  falsifies some clause of  $F$  then
    | Optionally learn one or more clauses  $C$  and add them to  $F$ ;
    |  $\rho \leftarrow \rho_0$ ;
    | return false;
  end
  if  $\rho$  satisfies  $F$  then
    | Output  $\rho$  as a satisfying assignment and terminate.
  end
  Pick some literal  $a$  not set by  $\rho$  (the decision literal);
  Extend  $\rho$  to set  $a$  true;
  Call DPLL-CL recursively;
  Unset the value of  $a$  in  $\rho$ ;
  Extend  $\rho$  by unit propagation for as long as possible;
  if the value of  $a$  is set in  $\rho$  (if so, it is false) then
    | continue (with the next loop iteration);
  end
  Update  $\rho$  to set  $a$  false;
  Call DPLL-CL recursively (again);
   $\rho \leftarrow \rho_0$ ;
  return false;
end loop

```

Figure 7.6. The recursive procedure DPLL-CL for DPLL with clause learning.

7.3.1.4. Restarts

The fourth ingredient in our CDCL list is the use of *restarts*. A restart consists of halting the CDCL search, while preserving the clauses learned from F so far, then starting a new CDCL search. As just noted, this already fits into the CDCL algorithm described earlier, as setting the new (backjumping) decision level L' equal to 0 causes a restart. The new CDCL search can use different decision literals, and this may provide an advantage in searching for either a satisfying assignment or a refutation. In practice, the use of restarts is crucial for CDCL solver performance. As is discussed later in this section, there are also theoretical reasons why restarts may be beneficial. There are several intuitive explanations of why restarts might be useful, but ultimately, it comes down to the fact that doing a restart allows the CDCL search to try out a different choice of decision literals. There have been extensive investigations of how to do *adaptive restarts* [AS12, Bie08] and how to choose decision literals, e.g., by using *variable state independent decaying sum (VSIDS)* [MMZ⁺01], *variable move to front (VMTF)* [Rya04], and *phase saving* [PD07]. Going into details about this is far beyond the scope of this survey, but see, e.g., [BF15] for an evaluation of different decision strategies, and [AS12, BF19, Hua07] for good discussions of restart strategies.

7.3.1.5. Putting It All Together

We are now ready to present pseudo-code for an abstract formulation of the CDCL algorithm. Unlike our earlier algorithms, this one is not implemented as a recursive procedure; this is because backjumping allows backtracking multiple decision

```

L ← 0;
ρ ← empty assignment;
loop
  Extend ρ by unit propagation for as long as possible;
  if ρ satisfies F then
    | return ρ as a satisfying assignment;
  else if ρ falsifies some clause of F then
    | if L = 0 then
    |   | return “Unsatisfiable”;
    | end
    Learn one or more clauses C and add them to F;
    Let L' < L be the minimal assertion level among the clauses learned;
    Unassign all literals set at levels > L';
    L ← L';
  else
    | Pick some unassigned literal a (the decision literal);
    | L ← L + 1;
    | Extend ρ to set a true;
  end
  continue (with the next iteration of the loop);
end loop

```

Figure 7.7. The CDCL algorithm (in skeletal form and without clause deletions).

levels at once. Instead, the CDCL algorithm maintains a current decision level L . Whenever a literal b is set, either as a decision literal or by unit propagation, it is given the current decision level as its level, denoted $lev(b)$. The CDCL algorithm is shown in Figure 7.7; its input is a formula F .

Our pseudo-code does not specify how to implement clause learning. A typical implementation will learn a 1UIP clause (with some postprocessing that we do not discuss here); this clause is asserting in that it allows a new literal to be set by unit propagation. The backjump level L' is then chosen as the assertion level of this clause, i.e., the minimum decision level at which this literal can be unit propagated. The partial assignment ρ will set a literal a true at level 0 if and only if the unit clause a is in F . It follows that if the CDCL algorithm returns “Unsatisfiable,” then the current set of clauses F is unsatisfiable. Since clause learning only learns clauses that are consequences of earlier clauses, this means that also the original (input) formula F is unsatisfiable.

If the CDCL algorithm uses 1UIP clause learning, or other clause learning schemes based on the conflict graph, then the learned clauses will be derivable by trivial resolution derivations (by the correspondence between trivial resolution and unit resolution). Thus, if the CDCL algorithm returns “Unsatisfiable”, the original formula F has a resolution refutation of size polynomial in the number of clauses learned by the CDCL algorithm.

Figure 7.8b shows an example of a full CDCL refutation for the formula

$$(u \vee x \vee y) \wedge (x \vee \bar{y} \vee z) \wedge (\bar{y} \vee \bar{z}) \wedge (\bar{x} \vee z) \wedge (\bar{x} \vee \bar{z}) \wedge (\bar{u} \vee w) \wedge (\bar{u} \vee \bar{w}) \quad (7.6)$$

based on 1UIP clause learning. Decision variables are shown in diamonds. Unit propagations are shown in rectangles. Dashed diamonds and boxes indicate assignments that were preserved after the previous conflict. Darker ovals indicate

learned clauses. As shown, the CDCL search finds three conflicts. The first conflict is found after \bar{w} and \bar{x} are chosen as decision literals at decision levels 1 and 2. The resulting learned clause $u \vee x$ is asserting, so x is set true by unit propagation at level 1. The second conflict learns the unit clause \bar{x} , which is an asserting clause setting x false at level 0. The CDCL solver then performs backjumping (nonchronological backtracking); namely, it backtracks to unset all values set at decision levels above the level of the asserted literal x . In this case, backjumping involves backtracking out of decision level 1, unassigning w and u , so that w is no longer a decision literal. The third conflict arises at level 0, and completes the CDCL procedure. However, for pedagogical reasons — to get a clearer connection to the resolution proof — the illustration assumes that the solver does not terminate immediately after detecting a conflict at decision level 0, but instead performs a final round of conflict analysis to formally derive the empty clause \perp . Figure 7.8c shows the corresponding resolution refutation of F . Note that each conflict forms a trivial resolution derivation relative to the current CNF formula F as augmented with learned clauses.

7.3.1.6. Clause Deletions

It should be mentioned that one aspect of CDCL solving that is absolutely crucial in practice, but that our discussion above completely ignores, is the use of *clause deletion*, or *clause erasure*. Clause deletion means removing some of the learned clauses. This helps reduce memory usage and, even more importantly, allows unit propagation to run faster. The disadvantage is that clause erasure might delete clauses that would have been useful in the future (but results in [KN20] indicate that in some cases erasing clauses can actually help the solver find shorter resolution refutations). Some theoretical results related to clause deletion will be discussed later in the context of resolution space in Sections 7.4.3 and 7.4.4.

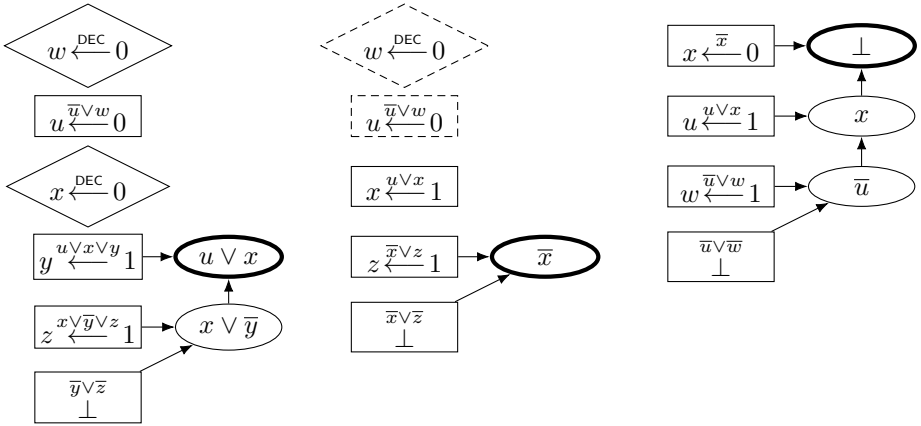

7.3.2. Proof Logging in CDCL Solvers

The output of a SAT solver given a CNF formula F will be either a satisfying assignment for F or the assertion that F is unsatisfiable. In the second case, it can be useful to not just assert that F is unsatisfiable, but also to produce a refutation of F so that this assertion can be verified. Of course, the execution of the SAT solver can serve as a kind of proof, but this is not ideal; first because there could be bugs in the design or implementation of the SAT solver, and second because it does not correspond to a useful proof system. A better option is to output a resolution refutation: this is always possible for the CDCL constructions we have discussed so far, as illustrated in Figure 7.8.

However, the fact that CDCL solvers (implicitly) produce resolution proofs does not necessarily mean that this is the best way of producing certificates of correctness. For a large formula the resolution proof can get very long, containing lots of details that are not really necessary for efficient verification. Also, forcing the solver to output all steps in every conflict analysis can incur a large overhead in running time. A way to get more concise certificates (see [GN03, Bie06, Van08, HHW13a]) is to use a *proof trace* consisting only of the sequence of learned clauses generated during the CDCL search (preferably with unneeded learned clauses

$$(\bar{u} \vee w) \wedge (u \vee x \vee y) \wedge (x \vee \bar{y} \vee z) \wedge (\bar{y} \vee \bar{z}) \wedge (\bar{x} \vee z) \wedge (\bar{x} \vee \bar{z}) \wedge (\bar{u} \vee w) \wedge (\bar{u} \vee \bar{w})$$

(a) The unsatisfiable CNF formula in (7.6).

(b) A CDCL refutation of the CNF formula in Figure 7.8a.

(c) The corresponding resolution refutation.

Figure 7.8. Part (a) shows the unsatisfiable CNF formula (7.6). Part (b) shows a complete CDCL run establishing the unsatisfiability of this CNF formula. Part (c) shows the resolution refutation corresponding to this CDCL execution.

omitted). For instance, in the example in Figure 7.8, the proof trace is just the sequence of clauses $u \vee x$, \bar{x} , \perp . Such a proof is called a *RUP proof*, since each clause follows by reverse unit propagation from F plus the preceding clauses in the sequence. The property of being RUP clause is checkable in polynomial time using unit propagation; thus the correctness of a RUP proof trace can be checked in time polynomially bounded by the size of F and the total size of the proof trace.

A very important aspect in applied SAT solving, which is also relevant for proof logging, is that extensive *preprocessing* of the input is performed before the main CDCL search algorithm starts, and some solvers, such as *Lingeling* [Lin], *CryptoMiniSat* [Cry], and *CaDiCaL* [CaD], even interleave preprocessing techniques with CDCL search; this is known as *inprocessing* [JHB12]. This involves using a number of techniques which, although known to be theoretically very bad in the worst case, are indispensable in practice. Many of these techniques can be formalized within resolution and hence in RUP proofs, but not all. Nowadays, RUP proof traces have therefore been supplanted by more sophisticated DRAT proofs [HHW13b]. DRAT proofs generalize RUP proofs, but can also simulate stronger methods of reasoning — in fact, all the way up to extended resolution,¹² as will be discussed later in Section 7.8.

7.3.3. Efficiency of CDCL Proof Search

Now that we have given formal descriptions of different methods for SAT solving, we can study the complexity of proofs as generated by these methods when they are used on unsatisfiable CNF formulas. As discussed above, the DPLL method corresponds to tree-like resolution, which can be exponentially worse than (general, DAG-like) resolution. Since CDCL is only looking for structurally very restricted proofs, it is natural to ask how efficient CDCL proof search can be compared to the best possible general resolution proof. (Henceforth, when we talk about CDCL, we mean CDCL *with restarts*, unless explicitly stated otherwise.) Note that if the formula is exponentially hard for resolution, then basic CDCL search cannot be expected to run fast since it is searching for a resolution proof. But what we can do is to benchmark the solver against the best possible outcome, i.e., the most efficient proof. Thus, we can ask whether a CDCL search strategy can implement efficient proof search in the sense that the algorithm finds a refutation which is no more than polynomially longer than, say, the shortest possible resolution refutation.

This turns out to be a deep and difficult question to answer. What is known is that there is no algorithm that can find resolution proofs efficiently unless $P = NP$ [AM20] (this recent paper strengthens previous results in [AR08, MPW19]). In formal proof complexity terminology, resolution is said to be *non-automatable*.

¹²It is important to note, however, that the power of DRAT proofs to simulate extended resolution is (at least as of yet) a purely theoretical result. Many reasoning techniques that, while powerful, fall well short of extended resolution, cannot currently be formalized in a practically efficient way in DRAT, two notable examples being cardinality reasoning and Gaussian reasoning. While it is possible in principle to handle cardinality reasoning or Gaussian reasoning in the DRAT proof system [HB18, BT19, HKB20], the attempts made so far to implement this in practice in state-of-the-art CDCL solvers have been far too inefficient.

What we can do instead is to seek bounds on the proof-theoretic strength of so-called *nondeterministic*¹³ solvers that are assumed to somehow magically make good choices for certain heuristics during the search. In a line of works including [BKS04, HBPV08, BHJ08] and culminating in the papers [PD11, AFT11], it was shown that nondeterministic CDCL can be as efficient as the resolution proof system except possibly for a polynomial blow-up.

More technically speaking, the assumptions needed are that the CDCL solver is allowed to magically choose decision variables and values to assign to these variables, and also keeps every single clause ever learned during the search. Furthermore, it has to make somewhat frequent restarts, but not more frequent than what is already standard in state-of-the-art solvers, and has to use some asserting clause learning scheme (in particular, 1UIP works fine, but a strength of the simulation is that any other asserting scheme will also be good enough). With these assumptions, the main result in [PD11] is that a CDCL solver can establish unsatisfiability of a CNF formula in time polynomial in the shortest resolution refutation of that formula. One possible way of interpreting this result is that in cases where the decision heuristic works well enough, and when the right learned clauses are kept in memory, then a CDCL solver could in principle run fast for formulas that possess short resolution proofs (although it follows from [AM20] that for any concrete choice of heuristics there are tricky formulas that will make these heuristics fail unless $P = NP$).

The construction of [PD11] showing that CDCL simulates resolution can be summarized as follows. Suppose that the formula F has a resolution refutation $\pi = (D_1, \dots, D_L = \perp)$. Intuitively, the goal for the CDCL search is to successively learn the clauses D_i for $i = 1, 2, \dots$ until it reaches $D_L = \perp$, which corresponds to a conflict at decision level 0 (as in the example in Figure 7.8). Learning exactly the clauses D_i might not always be possible, but a key insight in [PD11] is that the CDCL solver can instead learn other clauses which together are as powerful as D_i . For this, using a definition from [AFT11], we say that a set of clauses F' *absorbs* a clause $D = a_1 \vee \dots \vee a_k$ provided that setting any $k-1$ literals of D false allows either the remaining literal of D or the empty clause to be derived by unit propagation from the clauses of F' . As a small, concrete, example, the set of clauses $\{x_1 \vee y_1, \bar{y}_1 \vee x_2 \vee y_2, \bar{y}_2 \vee x_3\}$ absorbs $x_1 \vee x_2 \vee x_3$, since falsifying any two of the x_i -variables will propagate the third to true for both the clause and the clause set.

What absorption means is that it seems to an outside observer that the set of clauses F' contains D , since all unit propagations that would occur if D were in F' can be observed now as well. The construction of [PD11] allowing CDCL search to simulate the resolution refutation π is based on showing that the clause learning can work well enough to successively absorb the clauses D_1, \dots, D_L in the refutation π . Suppose that the solver has added enough learned clauses to the clause database $F' \supseteq F$ to have absorbed D_1, \dots, D_{i-1} . To absorb D_i , the CDCL solver repeatedly tries to falsify all literals in D_i . When this is no longer

¹³Note that the word “nondeterministic” is used here in the technical sense of the definition of the complexity class NP, where a computation can split into two branches at every step and succeeds in finding a solution if one of the (potentially exponentially many) branches does so. It thus has a very different meaning from “randomized,” where the requirement is that the successful branch should be found with high probability.

possible to do without the last unassigned literal in D_i being propagated, the clause has been absorbed. As long as it is possible to falsify D_i , then since the clauses resolved to obtain D_i are already absorbed by the inductive hypothesis, it follows that unit propagation will lead to a conflict. At this point, the solver can add a new learned clause to the clause database F' and restart. It can be shown that this process of falsifying D_i and adding a new learned clause can repeat at most a polynomial number of steps before D_i is absorbed.

The independent work [AFT11] obtained an alternative, more effective version of the simulation result by showing that if a formula F has a resolution refutation in bounded width (i.e., where every clause contains only a small number of literals), then CDCL using a decision strategy with enough randomness will decide F efficiently. At first sight this might not seem so impressive — after all, it is easy to see that in this case exhaustive search in bounded width also runs fast — but the point is that a CDCL solver is very far from doing exhaustive width search and does not care at all about the existence or non-existence of resolution refutations with only small clauses.

A downside of both of these results is that it is crucial for the SAT solver never to delete clauses. This is a very unrealistic assumption, since modern solvers typically throw away a majority of the clauses learned during search. It would be nice to extend the model of CDCL in [AFT11, PD11] to capture memory usage in a more realistic way, and then study the question of whether CDCL can simulate resolution efficiently with respect to both time and space. An attempt in this direction was made in [EJL⁺16], but the following problem still remains open. (We refer to Section 7.4.3 for the formal definitions of space.)

Open Problem 7.1. Suppose that F is a CNF formula that has a resolution refutation in simultaneous length L and space s . Does this imply that there is a CDCL proof of the unsatisfiability of F (as modelled in [AFT11, PD11, EJL⁺16]) in simultaneous length and space polynomial in L and s , respectively?

Another downside of [AFT11, PD11] is that the simulation of resolution by CDCL depends crucially on the choice of decision literals. However, the correct choice of decisions is made in a highly non-constructive way — namely, as discussed above, it consists of falsifying the literals in the clauses in the (unknown) shortest resolution refutation one at a time in the order they appear in the refutation, and to do this repeatedly for each clause until it is guaranteed to be absorbed. In other words, the usual heuristics for decisions (such as VSIDS and phase saving) do not come into play at all for the simulation of resolution by CDCL. Similarly, the concrete restart heuristic used plays no role — all that matters is that restarts are frequent enough. The way the construction goes, the solver makes progress towards its goal at the first conflict after every restart, but then it might not do anything useful until the next restart happens. One can show, though, that the solver also cannot do anything harmful while waiting for the next restart (but for this to hold it is crucial that the solver never deletes any learned clauses).

It is still mostly an open problem to establish theoretical results about how the commonly used CDCL heuristics contribute (or sometimes fail to contribute) to the success of CDCL search. This is challenging to do from a mathematical

point of view, however, since these heuristics are quite sophisticated and often depend on the full history of the CDCL execution so far.

For clause learning, a seemingly obvious approach would be to prioritize learning short clauses, but it seems to have been known in the SAT community that this does not work so well in practice. A theoretical explanation for this was given in [BSJ10], where it was shown that for formulas that require resolution proofs with large clauses CDCL solvers also need to learn and keep large clauses in order to run fast (i.e., it is not enough that large clauses appear as intermediate steps in the conflict analysis). Regarding clause deletion, the theoretical results in Sections 7.4.3 and 7.4.4 can be interpreted as saying that the quite aggressive deletion policies in modern CDCL solvers can incur a substantial (sometimes exponential) increase in running time, although this can only be rigorously proven for specially designed theoretical benchmark formulas. As to activity-related decision heuristics such as VSIDS [MMZ⁺01], VMTF [Rya04], or phase saving [PD07], there is very little by way of concrete theoretical results.

Open Problem 7.2. Prove simulation or separation results for resolution versus CDCL when the solver is constrained to use decision strategies such as VSIDS, VMTF, and/or phase saving.

A very recent paper [Vin20] shows, somewhat informally speaking, that there are unsatisfiable CNF formulas for which standard decision heuristics such as VSIDS and VMTF can be exponentially worse than optimal decisions. Another recent contribution [MPR20] studies the power of CDCL when the decision heuristic is replaced by a fixed ordering of the variables, but the strongest results are unfortunately for a model that is fairly far from practice when it comes to modelling unit propagation and clause learning.

An even more fundamental open problem is to understand the role of restarts for CDCL solvers and whether they add to the theoretical reasoning power. Phrased in theoretical language, the question is whether restarts are really necessary in order for CDCL to be able to simulate resolution, or whether this can be done also without restarts. To conclude this section, we briefly discuss two related approaches to studying this problem by modelling CDCL without restarts as a proof system, namely *pool resolution* [Van05] and *RegWRTI* [BHJ08].

A pool resolution refutation consists of a resolution refutation π with an associated regular depth-first traversal; in other words, there is a depth-first traversal of the DAG G_π such that at each point during the traversal the path from the current clause back to the empty clause does not resolve more than once on any given variable. The intuition is that a regular depth-first traversal corresponds to the CDCL search, so if clauses are learned as they are traversed, they do not need to be traversed again. The fact that CDCL never chooses a decision literal which is already set and that clause learning only learns clauses containing negated literals imposes a regularity condition for each path in the depth-first search. One aspect in which pool resolution seems stronger than CDCL, though, is that the depth-first traversal allows a much richer set of clauses to be “learned” than those derived by trivial resolution from the current clause database.

The RegWRTI system is similar in spirit to pool resolution, but it uses a restricted form of clause learning that (unlike pool resolution) allows learning only

clauses that can be learned using cuts in a conflict graph. Thus RegWRTI better approximates the way clause learning works in CDCL solvers. The definition of RegWRTI is a bit complicated, so we omit it here. It is open whether pool resolution or RegWRTI simulate resolution; indeed, several candidates for separation have failed to give a separation [BB12, BBJ14, BK14].

Pool resolution and RegWRTI do not fully capture CDCL without restarts, as they do not incorporate *self-subsumption* [SB09, HS09] (also called *clause minimization*) during clause learning. For an example of self-subsumption, see Figure 7.4, where the 1UIP clause $\bar{a} \vee \bar{b} \vee \bar{c} \vee \bar{y}$ can be resolved with the clause $\bar{a} \vee \bar{b} \vee c$ to yield a better learned clause $\bar{a} \vee \bar{b} \vee \bar{y}$. Since this resolves on the literal c even though c has been set false, it does not fit the framework of pool resolution or RegWRTI. It is possible that pool resolution or especially RegWRTI can simulate clause learning augmented with self-subsumption, but this is an open question.

Open Problem 7.3. Can CDCL as modelled in [AFT11, PD11, EJL⁺16], but without restarts, efficiently simulate resolution? Or is it possible to prove that resolution is stronger than such a model of CDCL, or even stronger than RegWRTI or pool resolution?

7.4. Resolution and Proof Complexity

The previous section described the close connections between the resolution proof system and SAT solvers based on conflict-driven clause learning. Thanks to these connections, one way of analysing the potential and limitations of CDCL proof search is to study resolution refutations and establish upper and lower bounds on the complexity of such refutations. A lower bound on resolution proof length gives a corresponding lower bound on CDCL execution time, since the proof search cannot run faster than the smallest resolution proof it could possibly find.¹⁴ Conversely, an upper bound on resolution refutation length points to at least the possibility of good performance by CDCL search algorithms. There are other ways to measure resolution proof complexity beside sheer length. Notably, bounding the width or space of resolution refutations can shed light on the effectiveness of different clause learning and clause erasure strategies. In this section, we review what is known about these different proof complexity measures for resolution.

7.4.1. Resolution Length

We start by recalling that the *length* (also referred to as the *size*) of a resolution refutation is the number of clauses in it, where the clauses are counted with repetitions (which is relevant for tree-like or regular refutations). In general, proof length/size is the most fundamental measure in proof complexity, and as just discussed, lower bounds for resolution length imply lower bounds on CDCL solver running time.

Any CNF formula of size N can be refuted in resolution in length $\exp(O(N))$, and there are formulas for which matching $\exp(\Omega(N))$ lower bounds are known.

¹⁴As already discussed, however, this does not take into account the effect of preprocessing techniques that cannot be formalized within the resolution proof system, but it is still the case that resolution lower bounds often imply hardness also in practice.

Let us discuss some examples of formulas known to be hard with respect to resolution length.

Our first example is the *pigeonhole principle (PHP)*, which says that “ m pigeons do not fit into n holes without sharing holes if $m > n$.” This is arguably the single most studied combinatorial principle in all of proof complexity (see [Raz02] for a survey). When written as an unsatisfiable CNF formula, this becomes the claim that, on the contrary, $m > n$ pigeons do fit into n holes. To encode this, one uses variables $p_{i,j}$ to denote “pigeon i goes into hole j ,” and write down the following clauses, where $i \neq i'$ range over $1, \dots, m$ and $j \neq j'$ range over $1, \dots, n$:

$$p_{i,1} \vee p_{i,2} \vee \dots \vee p_{i,n} \quad \text{[every pigeon } i \text{ gets a hole]} \quad (7.7a)$$

$$\bar{p}_{i,j} \vee \bar{p}_{i',j} \quad \text{[no hole } j \text{ gets two pigeons } i \neq i'] \quad (7.7b)$$

There are also variants where one in addition has “functionality” and/or “onto” axioms

$$\bar{p}_{i,j} \vee \bar{p}_{i,j'} \quad \text{[no pigeon } i \text{ gets two holes } j \neq j'] \quad (7.7c)$$

$$p_{1,j} \vee p_{2,j} \vee \dots \vee p_{m,j} \quad \text{[every hole } j \text{ gets a pigeon]} \quad (7.7d)$$

In a breakthrough result, Haken [Hak85] proved that the PHP formulas consisting of clauses (7.7a) and (7.7b) require length $\exp(\Omega(n))$ in resolution for $m = n + 1$ pigeons, and his proof can be extended to work also for the *onto FPHP formulas* consisting of all clauses (7.7a)–(7.7d).¹⁵ Later work [Raz04a, Raz03, Raz04b] has shown that all of the PHP formula variants remain hard even for arbitrarily many pigeons m , requiring resolution length $\exp(\Omega(n^\delta))$ for some $\delta > 0$ — such formulas with $m \gg n$ are referred to as *weak pigeonhole principle (WPHP) formulas*, since the claim made by the pigeonhole principle gets weaker and weaker as m increases compared to n . What all of these lower bounds mean, intuitively, is that the resolution proof system really cannot count: even faced with the preposterous claim that infinitely many pigeons can be mapped in a one-to-one fashion into a some finite number n of holes, resolution cannot refute this claim with a proof of length polynomially bounded in the number of holes.

Since pigeonhole principle formulas have size $N = \Theta(n^3)$, Haken’s lower bound is only of the form $\exp(\Omega(\sqrt[3]{N}))$ expressed in terms of formula size, however, and so does not quite match the $\exp(O(N))$ worst-case upper bound. The first truly exponential lower bound on length was obtained for *Tseitin formulas* (an example of which is shown in Figure 7.9), which encode (the negation of) the principle that “the sum of the vertex degrees in a graph is even.” Here the variables correspond to the edges in an undirected graph G of bounded degree. Every vertex in G is labelled 0 or 1 so that the sum of the vertex labels is odd.

¹⁵To generate these formulas in the standard DIMACS format used by SAT solvers, one can use the tool *CNFgen* [LENV17, CNF] with the command line `cnfgen php <m> <n>` to obtain PHP formulas with m pigeons and n holes, `cnfgen php --functional <m> <n>` for FPHP formulas with axioms (7.7c) also, `cnfgen php --onto <m> <n>` for onto PHP formulas with axioms (7.7d), and `cnfgen php --onto --functional <m> <n>` for onto FPHP formulas with all axioms clauses (7.7a)–(7.7d) discussed above. (Here and in all following *CNFgen* examples, the syntax <n> means that an actual value of n , without brackets, should be provided on the command line.)

Figure 7.9. Example Tseitin formula.

The Tseitin formula for G is the CNF formula which is the conjunction of the set of clauses expressing that for each vertex of G the parity of the number of true edges incident to that vertex is equal to the vertex label. See Figure 7.9b, which displays the formula corresponding to the labelled graph in Figure 7.9a.

If we sum over all vertices, the number of all true incident edges should be odd by the construction of the labelling. However, since such a sum counts each edge exactly twice it has to be even. Thus, the Tseitin formulas are indeed unsatisfiable. Urquhart [Urq87] established that Tseitin formulas require resolution length $\exp(\Omega(N))$ if the underlying graph is a well-connected so-called *expander graph*. We cannot discuss the fascinating theory of expander graphs here, and instead refer to [HLW06] for more information, but suffice it to say that, e.g., a randomly sampled regular graph is an excellent expander *asymptotically almost surely*, i.e., with overwhelmingly large probability,¹⁶ and there are also explicit constructions. Intuitively, the lower bound in [Urq87] shows that not only is resolution unable to count efficiently in general, but it cannot even do so mod 2.¹⁷

Another example of exponentially hard formulas are **random k -CNF formulas** which are generated by randomly sampling $\Delta \cdot n$ k -clauses over n variables for some large enough constant Δ depending on k . For instance, $\Delta \gtrsim 4.5$ is sufficient to get unsatisfiable 3-CNF formulas asymptotically almost surely [DBM00] (see also Chapter 10 on random satisfiability in this handbook). Chvátal and Szemerédi [CS88] established that resolution requires length $\exp(\Omega(N))$ to refute such formulas (again asymptotically almost surely).¹⁸

By now strong lower bounds have been shown for formulas encoding **tiling**

¹⁶Formally, we say that a sequence of events \mathcal{P}_n happen *asymptotically almost surely* (sometimes also referred to as *with high probability*) if $\lim_{n \rightarrow \infty} \Pr[\mathcal{P}_n] = 1$.

¹⁷To generate unsatisfiable Tseitin formulas in DIMACS format for random 4-regular graphs over n vertices (which yields formulas that are exponentially hard for resolution asymptotically almost surely) one can use *CNFgen* with the command line `cnfgen tseitin <n>` (or, more generally, `cnfgen tseitin <n> <d>` for d -regular graphs over n vertices as long as $d \cdot n$ is even). For a standard CDCL solver without Gaussian reasoning, Tseitin formulas over random 4-regular graphs become quite hard already for around 50 vertices.

¹⁸*CNFgen* generates random k -CNF formulas with m clauses over n variables with the command line `cnfgen randkcnf <k> <n> <m>`. Random 3-CNF formulas with n variables and $\Delta \cdot n$ clauses for $\Delta = 4.5$ are noticeably hard for CDCL solvers by the time $n = 350$ or so.

problems [Ale04, DR01], **k -colourability** [BCMM05], **independent set/clique**, and **vertex cover** [BIS07], and many other combinatorial principles. For clique formulas there is an interesting range of parameters where lower bounds are *not* known, however, and so we discuss this family of formulas next.

Given a positive integer k and a graph $G = (V, E)$ with vertices V and edges E , the clique formula encodes the claim that G has a k -clique. We have variables $x_{v,i}$ with the intended meaning “vertex v is the i th member of the clique” and also think of the vertices as $V = \{1, 2, \dots, n\}$ so that we can list them in order and compare them. Letting u, v range over vertices and i, j range over clique membership indices, the formula consists of the following clauses:

$$x_{1,i} \vee x_{2,i} \vee \dots \vee x_{n,i} \quad i \in [k], \quad (7.8a)$$

$$\bar{x}_{u,i} \vee \bar{x}_{v,i} \quad u, v \in V, u < v, i \in [k] \quad (7.8b)$$

$$\bar{x}_{v,i} \vee \bar{x}_{v,j} \quad v \in V, i, j \in [k], i < j \quad (7.8c)$$

$$\bar{x}_{u,i} \vee \bar{x}_{v,j} \quad (u, v) \notin E, i, j \in [k], i \neq j \quad (7.8d)$$

$$\bar{x}_{u,j} \vee \bar{x}_{v,i} \quad u, v \in V, u < v, i, j \in [k], i < j \quad (7.8e)$$

Clauses (7.8a), (7.8b), and (7.8c) just encode that there is precisely one vertex chosen to be the i th clique member. Clauses (7.8d) enforce the constraint that there must be edges between all vertices in the clique. Finally, the clauses (7.8e) remove a potential (and artificial) source of hardness by specifying that the vertices v_1, v_2, \dots, v_k chosen as clique members $1, 2, \dots, k$ should be listed in increasing order.

From a proof complexity point of view, clique formulas become interesting when the graph G does *not* have a k -clique but when this is hard to prove. This problem can clearly be solved in time roughly n^k simply by checking if any of the $\binom{n}{k}$ many sets of vertices of size k forms a clique. Such a simple approach can be formalized already in tree-like resolution, and yields refutations of polynomial length if k is constant. A popular conjecture is that the k -clique problem must require time $n^{\Omega(k)}$ in the worst case, or even on average when graphs are sampled at random (e.g., according to the Erdős-Rényi distribution where for an n -vertex graph every single edge out of the $\binom{n}{2}$ possible ones is included uniformly and independently at random with some appropriate probability p , called the edge density).¹⁹ A natural question is whether it is possible to prove such lower bounds unconditionally for proof systems that are strong enough to capture algorithmic methods used in practice.

For tree-like resolution, an optimal $n^{\Omega(k)}$ length lower bound (i.e., optimal up to constant factors in the exponent) was established in [BGL13] for k -clique formulas on Erdős-Rényi random graphs. When k is chosen very large, on the order of n^γ for some large enough γ , $0 < \gamma < 1$, it was shown in [BIS07, Pan19] that resolution requires length scaling like $\exp(n^\delta)$ for some $\delta > 0$ for Erdős-Rényi

¹⁹To generate k -clique formulas over n -vertex random graphs for small values of k that seem likely to require resolution refutations of length $n^{\Omega(k)}$, one can use *CNFgen* with the command line `cnfgen kclique (k) gnp (n) (p)` for $p = n^{-2/(k-2)}$, which is below the threshold edge density $n^{-2/(k-1)}$ for the appearance of k -cliques and hence will yield unsatisfiable formulas asymptotically almost surely. A concrete setting of parameters that seem to yield formulas with hardness that scales nontrivially with the number of vertices n in practice for CDCL solvers is $k = 10$ and $p = n^{-1/4}$.

random graphs. For smaller k , an optimal $n^{\Omega(k)}$ length lower bound was obtained for the restricted subsystem of *regular resolution* in [ABdR⁺18], but for general resolution it remains an open problem even to establish worst-case lower bounds for small k .

Open Problem 7.4. Prove average-case resolution length lower bounds $n^{\Omega(k)}$ for k -clique formulas over Erdős-Rényi random graphs with appropriate parameters, or worst-case length lower bounds for any family of graphs.

This problem is also of intrinsic interest in proof complexity, since these formulas do not seem to be amenable to the standard techniques for proving resolution lower bounds such as the *interpolation method* [Kra97, Pud97], *random restrictions* [BP96b], or the *length-width lower bound* in [BSW01]. We will discuss some of these techniques later in the survey.

We conclude our discussion of resolution length by mentioning one slightly more recent addition to the long list of challenging combinatorial formulas already mentioned, namely the *subset cardinality formulas* studied in [Spe10, VS10, MN14] (also known as *zero-one design* or *s-gen* formulas).

To construct these formulas, we start with an $n \times n$ $(0, 1)$ -matrix with 4 non-zero entries in each row and column except that one extra non-zero entry is added to some empty cell (as in Figure 7.10a, where the extra 1 in the bottom row is in bold face). The variables of the formula are the non-zero entries of the matrix, yielding a total of $4n + 1$ variables. For each row of 4 ones in the matrix, we write down the natural 3-CNF formula encoding the *positive cardinality constraint* that at least 2 variables must be true (as in the first set of clauses in Figure 7.10b), and for the row with 5 ones the 3-CNF formula encoding that a strict majority of 3 variables must be true. For the columns we instead encode *negative cardinality constraints* that a majority of the variables in each column must be false (see the last set of clauses in Figure 7.10b). The formula consisting of the conjunction of all these clauses must be unsatisfiable, since a strict majority of the variables cannot be true and false simultaneously. We will have reason to return to these formulas below when we discuss connections between CDCL and resolution, and also when discussing cutting planes and pseudo-Boolean solving.

It was shown empirically in [Spe10, VS10] that these formulas are very challenging for CDCL solvers, but there was no analysis of the theoretical hardness. Such an analysis was provided by [MN14], where it was established that subset cardinality formulas are indeed exponentially hard if the underlying matrix is an expander (informally, if every small-to-medium set of rows has non-zero entries in many distinct columns).²⁰

7.4.2. Resolution Width

A second complexity measure in resolution, which is almost as well studied as length, is the *width* of refutations measured as the size of a largest clause in a

²⁰ *CNFgen* generates subset cardinality formulas for random $n \times n$ matrices — which are expanding, and so yield formulas that are exponentially hard for resolution, asymptotically almost surely — with the command line `cnfgen subsetcard <n>`. These formulas get noticeably hard for CDCL solvers around $n = 25$.

$$\begin{array}{l}

 \wedge (\bar{x}_{4,11} \vee \bar{x}_{8,11} \vee \bar{x}_{11,11}) \\
 \wedge (\bar{x}_{4,11} \vee \bar{x}_{10,11} \vee \bar{x}_{11,11}) \\
 \wedge (\bar{x}_{8,11} \vee \bar{x}_{10,11} \vee \bar{x}_{11,11})
 \end{array}$$

(b) Cardinality constraints in CNF.

Figure 7.10. Matrix and (fragment of) corresponding subset cardinality formula.

resolution refutation. It is clear that the width needed to refute a formula is never larger than the number of variables n , which is in turn less than the total formula size N . It is also easy to see that an upper bound w on resolution width implies an upper bound $O((3n)^w)$ on resolution length, simply because the total number of distinct clauses of width at most w over n variables is less than $(3n)^w$. Incidentally, this simple counting argument turns out to be essentially tight, in that there are k -CNF formulas refutable in width w that require resolution length $n^{\Omega(w)}$, as shown in [ALN16].

Much less obviously, however, and much more interestingly, strong enough width lower bounds imply strong length lower bounds. Ben-Sasson and Wigderson [BSW01] (using methods based on [CEI96, IPS99]) showed that for a k -CNF formula over n variables it holds that

$$\text{refutation length} \geq \exp \left(\Omega \left(\frac{(\text{refutation width} - k)^2}{n} \right) \right) \quad (7.9)$$

where “refutation length” and “refutation width” mean the minimum length and minimum width, respectively, of any resolution refutations of the formula. (Note that these two minima could potentially be realized by different refutations.) The inequality (7.9) implies that if one can prove that a formula requires width $\omega(\sqrt{n \log n})$, this immediately yields a superpolynomial length lower bound, and a width lower bound $\Omega(N)$ in terms of the formula size N (which is lower-bounded by the number of variables n) implies a truly exponential $\exp(\Omega(N))$ length lower bound. Almost all known lower bounds on resolution length can be derived via width lower bounds in this way (in particular, essentially all the bounds discussed in Section 7.4.1²¹ although the ones predating [BSW01] were originally not obtained in this way).

For tree-like resolution refutations of k -CNF formulas, the paper [BSW01]

²¹To be precise, the exceptions are [Ale04, DR01, Raz04a, Raz03, Raz04b], where the number of variables n , and hence the formula size N , is at least as large as the refutation width squared, and where other methods must therefore be used to prove lower bounds on resolution length.

proved a sharper version

$$\text{tree-like refutation length} \geq 2^{\text{refutation width} - k} \quad (7.10)$$

of the bound in (7.9) for general resolution. This means that for tree-like resolution, even width lower bounds $\omega(\log N)$ yield superpolynomial length lower bounds. For general resolution, however, a width lower bound even as large as $\Omega(\sqrt{n \log n})$ does not imply any length lower bound according to (7.9). This raises the question of whether it is possible to improve the analysis so that (7.9) can be strengthened to something closer to (7.10) also for general resolution. Bonet and Galesi [BG01] showed that this is not the case by studying another interesting combinatorial benchmark formula, which we describe next.

The **ordering principle** says that “every finite (partially or totally) ordered set $\{e_1, \dots, e_n\}$ has a minimal element.” To encode the negation of this statement in CNF, we use variables $x_{i,j}$ to denote “ $e_i < e_j$ ” and write down the following clauses (for $i \neq j \neq k \neq i$ ranging over $1, \dots, n$):

$$\bar{x}_{i,j} \vee \bar{x}_{j,i} \quad [\text{anti-symmetry; not both } e_i < e_j \text{ and } e_j < e_i] \quad (7.11a)$$

$$\bar{x}_{i,j} \vee \bar{x}_{j,k} \vee x_{i,k} \quad [\text{transitivity; } e_i < e_j \text{ and } e_j < e_k \text{ implies } e_i < e_k] \quad (7.11b)$$

$$\bigvee_{1 \leq i \leq n, i \neq j} x_{i,j} \quad [e_j \text{ is not a minimal element}] \quad (7.11c)$$

One can also add axioms

$$x_{i,j} \vee x_{j,i} \quad [\text{totality; either } e_i < e_j \text{ or } e_j < e_i] \quad (7.11d)$$

to specify that the ordering has to be total.²² This yields a formula over $\Theta(n^2)$ variables of total size $N = \Theta(n^3)$. We remark that variants of ordering principle formulas also appear under the names **least number principle formula** and **graph tautology formula** in the literature.

It was conjectured in [Kri85] that these formulas should be exponentially hard for resolution, but Stålmarck [Stå96] showed that they are refutable in length $O(N)$ (even without the clauses (7.11d)).

As the formula is described above, it does not really make sense to ask about the refutation width, since already the axiom clauses (7.11c) have unbounded width. However, one can convert the formula to 3-CNF by applying the transformation from (7.1a) to (7.1b) to the wide axioms (7.11c), and for this version of the formula [BG01] established a width lower bound $\Omega(\sqrt[3]{N})$ (which is tight, and holds even if the axioms (7.11d) are also added). This shows that even polynomially large resolution width does not necessarily imply any length lower bounds for general resolution (and, in view of (7.10), it provides an exponential separation in proof power between general and tree-like resolution, although even stronger separations are known [BSIW04]).

²² *CNFgen* generates the ordering principle formula for a set of n elements with the command `cnfgen op <n>` and also adds totality axioms with `cnfgen op --total <n>`. These formulas are easy in practice for CDCL solvers that use VSIDS with a small enough decay factor or VMTF.

7.4.3. Resolution Space

The study of the space complexity of proofs, which was initiated in the late 1990s, was originally motivated by considerations of SAT solver memory usage, but has also turned out to be of intrinsic interest for proof complexity. Space can be measured in different ways — here we focus on the most well studied measure of *clause space*, which is the maximal number of clauses needed in memory while verifying the correctness of a resolution refutation.²³ Thus, in what follows below “space” will always mean “clause space.”

The space usage of a resolution refutation at step t is the number of clauses at steps $\leq t$ that are used at steps $\geq t$. Returning to our example resolution refutation in Figure 7.1, the space usage at step 8 is 5 (the clauses in memory at this point are clauses 1, 2, 6, 7, and 8). The space of a proof is obtained by measuring the space usage at each step in the proof and taking the maximum. Phrased differently, one can view the formula as being stored in read-only input memory, from where the axiom clauses can be read into working memory. The resolution rule can only be applied to clauses currently in working memory, and if a clause has been erased from working memory, then it is gone, and will have to be rederived if it is to be used again (or read again from the read-only input, in the case of axiom clauses). Then space measures how many clauses are used in working memory to perform the resolution refutation. Incidentally, it is not hard to see that the proof in Figure 7.1 is not optimal when it comes to minimizing space. We could do the same refutation in space 4 instead by processing the clauses in the order 4, 5, 6, 3, 7, 2, 8, 1, 9, 10. (In fact, it is even conceivable that if minimizing space is all we care about, then it might be beneficial to forget clauses and rederive them later, even if it means repeating the same steps in the resolution refutation multiple times. This indeed turns out to be the case, as discussed in Section 7.4.4 below.)

Perhaps somewhat surprisingly, any unsatisfiable CNF formula of size N can always be refuted in resolution space at most $N + O(1)$ as shown by [ET01],²⁴ though the resolution refutation thus obtained might have exponential length. Lower bounds on space were shown for pigeonhole principle formulas and Tseitin formulas in [ABSRW02, ET01] and for random k -CNF formulas in [BSG03]. For the latter two formula families the (optimal linear) lower bounds matched exactly previously known width lower bounds, and also the proof techniques had a very similar flavour. This led to the question of whether there was some deeper connection waiting to be discovered. In a very elegant paper, Atserias and Dal-

²³Note, though, that this measure underestimates the actual memory usage, since storing a clause requires more than a constant amount of memory (this is similar to how we ignore the size of clauses when defining the size of resolution proofs to be the total number of clauses in the proof). For completeness, we mention that there is also a measure *total space*, counting the total number of literals in memory (with repetitions), which has been studied in, e.g., [ABSRW02, BGT14, BBG⁺17, Bon16, GKT19].

²⁴This space upper bound can also be obtained simply by running CDCL (or even DPLL) as described in Section 7.3.1 with some arbitrary but fixed variable ordering, with the (non-standard) modification that after each backjump all clauses that are no longer needed to explain the propagation of literals in the current assignment are immediately erased.

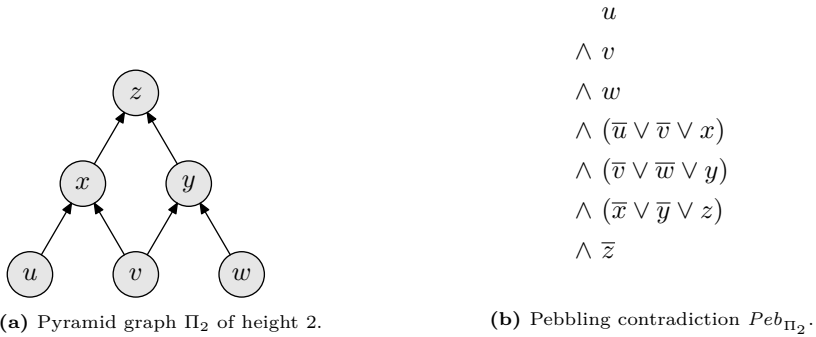

Figure 7.11. Example pebbling contradiction for the pyramid of height 2.

mau [AD08] confirmed this by showing that the inequality

$$\text{refutation space} \geq \text{refutation width} - k \quad (7.12)$$

holds for resolution refutations of k -CNF formulas. The proof of (7.12) is beautiful but uses a somewhat non-explicit argument based on finite model theory. A more explicit proof, which works by simple syntactic manipulations to construct a small-width refutation from a small-space refutation, was presented in [FLM⁺15].

Since for all formulas studied up to [AD08] the width and space complexity measures turned out to actually coincide, it is natural to ask whether (7.12) can be strengthened to an asymptotic equality. The answer to this question is negative. As shown in the sequence of works [Nor09a, NH13, BSN08], there are formulas that can be refuted in width $O(1)$ and length $O(N)$ but require space $\Omega(N/\log N)$ (i.e., formulas that are maximally easy for width but exhibit worst-case behaviour for space except for a log factor, and this result is tight since it can be shown (using a result from [HPV77] that is, incidentally, very related to the next topic of *pebbling*) that any formula refutable in length $O(N)$ can also be refuted in space $O(N/\log N)$).

The formulas used to obtain the separation result just described are **pebbling contradictions** (also called **pebbling formulas**) encoding so-called *pebble games* on bounded fan-in DAGs, which for the purposes of this discussion we additionally require to have a unique sink. In the “vanilla version” of the formula (illustrated in Figure 7.11), there is one variable associated to each vertex and clauses encoding that

- the source vertices are all true;
- if all immediate predecessors are true, then the successor vertex is true;
- but the sink is false.

There is an extensive literature on pebbling space and time-space trade-offs from the 1970s and 80s, with Pippenger [Pip80] and Savage [Sav98, Chapter 10] giving excellent overviews of some classic results in the area. Some more recent developments are covered in the upcoming survey [Nor20]. Pebbling contradic-

tions have been useful before in proof complexity in various contexts, e.g., in [RM99, BEGJ00, BSW01]. Since pebbling contradictions can be shown to be refutable in constant width but there are graphs for which the pebble game requires large space, one could hope that the pebbling properties of such DAGs would somehow carry over to resolution refutations of pebbling formulas and help us separate space and width.

Unfortunately, this hope cannot possibly materialize — a quick visual inspection of Figure 7.11b reveals that this is a Horn formula (i.e., having at most one positive literal in each clause), and such formulas are maximally easy for length, width, and space since they are decided by unit propagation. However, we can modify these formulas by substituting for every variable x an exclusive or $x_1 \oplus x_2$ of two new variables, and then expand to CNF in the canonical way to get a new formula. This process is called *XOR-ification* or *XOR-substitution* and is perhaps easiest to explain by example. Performing this substitution in the clause

$$\bar{x} \vee y \tag{7.13a}$$

we obtain the formula

$$\neg(x_1 \oplus x_2) \vee (y_1 \oplus y_2) , \tag{7.13b}$$

which when expanded out to CNF becomes

$$\begin{aligned} & (x_1 \vee \bar{x}_2 \vee y_1 \vee y_2) \\ & \wedge (x_1 \vee \bar{x}_2 \vee \bar{y}_1 \vee \bar{y}_2) \\ & \wedge (\bar{x}_1 \vee x_2 \vee y_1 \vee y_2) \\ & \wedge (\bar{x}_1 \vee x_2 \vee \bar{y}_1 \vee \bar{y}_2) . \end{aligned} \tag{7.13c}$$

As another example, applying XOR-substitution to Figure 7.11b yields the formula in Figure 7.12.²⁵

Using such XOR-substitution, it turns out that the pebbling contradiction inherits the time-space trade-offs of the pebbling DAG in terms of which it is defined [BSN08, BSN11] (and there is nothing magical with XOR — this can be shown to work also for substitution with other Boolean functions that have the right properties). Now the strong space-width separation described above is obtained by plugging in the pebbling DAGs studied in [PTC77, GT78].

7.4.4. Resolution Trade-offs

In the preceding sections, we have seen that for all the complexity measures of length, width, and space there are formulas which are maximally hard for these measures. Suppose, however, that we are given a formula that is guaranteed to be *easy* for two or more of these measures. Can we then find a resolution refutation that optimizes these complexity measures simultaneously? Or are there trade-offs, so that minimizing one measure must cause a sharp increase in the other measure? Such questions about trade-offs have a long history in computational

²⁵To generate pebbling formulas as in Figure 7.11b for pyramid graphs of height h , run *CNFgen* with the command line `cnfgen peb pyramid (h)`. Doing `cnfgen peb pyramid (h) -T xor 2` yields XOR-ified pebbling formulas as illustrated in Figure 7.12.

$$\begin{array}{ll}
(u_1 \vee u_2) & \wedge (v_1 \vee \bar{v}_2 \vee \bar{w}_1 \vee w_2 \vee y_1 \vee y_2) \\
\wedge (\bar{u}_1 \vee \bar{u}_2) & \wedge (v_1 \vee \bar{v}_2 \vee \bar{w}_1 \vee w_2 \vee \bar{y}_1 \vee \bar{y}_2) \\
\wedge (v_1 \vee v_2) & \wedge (\bar{v}_1 \vee v_2 \vee w_1 \vee \bar{w}_2 \vee y_1 \vee y_2) \\
\wedge (\bar{v}_1 \vee \bar{v}_2) & \wedge (\bar{v}_1 \vee v_2 \vee w_1 \vee \bar{w}_2 \vee \bar{y}_1 \vee \bar{y}_2) \\
\wedge (w_1 \vee w_2) & \wedge (\bar{v}_1 \vee v_2 \vee \bar{w}_1 \vee w_2 \vee y_1 \vee y_2) \\
\wedge (\bar{w}_1 \vee \bar{w}_2) & \wedge (\bar{v}_1 \vee v_2 \vee \bar{w}_1 \vee w_2 \vee \bar{y}_1 \vee \bar{y}_2) \\
\wedge (u_1 \vee \bar{u}_2 \vee v_1 \vee \bar{v}_2 \vee x_1 \vee x_2) & \wedge (x_1 \vee \bar{x}_2 \vee y_1 \vee \bar{y}_2 \vee z_1 \vee z_2) \\
\wedge (u_1 \vee \bar{u}_2 \vee v_1 \vee \bar{v}_2 \vee \bar{x}_1 \vee \bar{x}_2) & \wedge (x_1 \vee \bar{x}_2 \vee y_1 \vee \bar{y}_2 \vee \bar{z}_1 \vee \bar{z}_2) \\
\wedge (u_1 \vee \bar{u}_2 \vee \bar{v}_1 \vee v_2 \vee x_1 \vee x_2) & \wedge (x_1 \vee \bar{x}_2 \vee \bar{y}_1 \vee y_2 \vee z_1 \vee z_2) \\
\wedge (u_1 \vee \bar{u}_2 \vee \bar{v}_1 \vee v_2 \vee \bar{x}_1 \vee \bar{x}_2) & \wedge (x_1 \vee \bar{x}_2 \vee \bar{y}_1 \vee y_2 \vee \bar{z}_1 \vee \bar{z}_2) \\
\wedge (\bar{u}_1 \vee u_2 \vee v_1 \vee \bar{v}_2 \vee x_1 \vee x_2) & \wedge (\bar{x}_1 \vee x_2 \vee y_1 \vee \bar{y}_2 \vee z_1 \vee z_2) \\
\wedge (\bar{u}_1 \vee u_2 \vee v_1 \vee \bar{v}_2 \vee \bar{x}_1 \vee \bar{x}_2) & \wedge (\bar{x}_1 \vee x_2 \vee y_1 \vee \bar{y}_2 \vee \bar{z}_1 \vee \bar{z}_2) \\
\wedge (\bar{u}_1 \vee u_2 \vee \bar{v}_1 \vee v_2 \vee x_1 \vee x_2) & \wedge (\bar{x}_1 \vee x_2 \vee \bar{y}_1 \vee y_2 \vee z_1 \vee z_2) \\
\wedge (\bar{u}_1 \vee u_2 \vee \bar{v}_1 \vee v_2 \vee \bar{x}_1 \vee \bar{x}_2) & \wedge (\bar{x}_1 \vee x_2 \vee \bar{y}_1 \vee y_2 \vee \bar{z}_1 \vee \bar{z}_2) \\
\wedge (v_1 \vee \bar{v}_2 \vee w_1 \vee \bar{w}_2 \vee y_1 \vee y_2) & \wedge (z_1 \vee \bar{z}_2) \\
\wedge (v_1 \vee \bar{v}_2 \vee w_1 \vee \bar{w}_2 \vee \bar{y}_1 \vee \bar{y}_2) & \wedge (\bar{z}_1 \vee z_2)
\end{array}$$

Figure 7.12. Pebbling contradiction in Figure 7.11b with XOR-substitution.

complexity theory, but it seems that Ben-Sasson [BS09] was first to raise the issue in the context of proof complexity.

It should be noted that this kind of trade-off questions need to be phrased slightly more carefully in order to be really interesting. As observed in [Nor09b], it is often possible to prove trade-off results simply by gluing together two formulas F and G over disjoint sets of variables which have different proof complexity properties, and then obtain a trade-off result from the fact that any proof of unsatisfiability has to refute either F or G . In order to eliminate such examples and obtain formulas that have inherent trade-off properties, we can additionally require that the formulas in question should be minimally unsatisfiable, i.e., that if any clause in the formula is removed, then the residual formula is satisfiable. For most of the trade-off results we consider here, the formulas are of this flavour. Also, it can be noted that for the strongest trade-off results discussed below, the trick of gluing together disjoint formulas cannot yield trade-offs with so strong parameters anyway.

The first trade-off result in proof complexity seems to have been obtained in [BS09], where a strong space-width trade-off was established. Namely, there are formulas for which

- there are refutations in width $O(1)$;
- there are also refutations in space $O(1)$;
- but optimizing one measure causes (essentially) worst-case behaviour for the other measure, in that the product of the width and the space for any refutation must be $\Omega(N/\log N)$ (where N is the size of the formula, and the number of variables is also $\Theta(N)$).

This holds for the “vanilla version” of the pebbling contradictions in Figure 7.11b

(if one again uses the graphs studied in [PTC77, GT78]). Using techniques from [Raz16a], this space-width trade-off was strengthened in [BN20] to show that there are formulas over n variables for which resolution refutations in width w require space almost n^w , i.e., far above the linear worst-case upper bound for space.

Regarding trade-offs between length and space, it was shown in [BSN11, BBI16, BNT13] that there are formulas that can be refuted in short length and also in small space, but where even slightly optimizing one of these complexity measures causes a dramatic blow-up for the other measure. One way of obtaining such results is to take DAGs with strong pebbling time-space trade-offs (as in, e.g., [CS80, CS82, LT82, Nor12]) and consider substituted pebbling formulas (as in Figure 7.12) over such DAGs. To give an example of such a result from [BSN11], there are CNF formulas F_n of size $\Theta(n)$ and constants $\kappa' \ll \kappa$ such that:

- The formulas F_n have resolution refutations in space $\kappa' \cdot n / \log n$.
- It is also possible to refute F_n in resolution in length $O(n)$ and space $O(n)$ simultaneously.
- However, any resolution refutation of F_n in space at most $\kappa \cdot n / \log n$ has length $\exp(n^{\Omega(1)})$.

Another example of formulas exhibiting length-space trade-offs are Tseitin formulas over long, narrow rectangular grids. Building on [BBI16], it was shown in [BNT13] that there are formula families $\{F_{n,w}\}$, with $1 \leq w \leq n^{1/4}$, which are of size $\Theta(n)$ and have the following properties:

- The formulas F_n have resolution refutations in space $O(w \log n)$.
- It is also possible to refute F_n in length $n^{O(1)}2^w$ and space $2^w + n^{O(1)}$.
- But for any resolution refutation of F_n in space s the refutation length is lower-bounded by $\left(\frac{2^{\Omega(w)}}{s}\right)^{\Omega\left(\frac{\log \log n}{\log \log \log n}\right)}$.

One interesting aspect of this second result is that if we choose $w = \kappa \log n$ for some suitably large constant κ , then it follows that short refutations of these formulas require even superlinear space.²⁶ That is, although we know that any CNF formula can be refuted in linear space, short refutations can require space that is much larger than this worst-case upper bound. (It can also be noted that both of the above results are actually slightly stronger than as described here, but we omit the full technical details in order to give simpler statements.)

What a length-space trade-off result like the two examples above says is that if a resolution is of short length, then at some point during the refutation a lot of space is being used. Such results do not a priori rule out, though, that this high space usage could be an isolated spike, and that most of the time the refutation uses very little space. A more recent work [AdRNV17] established more robust trade-offs between length and *cumulative space*, exhibiting formulas where any

²⁶To generate such Tseitin formulas, run *CNFgen* with the command line `cnfgen tseitin randomodd grid (N) (M)` for N scaling like $\kappa \log(M)$ for some suitably large constant κ . It appears, though, that these formulas are just too hard to be solved by CDCL SAT solvers regardless of memory management, and so even though these formulas could potentially provide a time-space trade-off for SAT solvers this is more of a theoretical notion than something that could be observed in practice.

short proof has to use a lot of space throughout the resolution refutation.

For length versus width, we know that short refutation length implies small refutation width by (7.9). The proof of this inequality works by transforming a given short refutation into a narrow one, but the length blows up exponentially in the process. Thapen [Tha16] showed that this blow-up is unavoidable by exhibiting formulas for which there exist resolution refutations in short length, but for which any refutation in width as guaranteed by (7.9) has to be exponentially long. These formulas are slightly tricky to describe, however, and so we do not do so here. A technical issue with Thapen’s result is that for all other trade-offs discussed above there are k -CNF formulas (for $k = O(1)$) that exhibit this behaviour, but Thapen’s formulas have clauses of logarithmic width. A resolution length-width trade-off result as in [Tha16] but for k -CNF formulas was recently obtained in [LNSS20]. We also want to mention in this context that in a very intriguing work Razborov [Raz16a] obtained doubly exponential length-width trade-offs in tree-like resolution (this is measured in the number of variables in the formulas, which have exponential size and polynomial width).

7.4.5. Theoretical Complexity Measures and Hardness in Practice

The next topic we wish to discuss is whether practical hardness for CDCL is in any way related to the complexity measures of resolution length, width, and space. One interesting observation in this context is that it follows from the results reviewed in Section 7.4 — if we “normalize” length by taking a logarithm, since it can be exponential in the formula size N whereas the worst-case upper bounds for width and space are linear — that for any k -CNF formula the inequalities

$$\log(\text{refutation length}) \lesssim \text{refutation width} \lesssim \text{refutation space} \quad (7.14)$$

hold. Thus, length, width, and space form an hierarchy of increasingly strict hardness measures. Let us briefly discuss the measures again in this light:

- We know that length provides a lower bound on CDCL running time²⁷ and that CDCL polynomially simulates resolution [PD11]. However, the results in [AM20, AR08, MPW19] suggest that short resolution proofs should be intractable to find in the worst case.
- Regarding width, searching for proofs in small width is apparently a well-known heuristic in the AI community, and [AFT11] proved that CDCL has the potential to run fast if such proofs exist. (Also, note that for formulas with resolution proofs in constant width the impossibility result in [AM20] does not apply, since for such formulas exhaustive search for small-width resolution proofs runs in polynomial time.)
- As to space, memory consumption is an important bottleneck for SAT solvers in practice, and space complexity results provide lower bounds on CDCL clause database size. One downside of this is that the bounds can be at most linear, and the solver would certainly use a linear amount of memory just to store the input. However, it is important to note that the

²⁷Again, except if some non-resolution-based preprocessing or inprocessing techniques happen to be very successful.

space lower bounds can be shown to hold even in a model where we only charge for clauses in addition to the input clauses, and since it is a proof complexity lower bound it applies even to solvers which would somehow magically know *exactly* which clauses they need to keep. It could therefore be argued that in reality probably much more memory than this bare minimum should be needed.

Are width or even space lower bounds relevant indicators of CDCL hardness? Or could it be true in practice that CDCL does essentially as well as resolution with respect to length/running time? These are not mathematically well-defined questions, since state-of-the-art CDCL solvers are moving targets, but perhaps it could still be possible to perform experiments and draw interesting conclusions? Such an approach was proposed in [ABLM08], and the paper [JMNv12] reports on what seems to have been the first systematic attempt to implement this program.

In view of the discussion above it seems too optimistic that length complexity should be a reliable indicator of CDCL hardness. The work in [JMNv12] was therefore focused on comparing width and space by running extensive experiments on formulas with constant width complexity (and linear length complexity) but varying space complexity to see whether running time correlated with space. These experiments produced lots of interesting data, but it seems fair to say that the results are inconclusive. For some families of formulas the correlation between running time and space complexity looks very nice, but for other formulas the results seem quite chaotic.

One comment worth making here is that the experiments in [JMNv12] only considered the worst-case space complexity of formulas. It might be that it would be more relevant to study formulas exhibiting length-space trade-offs as in [BSN11, BBI16, BNT13] or cumulative space lower bounds as in [AdRNV17]. Another issue that should be pointed out is that formulas with low width complexity and varying space complexity are hard to find — pretty much the only known examples are the substituted pebbling formulas discussed in Section 7.4.3. Thus, it is not even clear whether the experiments measured differences in width and space complexity or some other property specific to these particular formulas. This problem seems inherent, however. One cannot just pick arbitrary benchmark formulas and compute the width and space complexity for them before running experiments, since deciding width is EXPTIME-complete [Ber12] and deciding space appears likely to be PSPACE-complete.

7.4.6. Using Theory Benchmarks to Shed Light on CDCL Heuristics

Although modern CDCL solvers are routinely used to solve real-world instances with hundreds of thousands or even millions of variables, it seems fair to say that it is still very poorly understood how these solvers can be so unreasonably effective. As should be clear from the description in Section 7.3, the basic architecture of CDCL solvers is fairly simple, but the secret behind the impressive performance of state-of-the-art solvers lies in a careful implementation of the basic CDCL algorithm with highly optimized data structures, as well in the use of dozens of sophisticated heuristics.

Unfortunately, many of these heuristics interact in subtle ways, which makes

it hard to assess their relative importance. A natural approach to gain a better understanding would be to collect “real-world benchmarks” and run experiments on an instrumented CDCL solver with different parameter settings to investigate how they contribute to overall performance, as proposed in [LMS02, KSM11], or even to study the resolution proofs corresponding to the solver executions [Sim14]. It seems quite tricky to implement this idea in a satisfactory way, however. The problem is that set of available benchmarks is somewhat limited, and is also a highly heterogeneous collection in terms of formula properties. For this reason it turns out to be challenging to obtain statistically significant data that would admit drawing general conclusions.

The recent paper [EGCG⁺18] instead put forth the proposition that a better understanding of CDCL could be obtained by running experiments on carefully chosen theoretical benchmarks. By tuning various parameters, one can study what impact each heuristic has on performance and how this correlates with the theoretical properties of the formulas. An obvious objection is that it is very unclear why such a study of crafted benchmarks should have any practical relevance, but some arguments in favour of this approach given in [EGCG⁺18] are as follows:

- The benchmarks are *scalable*, meaning that one can generate “the same” formula for different sizes and study how performance scales as the instance size increases. (This simple but powerful idea was perhaps first articulated clearly in an applied SAT solving setting in [PV05].)
- The benchmarks are chosen to have different *extremal* properties in a proof-complexity-theoretic sense, meaning that they can be viewed as challenging benchmarks for different heuristics for variable decisions, clause deletions, restarts, et cetera.
- Finally, in contrast to most combinatorial benchmarks traditionally used in the *SAT competitions* [SAT], which are known to be very hard for resolution, the benchmarks in [EGCG⁺18] have been constructed so as to be *easy* in the sense of having very short resolution proofs of unsatisfiability that CDCL solvers could potentially find. In view of this, it can be argued that the performance of the solver provides a measure of the quality of the proof search and how it is affected by different heuristics.

Below follow the main conclusions reported in [EGCG⁺18] after comparing the empirical results with theoretical properties of the benchmarks:

1. Learned clauses are absolutely critical for performance. It is true that the information gathered while *learning* the clauses is important for guiding other heuristics, but this is not enough — the solvers crucially need to also *store* the clauses to realize the exponential increase in reasoning power from tree-like (DPLL-style) proofs to DAG-like resolution proofs.
2. While the mathematical question of whether restarts are just a helpful heuristic or are fundamentally needed for CDCL solvers to harness the full power of resolution remains wide open, the experimental results provide some circumstantial evidence that the latter might be the case. Also, *adaptive restarts* as in [AS12] often work markedly better than the fixed-interval so-called *Luby sequence* restarts in [ES04]. More support for this observa-

tion was provided very recently in [KN20].

3. For formulas inspired by time-space trade-off results, too aggressive clause erasure can incur a stiff penalty in running time also in practice. And when memory is tight, the *literal block distance (LBD)* heuristic [AS09] often does a particularly good job at identifying useful clauses.
4. For VSIDS variable decisions [MMZ⁺01] the choice of decay factor can sometimes be vitally important. It is not at all clear why, but one hypothesis is that this might be connected to whether the proof search needs to find DAG-like proofs or whether tree-like proofs are good enough. One can also see that VSIDS decisions can sometimes go badly wrong for easy but tricky formulas, which suggests that there is room for further improvements in variable selection heuristics. Somewhat disappointingly, [EGCG⁺18] did not find any support for the hypothesis that the newly proposed *learning-rate based branching (LRB)* heuristic [LGPC16] would be better than, or even distinguishable from, VSIDS.

It should perhaps be stressed that none of these findings should be considered to be a priori obvious, since proof complexity is inherently non-constructive whereas CDCL is about algorithmic proof search. Another point to emphasize is that the above findings are in no way rigorous results, but more a way of collecting circumstantial evidence for connections between theory and practice. Much work still remains to gain a more solid, mathematical understanding of when and why CDCL solvers work.

7.5. Algebraic Proof Systems

We now switch topics to *algebraic proof systems*, where formulas are translated to polynomials so that questions of satisfiability or unsatisfiability can be answered using algebraic methods of reasoning.

In what follows, we will let \mathbb{F} be a field (which will usually be the finite field $\text{GF}(2)$ with two elements $\{0, 1\}$ in practical SAT solving applications, but can be any field from the point of view of proof complexity) and $\vec{x} = \{x_1, \dots, x_n\}$ be a set of variables. Algebraic proof systems deal with polynomials in the polynomial ring over \mathbb{F} , i.e., multivariate polynomials in the variables x_1, \dots, x_n with coefficients from \mathbb{F} . A *monomial* m is a product of variables $m = \prod_{i=1}^n x_i^{e_i}$ for $e_i \in \mathbb{N}$. If $e_i \in \{0, 1\}$ for all i we say that the monomial is *multilinear* (this is sometimes also referred to as being *square-free*). A *term* $t = \alpha m$ is a monomial m multiplied by some field element $\alpha \in \mathbb{F}$.²⁸

7.5.1. Nullstellensatz

As our first example of an algebraic proof system we discuss *Nullstellensatz* introduced by Beame et al. [BIK⁺94]. A *Nullstellensatz refutation* of a set of polynomials $\mathcal{P} = \{p_i(\vec{x}) \mid i \in [m]\}$ in the polynomial ring $\mathbb{F}[\vec{x}]$ is a syntactic equality

²⁸We remark that the exact meaning of the terms “monomial” and “term” varies in the literature, but our choice of terminology here seems well in line with common usage in proof complexity.

$$\sum_{i=1}^m r_i(\vec{x}) \cdot p_i(\vec{x}) + \sum_{j=1}^n s_j(\vec{x}) \cdot (x_j^2 - x_j) = 1, \quad (7.15)$$

where r_i, s_j are also polynomials in $\mathbb{F}[\vec{x}]$. In algebraic language, what this shows is that the multiplicative identity 1 of the field \mathbb{F} lies in the polynomial ideal generated by $\mathcal{P} \cup \{x_j^2 - x_j \mid j \in [n]\}$. By Hilbert's Nullstellensatz, such a refutation (7.15) exists if and only if there is no common $\{0, 1\}$ -valued root for the set of polynomials \mathcal{P} .

Nullstellensatz can also be viewed as a proof system for certifying the unsatisfiability of CNF formulas. In this setting we first translate clauses of the form

$$C = \bigvee_{x \in P} x \vee \bigvee_{y \in N} \bar{y} \quad (7.16a)$$

to polynomials

$$p(C) = \prod_{x \in P} (1 - x) \cdot \prod_{y \in N} y. \quad (7.16b)$$

As a concrete example, $D = x \vee y \vee \bar{z}$ gets translated to $p(D) = (1 - x)(1 - y)z = z - yz - xz + xyz$.²⁹ Then a Nullstellensatz refutation of $\{p(C_i) \mid i \in [m]\}$ can be viewed as a refutation of the CNF formula $F = \bigwedge_{i=1}^m C_i$. This is so since an assignment to the variables in F (where we think of 1 as true and 0 as false) is satisfying precisely if all the polynomials $\{p(C_i) \mid i \in [m]\}$ vanish, i.e., evaluate to 0, and a Nullstellensatz refutation rules out that such a satisfying assignment exists.

The *size* of a Nullstellensatz refutation is defined to be the total number of monomials encountered when all products of polynomials are expanded out as linear combinations of monomials. To be more precise, let $mSize(p)$ denote the number of monomials in a polynomial p written as a linear combination of monomials (so that for our example clause $D = x \vee y \vee \bar{z}$ above we have $mSize(p(D)) = 4$). Then the size of a Nullstellensatz refutation of the form (7.15) is

$$\sum_{i=1}^m mSize(r_i(\vec{x})) \cdot mSize(p_i(\vec{x})) + \sum_{j=1}^n 2 \cdot mSize(s_j(\vec{x})). \quad (7.17)$$

We remark that this is not the only possible way of measuring size. It can be noted that the definition (7.17) is quite wasteful in that it forces us to represent the proof in a very inefficient way. Other papers in the so-called *semialgebraic* proof complexity literature, such as [GHP02b, KI06, DMR09], instead define size

²⁹Note that in this translation we are thinking of 1 as *true* and 0 as *false*, which is standard in proof complexity. It can be argued, though, that in the specific context of algebraic proof systems a more natural convention is to flip the values and identify 0 with *true* and 1 with *false*, just as a clause evaluating to true is identified with the corresponding polynomial evaluating to 0. If we adopt this flipped convention, then $x \vee y \vee \bar{z}$ would be translated to $xy(1 - z) = xy - xyz$. There is no clear consensus on this matter in the algebraic proof complexity literature, however, and so for simplicity we will identify 0 with *false* and 1 with *true* throughout this survey to be consistent with how other proof systems view the constants 0 and 1.

in terms of the polynomials in isolation, more along the lines of

$$\sum_{i=1}^m (m\text{Size}(r_i(\vec{x})) + m\text{Size}(p_i(\vec{x}))) + \sum_{j=1}^n (m\text{Size}(s_j(\vec{x})) + 2) \quad (7.18)$$

or as the bit size or “any reasonable size” of the representation of all polynomials $r_i(\vec{x}), p_i(\vec{x}), s_j(\vec{x})$. However, our definition (7.17) is consistent with the general definition of size for so-called algebraic and semialgebraic proof systems in [ALN16, Ber18, AO19], and, in particular, matches the size definition in the other algebraic proof systems that will be discussed later in this section.³⁰

A much more well-studied measure for Nullstellensatz than size is *degree*, which we define as $\max\{\deg(r_i(\vec{x}) \cdot p_i(\vec{x})), \deg(s_j(\vec{x}) \cdot (x_j^2 - x_j))\}$. In order to prove a lower bound d on Nullstellensatz degree for refuting \mathcal{P} , one can construct a d -*design*, which is a map D from degree- d polynomials in $\mathbb{F}[\vec{x}]$ to \mathbb{F} such that

1. D is linear, i.e., $D(\alpha p + \beta q) = \alpha D(p) + \beta D(q)$ for $\alpha, \beta \in \mathbb{F}$;
2. $D(1) = 1$;
3. $D(rp) = 0$ for all $p \in \mathcal{P}$ and $r \in \mathbb{F}[\vec{x}]$ such that $\deg(rp) \leq d$;
4. $D(x^2s) = D(xs)$ for all $s \in \mathbb{F}[\vec{x}]$ such that $\deg(s) \leq d - 2$.

Designs provide a characterization of Nullstellensatz degree in that there is a d -design for \mathcal{P} if and only if there is no Nullstellensatz refutation of \mathcal{P} in degree d (this is clearly spelled out in [Bus98] but is mentioned there to have been known before). The only-if direction is clear — applying D to a purported Nullstellensatz refutation of the form (7.15) yields 0 on the left-hand side but 1 on the right-hand side, which is a contradiction. The if-direction requires more work, but follows from linear programming duality.

Lower bounds on Nullstellensatz degree have been proven for formulas encoding combinatorial principles such as the pigeonhole principle [BCE⁺98] and pebbling contradictions [BOCIP02], which have already been described in previous sections, and also for other formulas encoding the *induction principle* [BP98b], *house-sitting principle* [CEI96, Bus98], and *matching* [BIK⁺97], most of which we will not discuss further in this survey.

It seems fair to say that research in algebraic proof complexity soon moved on from Nullstellensatz to stronger systems such as *polynomial calculus* [CEI96], which we will discuss shortly. Briefly (and somewhat informally), the difference between Nullstellensatz and polynomial calculus is that in the latter proof system the proof that 1 lies in the ideal generated by $\mathcal{P} \cup \{x_j^2 - x_j \mid j \in [n]\}$ can be constructed dynamically by a step-by-step derivation, which sometimes makes it possible to decrease both degree and size significantly (while, in the opposite direction, the many lower bounds on degree and size later established for

³⁰We remark that in the end the difference between these two theoretical size measures is not too important, since the two measures (7.17) and (7.18) are at most a square apart, and when measuring size in proof complexity we typically focus on the distinction between polynomial and superpolynomial. In addition, and more importantly, when we are dealing with k -CNF formulas with $k = O(1)$, as we are mostly doing in this survey, then the two size definitions are the same up to a constant factor 2^k . We refer the reader to Section 2.4 in [AH19] for a more detailed discussion of the definition of proof size in algebraic and semialgebraic proof systems.

polynomial calculus, as discussed in Section 7.5.2, certainly apply also to Nullstellensatz). The Nullstellensatz proof system has seen somewhat of a revival in a recent line of works [RPRC16, PR17, PR18, GKRS19, dRMN⁺20] showing that Nullstellensatz degree lower bounds can be “lifted” to lower bounds in stronger computational models. We will briefly discuss lifting in Section 7.7.1 and then see some examples of these ideas can be used in proof complexity in the rest of Section 7.7. The size complexity measure for Nullstellensatz has also received attention in recent papers such as [Ber18, AO19, dRNM19].

When proving lower bounds for algebraic proof systems it is often convenient to consider a *multilinear* setting where refutations are presented in the quotient ring $\mathbb{F}[\vec{x}]/\{x_j^2 - x_j \mid j \in [n]\}$. Since the Boolean axioms $x_j^2 - x_j$ are no longer needed, the refutation (7.15) can be written simply as

$$\sum_{i=1}^m r_i(\vec{x}) \cdot p_i(\vec{x}) = 1, \quad (7.19)$$

where we assume that all results of multiplications are implicitly multilinearized. It is clear that any refutation on the form (7.15) remains valid after multilinearization, and so the size and degree measures can only decrease in a multilinear setting.

7.5.2. Polynomial Calculus

The proof system *polynomial calculus* (*PC*) was introduced in [CEI96] to model Gröbner basis computations (and was originally called the “Gröbner basis proof system,” although by now the name “polynomial calculus” is firmly established). As in Nullstellensatz, the setup is that we have a set of polynomials \mathcal{P} over variables x_1, \dots, x_n , where the polynomial coefficients live in some field \mathbb{F} . The goal is to prove that the polynomials $\mathcal{P} \cup \{x_j^2 - x_j \mid j \in [n]\}$ have no common root. When operating with CNF formulas, we first translate the clauses to polynomials using the transformation from (7.16a) to (7.16b).

It is important to observe that, from an algebraic point of view, the variables can take as values any elements in the field \mathbb{F} . Hence, we need to add constraints enforcing 0/1 assignments. We are also allowed to take linear combinations of polynomials, or to multiply a polynomial by any monomial, since any common root for the original polynomials is preserved under such operations. This leads to the following set of derivation rules for polynomial calculus:

$$\text{Boolean axioms} \quad \frac{}{x_j^2 - x_j} \quad (7.20a)$$

$$\text{Linear combination} \quad \frac{p}{\alpha p + \beta q} \quad (\alpha, \beta \in \mathbb{F}) \quad (7.20b)$$

$$\text{Multiplication} \quad \frac{p}{mp} \quad (m \text{ any monomial}) \quad (7.20c)$$

A polynomial calculus refutation of \mathcal{P} also allows polynomials from \mathcal{P} as axioms; the refutation ends when 1 has been derived, showing that the polynomial equations have no common root, or equivalently when \mathcal{P} is an translation of a CNF

formula, that this formula is unsatisfiable. The polynomial calculus proof system is sound and complete, not only for CNF formulas but also for inconsistent systems of polynomial equations in general. As for Nullstellensatz, we can consider the setting where all polynomials are multilinear, because any higher powers of variables can always be eliminated using the Boolean axioms (7.20a).

To define the complexity measures of *size*, *degree*, and *space*, we write out the polynomials in a refutation as linear combinations of monomials. Then the *size* of a refutation, which is the analogue of resolution length, is the total number of monomials in the refutation (counted with repetitions), the *degree*, corresponding to resolution width, is the largest degree of any monomial in it, and the (*monomial*) *space*, which is the analogue of resolution (clause) space, is the maximal number of monomials in memory at any point during the refutation (again counted with repetitions). One can also define a *length* measure for polynomial calculus, which is the number of derivation steps, but this can be exponentially smaller than the size, which is the more relevant measure to study here.³¹

The representation of a clause $\bigvee_{i=1}^n x_i$ as a polynomial in polynomial calculus is $\prod_{i=1}^n (1 - x_i)$, which means that the number of monomials is exponential in the clause width. This problem arises only for positive literals, however — a large clause with only negative literals is translated to a single monomial. To get a cleaner and more symmetric treatment, in [ABSRW02] the proof system *polynomial calculus (with) resolution*, or *PCR* for short, was introduced. The idea is to add an extra set of parallel formal variables x'_j , $j \in [n]$, sometimes referred to as *twin variables*, so that positive and negative literals can both be represented in an efficient fashion.

Lines in a PCR proof are polynomials over the ring $\mathbb{F}[x_1, x'_1, \dots, x_n, x'_n]$, where as before \mathbb{F} is some field. We have all the axioms and rules of polynomial calculus plus the axiom

$$\text{Negation} \quad \frac{}{x_j + x'_j - 1} . \quad (7.20d)$$

Size, length, and degree are defined as for polynomial calculus, and the (monomial) space of a PCR refutation is again the maximal number of monomials in any configuration counted with repetitions.

It is important to understand that from an algebraic point of view the variables x_j and x'_j are completely independent. The point of the negation rule, therefore, is to force x_j and x'_j to take opposite values in $\{0, 1\}$, so that they respect the intended meaning of negation. It is worth noting that in actual Gröbner basis calculations one would not have both x_j and x'_j , so the introduction of “twin variables” is just to get a nicer proof system from a theoretical point of view. Our example clause $D = x \vee y \vee \bar{z}$ is rendered as $x'y'z$ in PCR.

One gets the same degree bounds for polynomial calculus resolution as in polynomial calculus, (just substitute $1 - x$ for x'), but one can potentially avoid an exponential blow-up in size measured in the number of monomials (and thus also for space). There are k -CNF formulas for which PCR is exponentially more

³¹In fact, if we consider the multilinear setting, where there are no Boolean axioms and instead multiplication is defined to return the multilinearized result, then it is not hard to show that any CNF formula with m clauses over n variables can be refuted in polynomial calculus in length $O(mn)$. See, e.g., [MN15] for a proof of this fact.

$$\begin{array}{c}
 \frac{x \vee \bar{y} \vee z \quad \bar{y} \vee \bar{z}}{x \vee \bar{y}} \\
 \text{(a) Resolution step.}
 \end{array}
 \qquad
 \begin{array}{c}
 \frac{\frac{\mathbf{yz}}{x'yz} \quad \frac{z' + z - 1}{x'yz' + x'yz - x'y}}{\mathbf{x'yz'}}}{\mathbf{x'y}} \\
 \text{(b) Corresponding PCR derivation.}
 \end{array}$$

Figure 7.13. Example of simulation of resolution step by PCR.

powerful than PC with respect to size [dRLM⁺20]. In PCR, monomial space is a natural generalization of clause space since every clause translates into a monomial as just explained in the example above.

Clearly, PC and PCR are very closely related, and in what follows we will sometimes be a bit sloppy and write just “polynomial calculus” when the distinction between the two is not important. We write “polynomial calculus resolution” or “PCR” to highlight when a claim only holds for polynomial calculus with twin variables for positive and negative literals.

7.5.3. Nullstellensatz, Polynomial Calculus, and Resolution

Polynomial calculus resolution can simulate resolution efficiently with respect to length/size, width/degree, and space simultaneously simply by mimicking refutations step by step. This means that all worst-case upper bounds for resolution immediately carry over to PCR. For an example of how this works, see the simulation of the resolution step in Figure 7.13a by the derivation in Figure 7.13b, where the polynomials corresponding to the simulated clauses are in boldface.

Polynomial calculus can be strictly stronger than resolution with respect to size and degree. For instance, over $\text{GF}(2)$ it is not hard to see that Tseitin formulas can be refuted in size $O(N \log N)$ and degree $O(1)$ by doing Gaussian elimination. Another example are the onto functional pigeonhole principle (FPHP) formulas (7.7a)–(7.7d), which were shown to be easy in [Rii93]. It remains open whether such separations can be found also for space, however.

Open Problem 7.5. Prove (or disprove) that polynomial calculus resolution is strictly stronger than resolution with respect to space.³²

The proof systems Nullstellensatz and polynomial calculus without twin variables are *incomparable* to resolution with respect to size/length — there are formulas for which both Nullstellensatz and PC are exponentially more efficient than resolution, and other formulas for which resolution is exponentially better.

7.5.4. Size and Degree for Nullstellensatz and Polynomial Calculus

A lot of what is known about length versus width in resolution carries over to size versus degree in polynomial calculus, whereas Nullstellensatz is mostly different.

³²A constant-factor separation is claimed in [ABSRW02], but this result is for the slightly different monomial space measure where every distinct monomial is only charged once but an arbitrary number of copies of this monomial (in different polynomials) can be had for free.

It is not hard to show that for both Nullstellensatz and polynomial calculus upper bounds on degree imply upper bounds on size, in the sense that if a CNF formula over n variables can be refuted in degree d , then such a refutation can be carried out in size $n^{O(d)}$. This is qualitatively similar to the bound for resolution, although the arguments are a bit more involved. Just as for resolution, this upper bound has been proven to be tight up to constant factors in the exponent for polynomial calculus [ALN16], and it follows from [DLLMO09a] that this also holds for Nullstellensatz.

In the other direction, a lower bound on size in terms of degree exactly analogous to the size-width bound (7.9) for resolution [BSW01] holds also for polynomial calculus, as shown in [IPS99]. For Nullstellensatz it is not possible to obtain lower bounds on size from degree lower bounds in this way, and pebbling formulas provide a counter-example [BOCIP02].

Interestingly, the paper [IPS99] is a precursor to [BSW01], and although it was far from obvious at the time it turns out that one can run exactly the same proof for both resolution and polynomial calculus. As for resolution, the ordering principle formulas in (7.11a)–(7.11d) witness the optimality of this size-degree lower bound, as shown by [GL10b]. As for resolution, almost all size lower bounds are derived via degree lower bounds.

The basic tool for proving polynomial calculus degree lower bounds is that of R -operators, which are analogues of the d -designs used for Nullstellensatz. As proposed in [Raz98], the idea is to give an overapproximation of what polynomials can be derived in degree at most d by defining an operator R on multilinear polynomials such that all degree- d consequences of the axioms are contained in the set $\{p \mid R(p) = 0\}$. The degree lower bound then follows by showing that $R(1) \neq 0$.

Formally, let $d \in \mathbb{N}^+$ be a positive integer. Suppose that there exists a linear operator R on a set \mathcal{P} of (multilinear) polynomials of degree at most d with the following properties:

1. $R(1) \neq 0$.
2. $R(f) = 0$ for all axioms $f \in \mathcal{P}$.
3. For every term t with $\text{Deg}(t) < d$ and every variable x it holds that $R(xt) = R(xR(t))$.

Then any polynomial calculus refutation of \mathcal{P} requires degree strictly greater than d . (Note that here we can restrict our attention to PC without twin variables for literals, since the degree measure is the same for PC and PCR.)

The proof of this claim is not hard. The basic idea is that R will map all axioms to 0 by property 2, and further derivation steps in degree at most d will yield polynomials that also map to 0 by the linearity of R and property 3 (where we use that without loss of generality we can implement multiplication by a monomial by multiplying by all variables in it one by one). But then property 1 implies that no derivation in degree at most d can reach 1 and establish contradiction. However, constructing such operators to obtain degree lower bounds seems much harder than proving resolution width lower bounds, and the technical machinery is much less well developed.

With the exception of Tseitin formulas and onto functional pigeonhole prin-

ciple (FPHP) formulas, all the formulas discussed in detail in Section 7.4.1 are equally hard also with respect to polynomial calculus size, which can be shown via degree lower bounds arguments:

- Hardness of the standard CNF encoding (7.7a)–(7.7b) of pigeonhole principle formulas³³ follows from [AR03], with some earlier work on other non-CNF encodings in [Raz98, IPS99]. The proof in [AR03] works also if onto clauses (7.7d) are added, and more recently it was shown in [MN15] that FPHP formulas with clauses (7.7a)–(7.7c) are also hard (whereas with both onto and functionality axioms added the formulas are easy, as noted above).
- Strong degree and size lower bounds on random k -CNF formulas were shown in [BSI99] for polynomial calculus over fields of characteristic distinct from 2, and lower bounds in any characteristic including 2 were established by different methods in [AR03].
- For the subset cardinality formulas in Figure 7.10, polynomial calculus degree and size lower bounds were obtained in [MN14].
- Also, “Tseitin formulas with the wrong modulus” are hard — one can define Tseitin-like formulas encoding counting modulo primes q , and such formulas are hard over fields of characteristic $p \neq q$ [BGIP01, AR03].

We also wish to discuss briefly two formula families for which we currently do not know how to prove lower bounds on polynomial calculus degree or size. Recall that a *legal k -colouring* of an undirected graph $G = (V, E)$ is a mapping $\chi : V \rightarrow [k]$ such that for every edge $(u, v) \in E$ it holds that $\chi(u) \neq \chi(v)$. The *k -colouring formula* for a graph G is the set of polynomials

$$\sum_{j=1}^k x_{v,j} - 1 \qquad v \in V(G), \qquad (7.21a)$$

$$x_{v,j}x_{v,j'} \qquad v \in V(G), j \neq j' \in [k], \qquad (7.21b)$$

$$x_{u,j}x_{v,j} \qquad (u, v) \in E(G), j \in [k], \qquad (7.21c)$$

with the intended interpretation that $x_{v,j} = 1$ if vertex v has colour $\chi(v) = j$. It is clear that these polynomials have a common $\{0, 1\}$ -valued root if and only if there exists a legal k -colouring, in which case we say that G is *k -colourable*. We wish to prove lower bounds on the complexity of disproving this formula for graphs G that are *not* k -colourable. (We remark that we can also represent (7.21a)–(7.21c) as a CNF formula by rewriting the only non-clausal constraints (7.21a) as the clause $\bigvee_{j=1}^k x_{v,j}$, but the exact representation does not matter for this discussion.)

For resolution, it was shown in [BCMM05] that if one samples a graph G at random with appropriate edge probabilities, then with overwhelming probability G is not k -colourable, but resolution still requires linear width, and hence exponential length, to refute the k -colouring formula over G .³⁴ This gives a very strong

³³Here a twist is needed since these formulas have high initial degree, but we will not go into this. The most elegant solution is to consider so-called graph PHP formulas as discussed in, e.g., [BSW01, MN15].

³⁴CNF versions (in the standard DIMACS format used by SAT solvers) of 3-colouring formulas over n -vertex random graphs with appropriate parameters can be obtained with

Figure 7.14. Example of even colouring (EC) formula (satisfiable instance).

average-case lower bound over a whole distribution of inputs. For polynomial calculus, all that is known is that one can construct specific worst-case instances that are exponentially hard [LN17], but we cannot yet rule out that k -colouring would be an easy problem for Gröbner basis computations in an average-case setting (although it seems absurd that this would be the case).

Open Problem 7.6. Prove linear lower bound on polynomial calculus degree, and hence exponential lower bounds on size, for k -colouring formulas over randomly sampled graphs analogously to the average-case lower bound for resolution in [BCMM05].

Another quite intriguing family of benchmark formulas are the *even colouring (EC) formulas* constructed by Markström [Mar06] (see Figure 7.14 for an example). These formulas are defined over connected graphs with all vertices having even degree. For a fixed graph $G = (V, E)$ we consider every edge $e \in E$ to be a variable and let the formula consist of the (CNF encodings of) the constraints

$$\sum_{e \in E(v)} e = \deg(v)/2 \quad v \in V, \quad (7.22)$$

where $E(v)$ denotes the set of edges incident to v . The constraints (7.22) require that the edges should be labelled 0/1 in such a way that for every vertex v in V the number of 0-edges and 1-edges incident to v is equal. If the total number of edges in the graph is even, then this formula is satisfiable — since the graph has all vertices of even degree it also has an Eulerian cycle, and we can fix any such cycle and label every second edge 0 and 1, respectively. If the number of edges is odd, however, then summing up (7.22) over all vertices yields $2 \cdot \sum_{e \in E(G)} e = |E(G)|$ which is clearly a contradiction since an odd number cannot be divisible by 2.

the tool *CNFgen* [LENV17, CNF] using the command line `cnfgen kcolor 3 gnp <n> <p>` for $p = 5/(n - 1)$. These formulas start getting quite challenging for SAT solvers around $n = 800$. (It should be noted that this edge density is slightly too low to get the theoretical guarantees from [AM99] that the graphs are not 3-colourable, and thus that the formulas are unsatisfiable, asymptotically almost surely, but empirically this seems to hold. Choosing $p = 5.5/(n - 1)$ should be enough to also get theoretical guarantees, but yields more overconstrained formulas, meaning that n has to be chosen larger before the exponential hardness manifests itself.)

If the graph G is a good enough expander graph, then a fairly standard extension of the techniques in [BSW01] can be used to prove that the even colouring formula over G requires linear width, and hence also exponential length, for resolution.³⁵ However, a moment of reflection reveals that over $\text{GF}(2)$ it is easy to derive polynomials $\sum_{e \in E(v)} e - \deg(v)/2$ from (7.22), and summing these polynomials for all $v \in V$ yields $2 \cdot \sum_{e \in E(G)} e - |E(G)| = 1$ (where the calculations are in $\text{GF}(2)$). Thus, even colouring formulas are easy over $\text{GF}(2)$, or more generally over any field of characteristic 2.

Open Problem 7.7. Are even colouring formulas over expander graphs hard for polynomial calculus over fields of characteristic distinct from 2?

7.5.5. Polynomial Calculus Space

We next turn to a discussion of space complexity. This measure does not make too much sense for Nullstellensatz, since refutations of the form (7.15) are presented in “one shot” and it is hard to talk about any intermediate results. Thus, our discussion of space will focus on polynomial calculus.

Recall that for resolution we measure space as the number of clauses in memory, and since clauses turn into monomials in polynomial calculus resolution the natural analogue here is monomial space (in our discussion of space we are always focusing on PCR, since this proof system allows for a more efficient representation of disjunctive clauses as discussed above). The first monomial space lower bounds were shown for pigeonhole principle formulas in [ABSRW02]. These formulas have wide axioms, however, and if one applies the 3-CNF conversion from (7.1a) to (7.1b) the lower bound proof breaks down.

Monomial space lower bounds for formulas of bounded width were proven only in [FLN⁺15] for an obfuscated 4-CNF version of PHP formulas. This was followed by optimal, linear lower bounds for random 4-CNF formulas [BG15], and then for Tseitin formulas over expanders but with the added assumptions that either these graphs are sampled randomly or one adds two copies of every edge to get a multigraph [FLM⁺13].³⁶ Somewhat intriguingly, none of these papers could show any nontrivial lower bounds for any 3-CNF formulas. This barrier was finally overcome by [BBG⁺17], where optimal lower bounds for random 3-CNF formulas were established. However, the following open problems show that we still do not understand polynomial calculus space very well.

Open Problem 7.8. Prove linear lower bounds on polynomial calculus space for refutations of Tseitin formulas over d -regular expander graphs for $d = 3$ or even $d > 3$ using no other assumptions than expansion only.

Open Problem 7.9. Prove that pigeonhole principle formulas require large monomial space in polynomial calculus even when converted to 3-CNF.

³⁵To generate unsatisfiable even colouring formulas over 6-regular random graphs, which are expanding asymptotically almost surely, one can use *CNFgen* with the command line `cnfgen ec gnd <n> 6` for the number of vertices n in the graph chosen odd. For CDCL solvers, these formulas become noticeably hard around $n = 21$.

³⁶It is worth noting that these space lower bounds hold for any characteristic, so although Tseitin formulas have small-size refutations over $\text{GF}(2)$, such refutations still require large space.

Another intriguing question is whether an analogue of the fact that resolution width is a lower bound for resolution space (7.12) holds also for polynomial calculus.

Open Problem 7.10. Is it true that $\text{space} \geq \text{degree} - O(1)$ for k -CNF formulas in polynomial calculus?

For a long time, essentially nothing was known about this problem, except that the work [FLM⁺13] made what can be described as some limited progress by showing that if a formula requires large resolution width (which is a necessary, but not sufficient, condition for high degree), then the XOR-substituted version of the formula (as in (7.13a)–(7.13c)) requires large monomial space. When applied to Tseitin-like formulas over expander graphs, this result yields an optimal separation of space and degree. Namely, it follows that these formulas can be refuted in degree $O(1)$ but require space $\Omega(N)$. To obtain such separations we have to commit to a finite characteristic p of the underlying field, however, and the formulas encoding counting mod p will separate space and degree only for fields of this characteristic. It would be nice to get a separation that would work in any characteristic, and the candidate formulas to obtain such a result readily present themselves.

Open Problem 7.11. Prove (or disprove) that XOR-substituted pebbling formulas as in Figure 7.12 require monomial space lower-bounded by the pebbling space of the underlying DAG (which if true would yield an essentially optimal space-degree separation independent of the field characteristic).

Recently, some quite exciting news regarding Open Problem 7.10 was announced [GKT19], namely that the PCR monomial space of refuting a formula is lower-bounded by the square root of the resolution refutation width (which, as mentioned above, is stronger than the corresponding lower bound in terms of degree, since resolution width can be much larger than polynomial calculus degree). This also implies lower bounds for the formulas mentioned in Open Problems 7.8 and 7.9 and provides a separation between degree and space that is independent of the characteristic as called for in Open Problem 7.11, although all of these results are off by a square root from what would have been expected. It is not clear whether the bounds obtained in this way are tight or not.

7.5.6. Trade-off Results for Nullstellensatz and Polynomial Calculus

When it comes to trade-offs in polynomial calculus we again recognize most of the picture from resolution, but there are also some differences. Here is a summary of what is known (where the upper bounds in all of the results hold for PC, i.e., polynomial calculus without twin variables, whereas the lower bound apply also for the PCR proof system with twin variables):

- For space versus degree in polynomial calculus we know strong, essentially optimal trade-offs from [BNT13], and the formulas exhibiting such trade-offs are the same vanilla pebbling contradictions as for resolution (for which we get exactly the same bounds as in Section 7.4.4). However, it is *not* known whether a result analogous to [BN20] holds, i.e., whether polynomial calculus refutations in small degree can require superlinear space.

- The paper [BNT13] also showed strong size-space trade-offs, and again the formulas used are substituted pebbling contradictions over appropriate DAGs and Tseitin formulas over long, narrow grids. Here there is some loss in parameters as compared to resolution, however, which seems to be due to limitations of the proof techniques rather than to actual differences in formula behaviour. Also, the Tseitin formula trade-off results do not hold over fields of characteristic 2. Overall, though, the size-space trade-offs are very similar to the length-space trade-offs for resolution discussed in Section 7.4.4, and we omit the details.
- The size blow-up in [IPS99] when degree is decreased is necessary, and can be obtained for k -CNF formulas of constant width $k = O(1)$, by using the same ideas as in [Tha16] and then adding a number of extra tweaks to make the argument go through in polynomial calculus as shown in [LNSS20].

In view of the above, we have two final open problems about polynomial calculus that we want to highlight in this section.

Open Problem 7.12. Establish size-space trade-offs for polynomial calculus that hold regardless of the characteristic of the underlying field (in contrast to [BNT13]).

Open Problem 7.13. Are there formulas over n variables for which polynomial calculus refutations in degree d require monomial space almost n^d , or at least $\omega(n)$?

We wish to mention also that for the weaker Nullstellensatz proof systems size-degree trade-offs were recently shown in [dRNMR19]. For instance, there is a family of 3-CNF formulas $\{F_n\}_{n=1}^{\infty}$ of size $\Theta(n)$ such that:

1. There is a Nullstellensatz refutation of F_n in degree $O(\sqrt[6]{n} \log n)$.
2. There is a Nullstellensatz refutation of F_n of nearly linear size $O(n^{1+\epsilon})$ and degree $O(\sqrt[3]{n} \log n)$.
3. Any Nullstellensatz refutation of F_n in degree at most $\sqrt[3]{n}$ must have exponential size.

The formulas F_n are vanilla pebbling contradictions without substitution generated from suitably chosen graphs.

7.5.7. Algebraic SAT Solving

We conclude this section with a(n all too) brief discussion of algebraic SAT solving. There seems to have been quite some excitement, at least in the theory community, about the Gröbner basis approach to SAT solving after the paper [CEI96] appeared. However, the hoped for improvement in performance from this method failed to materialize in practice. Instead, the CDCL revolution happened. . .

Some Gröbner basis SAT solvers have been developed, the most notable example perhaps being *PolyBoRi* [BD09, BDG⁺09], but these solvers do not seem competitive with resolution-based solvers (and, sadly, *PolyBoRi* is no longer maintained). Some SAT solvers such as *March* [HvM06] and *CryptoMiniSat* [Cry] successfully implement Gaussian elimination [HvM05], but this is only very limited form of polynomial calculus reasoning.

Is it harder to build good algebraic SAT solvers than CDCL solvers? Or is it just that too little work has been done? (Witness that it took over 40 years for resolution-based SAT solvers to become really efficient.) Or is it perhaps a little bit of both? It can be noted in this context that it was recently shown that efficient proof search is NP-hard for Nullstellensatz and polynomial calculus [dRGN⁺20] (strengthening an earlier paper [GL10a]) — i.e., these proof systems are not automatable — but it is not clear that this should be an obstacle in practice, since very successful SAT solvers have been built on top of resolution despite the non-automatability of this proof system [AM20].

Whatever the answer is to these questions, it seems clear that one needs to find some kind of shortcut in order to use Gröbner bases for efficient SAT solving. A full Gröbner basis computation does too much work, since it allows us not only to decide satisfiability but also to read off the number of satisfying assignments, which is widely believed to be a strictly harder problem.

This slightly downbeat discussion of algebraic SAT solving should not be taken to mean that algebraic methods cannot be used for successfully solving hard combinatorial problems, however. To give a positive example, in the sequence of papers [DLLMM08, DLLMO9b, DLLMM11], a body of work that was recognised with the *INFORMS Computing Society Prize 2010*, the authors solve graph colouring problems (with great success) essentially by constructing Nullstellensatz certificates of non-colourability. Hence, for some NP-complete problems it seems that even lowly Nullstellensatz can be a quite powerful approach.

Another very interesting line of work is exemplified by the papers [RBK17, RBK18, KBK19] using Gröbner bases computations to attack the challenging problem of verifying multiplier circuits. As a part of this work, the authors develop a formal proof logging system to certify correctness, called *practical algebraic calculus (PAC)*, and this proof system is nothing other than polynomial calculus (but with the field \mathbb{F} chosen to be the rational numbers \mathbb{Q} rather than a finite field).

7.6. Cutting Planes and Pseudo-Boolean Solving

The *cutting planes* proof system [CCT87], which formalizes the integer linear programming algorithm in [Gom63, Chv73] and underlies so-called *pseudo-Boolean (PB) solvers*, operates with linear inequalities over the reals with integer coefficients. To reason about CNF formulas in cutting planes, the disjunctive clauses are translated to linear inequalities, which are then manipulated to derive a contradiction. Thus, the question of Boolean satisfiability is reduced to the geometry of polytopes over the real numbers. Just as algebraic proof systems can deal not only with translated CNF formulas but with arbitrary sets of polynomials, cutting planes can operate on arbitrary 0-1 integer linear constraints, which we will also refer to as *pseudo-Boolean constraints*. A *pseudo-Boolean formula* is a set of pseudo-Boolean constraints (also known as a 0-1 *integer linear program*).

In the standard proof complexity setting, we use only positive literals (un-negated variables) and identify \bar{z} with $1 - z$ so that, for instance, the clause $x \vee y \vee \bar{z}$ gets translated to $x + y + (1 - z) \geq 1$, or $x + y - z \geq 0$ after we have moved all integer constants to the right-hand side. However, in order to give a description of

cutting planes that is helpful also when we want to reason about pseudo-Boolean solvers, and in order to get compact notation, it is more useful to keep negated literals as variables in their own right, and to insist that all inequalities consist of linear combinations of (positive or negative) literals with only non-negative coefficients.³⁷ It will also be convenient here to use the notation x^σ , $\sigma \in \{0, 1\}$, mentioned in Section 7.2, where we recall that $x^1 = x$ and $x^0 = \bar{x}$. With this notation, assuming that our set of variables is $\{x_1, \dots, x_n\}$ we can write all linear constraints in *normalized form*

$$\sum_{i \in [n], \sigma \in \{0, 1\}} a_i^\sigma x_i^\sigma \geq A, \quad (7.23)$$

where for all $i \in [n]$ and $\sigma \in \{0, 1\}$ it holds that $a_i^\sigma \in \mathbb{N}$ and $\min\{a_i^0, a_i^1\} = 0$ (the latter condition specifies that variables occur only with one sign in any given inequality), and where $A \in \mathbb{N}^+$ (this constant term is often referred to as the *degree of falsity*, or just *degree*, in an applied pseudo-Boolean solving context). In what follows, all expressions of the type (7.23) are supposed to be in normalized form, and all sums are assumed to be taken over all combinations of $i \in [n]$ and $\sigma \in \{0, 1\}$ except as specified under the summation sign.

If the input is a CNF formula F we just view every clause $C \in F$ of the form

$$C = x_1^{\sigma_1} \vee x_2^{\sigma_2} \vee \dots \vee x_w^{\sigma_w} \quad (7.24a)$$

as a linear constraint

$$x_1^{\sigma_1} + x_2^{\sigma_2} + \dots + x_w^{\sigma_w} \geq 1. \quad (7.24b)$$

That is, a disjunctive clause is simply a constraint on the form (7.23) where $a_i^\sigma \in \{0, 1\}$ and $A = 1$ (in particular, our example clause $x \vee y \vee \bar{z}$ now becomes $x^1 + y^1 + z^0 \geq 1$). Hence, CNF formulas can be viewed as a special case of pseudo-Boolean formulas).

Pseudo-Boolean constraints can be exponentially more concise than CNF, as is shown by a comparison of the constraint

$$x_1 + x_2 + x_3 + x_4 + x_5 + x_6 \geq 3 \quad (7.25a)$$

with

$$\begin{aligned} & (x_1 \vee x_2 \vee x_3 \vee x_4) \wedge (x_1 \vee x_2 \vee x_3 \vee x_5) \wedge (x_1 \vee x_2 \vee x_3 \vee x_6) \\ & \wedge (x_1 \vee x_2 \vee x_4 \vee x_5) \wedge (x_1 \vee x_2 \vee x_4 \vee x_6) \wedge (x_1 \vee x_2 \vee x_5 \vee x_6) \\ & \wedge (x_1 \vee x_3 \vee x_4 \vee x_5) \wedge (x_1 \vee x_3 \vee x_4 \vee x_6) \wedge (x_1 \vee x_3 \vee x_5 \vee x_6) \\ & \wedge (x_1 \vee x_4 \vee x_5 \vee x_6) \wedge (x_2 \vee x_3 \vee x_4 \vee x_5) \wedge (x_2 \vee x_3 \vee x_4 \vee x_6) \\ & \wedge (x_2 \vee x_3 \vee x_5 \vee x_6) \wedge (x_2 \vee x_4 \vee x_5 \vee x_6) \wedge (x_3 \vee x_4 \vee x_5 \vee x_6) \end{aligned} \quad (7.25b)$$

(note that we are assuming here that it is not allowed to introduce new variables to encode the constraints — as discussed in Section 7.8, such extension variables

³⁷This is analogous to how twin variables were introduced for polynomial calculus in Section 7.5.2, except that for cutting planes this does not affect the reasoning power of the proof system in any significant way.

can change the properties of proof systems dramatically). Constraints of the form

$$x_1^{\sigma_1} + x_2^{\sigma_2} + \dots + x_w^{\sigma_w} \geq A, \tag{7.26}$$

i.e., such that $a_i^\sigma \in \{0,1\}$ holds for all coefficients a_i^σ , are called *cardinality constraints*, since they encode that at least A of the literals in the constraint are true. We can also have general pseudo-Boolean constraints such as, say, $x_1 + 2\bar{x}_2 + 3x_3 + 4\bar{x}_4 + 5x_5 \geq 7$.

7.6.1. Pseudo-Boolean Rules of Reasoning

Not only are pseudo-Boolean constraints much more concise than clauses, but the rules used to manipulate them are also more powerful. Using the normalized form (7.23), the derivation rules in the standard proof complexity definition of cutting planes are

$$\text{Literal axioms} \frac{}{x_i^\sigma \geq 0} \tag{7.27a}$$

$$\text{Multiplication} \frac{\sum a_i^\sigma x_i^\sigma \geq A}{\sum ca_i^\sigma x_i^\sigma \geq cA} \quad c \in \mathbb{N}^+ \tag{7.27b}$$

$$\text{Addition} \frac{\sum a_i^\sigma x_i^\sigma \geq A \quad \sum b_i^\sigma x_i^\sigma \geq B}{\sum (a_i^\sigma + b_i^\sigma) x_i^\sigma \geq A + B} \tag{7.27c}$$

$$\text{Division} \frac{\sum ca_i^\sigma x_i^\sigma \geq A}{\sum a_i^\sigma x_i^\sigma \geq \lceil A/c \rceil} \quad c \in \mathbb{N}^+ \tag{7.27d}$$

where in the addition rule (7.27c) we implicitly assume that the result is rewritten in normalized form. Let us illustrate this by a small example. It is important to note that when we add literals of opposite sign, the result is

$$x_i^1 + x_i^0 = x_i^1 + (1 - x_i^1) = 1 \tag{7.28}$$

(which is just another way of saying that it will always be the case that exactly one of the literals x_i and \bar{x}_i is true). If we have the two constraints

$$x + 2y + 3z + 4\bar{w} \geq 5 \tag{7.29}$$

and

$$3x + 2\bar{y} + \bar{z} + \bar{w} \geq 3, \tag{7.30}$$

then by applying the addition rule (7.27c) we get the expression

$$(1 + 3)x + (2 - 2)y + (3 - 1)z + (4 + 1)\bar{w} \geq 5 + 3 - (2 + 1) \tag{7.31a}$$

which in the normalized form (7.23) becomes

$$4x + 2z + 5\bar{w} \geq 5 \tag{7.31b}$$

(where we suppress terms with zero coefficients). We note that when adding (7.29) and (7.30) to obtain (7.31b) the coefficients for y and \bar{y} cancel so that

this variable disappears. In general, when we add two constraints $\sum a_i^\sigma x_i^\sigma \geq A$ and $\sum b_i^\sigma x_i^\sigma \geq B$ such that there is a variable x_i and a $\sigma \in \{0, 1\}$ for which $a_i^\sigma = b_i^{1-\sigma} > 0$, we say that this is an instance of *cancelling addition*.

More generally, when two linear constraints $\sum a_i^\sigma x_i^\sigma \geq A$ and $\sum b_i^\sigma x_i^\sigma \geq B$ share a variable x_j for which $a_j^\sigma > 0$ and $b_j^{1-\sigma} > 0$ hold, then we can multiply the constraints by the smallest numbers c_A and c_B such that $c_A a_j^\sigma = c_B b_j^{1-\sigma}$, and then apply cancelling addition. If we return to the constraints (7.29) and (7.30) but now focus on the variable z , then we can multiply the second constraint by 3 and then add to get

$$\frac{x + 2y + 3z + 4\bar{w} \geq 5 \quad \frac{3x + 2\bar{y} + \bar{z} + \bar{w} \geq 3}{9x + 6\bar{y} + 3\bar{z} + 3\bar{w} \geq 9}}{10x + 4\bar{y} + 7\bar{w} \geq 9} \quad (7.32)$$

More abstractly, writing $d = \gcd(a_j, b_j)$ for the greatest common divisor of a_j and b_j , so that the smallest numbers c_A and c_B such that $c_A a_j = c_B b_j$ are $c_A = b_j/d$ and $c_B = a_j/d$, the formal specification of this rule is

$$\frac{a_j x_j^\sigma + \sum_{i \neq j, \sigma} a_i^\sigma x_i^\sigma \geq A \quad b_j x_j^{1-\sigma} + \sum_{i \neq j, \sigma} b_i^\sigma x_i^\sigma \geq B}{\sum_{i \neq j, \sigma} ((b_j a_i^\sigma / d) + (a_j b_i^\sigma / d)) x_i^\sigma \geq b_j A / d + a_j B / d - a_j b_j / d} \quad (7.33)$$

(where as before we implicitly assume that the result of the linear combination is put into normalized form). Note that this can be viewed as a kind of generalization of the resolution rule (7.2) from disjunctive clauses to general linear constraints. We therefore refer to (7.33) as *generalized resolution* (or sometimes *cancelling linear combination*), and we say that the two constraints are *resolved over* x_j . This rule essentially goes back to Hooker [Hoo88, Hoo92] (although Hooker's definition is slightly different in that the cancelling addition has to be followed by a division step). It is worth noting, though, that one difference compared to the resolution rule for disjunctive clauses is that it may be possible to resolve the same pair of constraints over several different variables, which can yield different results (as in (7.31b) and (7.32) above).

Given a set of linear inequalities, one can show that there is no $\{0, 1\}$ -valued solution by using the cutting planes rules to derive the inequality $0 \geq 1$ from the given linear inequalities. It is clear that such a refutation can exist only if the instance is indeed unsatisfiable. The other direction also holds, but requires more work to establish [Chv73, CCT87]; for the special case of translations of CNF formulas, this follows from the cutting planes can simulate resolution as discussed in Section 7.7.2 below).

We want to highlight that in the division rule (7.27d) (which is also referred to as the *Chvátal-Gomory cut* rule) we can divide with the common factor c on the left and then *divide and round up* the constant term on the right to the closest integer, since we know that we are only interested in $\{0, 1\}$ -valued solutions. This division rule is where the power of cutting planes lies. (And, indeed, this is how it must be, since a moment of thought reveals that the other rules are sound also for real-valued variables, and so without the division rule we would not be able to distinguish sets of linear inequalities that have real-valued solutions but no $\{0, 1\}$ -valued solutions.)

It is not hard to see that we can modify the definitions slightly to obtain a more cleanly stated *general division* rule

$$\frac{\sum a_i^\sigma x_i^\sigma \geq A}{\sum \lceil a_i^\sigma / c \rceil x_i^\sigma \geq \lceil A/c \rceil} \quad c \in \mathbb{N}^+ \tag{7.34}$$

without changing anything essential, since this rule can easily be simulated by using rules (7.27a) and (7.27d). Therefore, although the standard definition of division in the proof complexity literature is as in (7.27d), without loss of generality we will use rule (7.34) (though it should be noted that the correctness of (7.34) hinges on the fact that we are using normalized form).

A small example just to illustrate how the rules can be combined is the derivation

$$\frac{\begin{array}{l} 6x + 2y + 3z \geq 5 \\ \frac{x + 2y + w \geq 1}{2x + 4y + 2w \geq 2} \text{ Multiplication by 2} \end{array}}{8x + 6y + 3z + 2w \geq 7} \text{ Addition} \tag{7.35}$$

$$\frac{8x + 6y + 3z + 2w \geq 7}{3x + 2y + z + w \geq 3} \text{ Division by 3}$$

where we note that in this case we do not lose any information in the final division step. This is not always true when using the general division rule (7.34) — for instance, a further division of $3x + 2y + z + w \geq 3$ by 3 would yield the clause $x + y + z + w \geq 1$, which is a strictly weaker constraint.

Pseudo-Boolean solvers such as *Sat4j* [LP10] do not implement the full set of cutting planes derivation rules as presented above, however. To describe how they work, we need to introduce two other rules, namely

$$\text{Weakening} \frac{\sum_{(i,\sigma)} a_i^\sigma x_i^\sigma \geq A}{\sum_{(i,\sigma), i \neq j} a_i^\sigma x_i^\sigma \geq A - (a_j^0 + a_j^1)} \tag{7.36a}$$

and

$$\text{Saturation} \frac{\sum_{(i,\sigma)} a_i^\sigma x_i^\sigma \geq A}{\sum_{(i,\sigma)} \min\{a_i^\sigma, A\} \cdot x_i^\sigma \geq A} . \tag{7.36b}$$

The weakening rule is merely a convenient shorthand for one application each of the rules (7.27a), (7.27b), and (7.27c). Just as division, saturation is a special rule in that it is sound only for integral solutions. A second small toy example

$$\frac{\begin{array}{l} 2x + y + z + \geq 2 \\ \frac{3\bar{x} + 2y + 2\bar{z} + u + w \geq 5}{3\bar{x} + 2y + u + w \geq 3} \text{ Weakening on } z \end{array}}{7y + 3z + 2u + 2w \geq 6} \text{ Resolution on } x \tag{7.37}$$

$$\frac{7y + 3z + 2u + 2w \geq 6}{6y + 3z + 2u + 2w \geq 6} \text{ Saturation}$$

shows how weakening, generalized resolution, and saturation can be combined. (Again, the statement of the saturation rule in (7.36b) is crucially using normalized form.)

In the proof complexity literature the focus has been on investigating the general cutting planes proof system with the derivation rules (7.27a)–(7.27c)

and (7.34). To understand the reasoning power of pseudo-Boolean solvers, however, it makes sense to study also other versions of the cutting planes proof system where (i) the saturation rule (7.36b) is used instead of the division rule (*cutting planes with saturation*), or (ii) all applications of (7.27b) and (7.27c) have to be combined into applications of the generalized resolution rule (7.33) (*cutting planes with resolution*), or (iii) both of these modifications are applied at the same time (*cutting planes with saturation and resolution*). We will return to these different versions of the cutting planes proof system in Section 7.7.4.

7.6.2. Conflict-Driven Pseudo-Boolean Solving

To explain why the different flavours of cutting planes just introduced are interesting from an applied point of view, we next turn to pseudo-Boolean solvers and how they can be used to determine the satisfiability of sets of pseudo-Boolean constraints, which we recall are referred to as pseudo-Boolean formulas.

One approach to solving pseudo-Boolean formulas is to convert them to CNF, either lazily by learning clauses from PB constraints during conflict analysis, as in *clasp* [GKKS09] and one of the version in the *Sat4j* library [LP10], or eagerly by re-encoding the whole formula to CNF (typically introducing new auxiliary variables, or extension variables) and running a CDCL solver as in, e.g., *MiniSat+* [ES06], *Open-WBO* [MML14], or *NaPS* [SN15]. In the context of cutting planes we are more interested in solvers doing native pseudo-Boolean reasoning, such as *PRS* [DG02], *Galena* [CK05], *Pueblo* [SS06], *Sat4j* [LP10], and *RoundingSat* [EN18], so this is where our focus will be below (we mention, though, that related, but slightly different, ideas were also explored in *bsolo* [MMS06]). Our discussion of pseudo-Boolean solvers cannot come anywhere close to doing full justice to the topic of pseudo-Boolean solving or the even richer area of pseudo-Boolean optimization — for this, we refer the reader to Chapter 28 in this handbook. Another source of much useful information is Dixon’s PhD thesis [Dix04].

In our discussion of pseudo-Boolean solving, the standard setting is that the input is a PB formula without 0-1 solutions, and the goal of the solver is to decide that the formula is contradictory. For readers more interested in optimization, note that the above scenario arises also when the optimal solution has been found and the solver should prove that the (linear) objective function cannot be better than in the current solution.

Just as CDCL solvers can be viewed as searching for resolution proofs, we will see that the pseudo-Boolean solving techniques we will discuss generate proofs in different subsystems of cutting planes. Simplifying drastically, when building a pseudo-Boolean solver on top of cutting planes we have the following choices:

1. Boolean rule: (a) saturation or (b) division.
2. Linear combinations: (a) generalized resolution or (b) no restrictions.

As we will soon see, the choice of generalized resolution seems inherent in a conflict-driven setting, which is what we are focusing on here. However, which Boolean rule to prefer is less clear. Saturation was used in the seminal paper [CK05] and has also been the rule of choice in what is arguably the most popular pseudo-Boolean solver to date, namely *Sat4j* [LP10]. Division appeared

only recently in *RoundingSat* [EN18] (although it was suggested in a more general integer linear programming setting in [JdM13]). We will return to a discussion of saturation versus division later, but let us first describe the general setup.

Naively, when generalizing CDCL to a pseudo-Boolean setting we just want to build a solver that decides on variable values and propagates forced values until conflict, at which point a new linear constraint is learned and the solver backtracks. To decide when constraints are propagating or conflicting it is convenient to use the concept of *slack*, which we define next.

The *slack* of a constraint $\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A$ under a partial assignment ρ (which we should think of as the variables currently assigned on the trail) measures how far $\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A$ is from being falsified by ρ , and is defined as

$$\text{slack} \left(\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A; \rho \right) = \sum_{\rho(x_i^\sigma) \neq 0} a_i^\sigma - A, \quad (7.38)$$

i.e., the sum of the coefficients of all literals that are *not* falsified by ρ minus the constant term. To illustrate with a special case, the slack of a disjunctive clause is the number of non-falsified literals in the clause minus 1. The constraint $\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A$ is *conflicting* under ρ if

$$\text{slack} \left(\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A; \rho \right) < 0 \quad (7.39)$$

and, for x_{i^*} not in the domain of ρ , it *propagates* $x_{i^*}^{\sigma^*}$ under ρ if

$$0 \leq \text{slack} \left(\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A; \rho \right) < a_{i^*}^{\sigma^*} \quad (7.40)$$

(which is just another way of saying that we have to set $x_{i^*}^{\sigma^*}$ to true, or else there will be no way to satisfy the constraint). The above definitions might be easier to digest by studying the example in Figure 7.15 of how the slack changes for the constraint $C \doteq x_1 + 2\bar{x}_2 + 3x_3 + 4\bar{x}_4 + 5x_5 \geq 7$ under different partial assignments ρ on the trail. The initial slack is just the sum of the coefficients minus the degree. If x_5 is assigned to false, then x_4 is propagated to false according to (7.40). Assigning a variable to its propagated value does not change the slack. If now the solver for some other reason sets x_3 to false and x_2 to true, we have a conflict according to (7.39). Note that in contrast to clauses in CDCL, a pseudo-Boolean constraint can be conflicting even though not all variables in it have been assigned.

7.6.2.1. A First (Failed) Attempt at Pseudo-Boolean Conflict Analysis

Now we can give a slightly more detailed (though still incomplete) sketch of how we would like our pseudo-Boolean solver to work:

1. While there is no conflict, iteratively propagate all literals $x_{i^*}^{\sigma^*}$ such that there is a constraint for which $0 \leq \text{slack}(\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A; \rho) < a_{i^*}^{\sigma^*}$ (i.e., add the literals to the current assignment ρ).

ρ	$\text{slack}(C; \rho)$	Comment
\emptyset	8	Sum of coefficients minus degree of falsity.
(\bar{x}_5)	3	Propagates \bar{x}_4 , since coefficient $>$ slack.
(\bar{x}_5, \bar{x}_4)	3	Propagation does not change slack.
$(\bar{x}_5, \bar{x}_4, \bar{x}_3, x_2)$	-2	Conflict, since slack $<$ 0.

Figure 7.15. Slack of $C \doteq x_1 + 2\bar{x}_2 + 3x_3 + 4\bar{x}_4 + 5x_5 \geq 7$ for different trails ρ .

2. If there is no conflict, find some unassigned literal x_i^σ , decide to set it to true (i.e., add x_i^σ to ρ), and go to step 1.
3. Otherwise, fix some conflicting constraint $\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A$, i.e., such that $\text{slack}(\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A; \rho) < 0$, and resolve it with the propagating constraints found in step 1 in reverse chronological order until we derive a constraint that is the analogue of an asserting clause.
4. Add this constraint to the formula, backtrack to the first point in the trail where the constraint is not falsified, and go to step 1.

From this description it is possible to see why the generalized resolution enters the picture in a natural way — the only time we use linear combinations is in step 3, where there are two constraints that have opposing opinions about what value the current variable under consideration should take.

The simple approach outlined above will not quite work. In what remains of this subsection, we first show an example why it fails, and then discuss what can be done to fix the problem. From the examples in Section 7.3 we can see that an important invariant during CDCL conflict analysis is that the assignment that is “left on the trail” always falsifies the currently derived clause. This means that every derived constraint “explains” the conflict by showing what assignments on the trail are inconsistent, and we can continue the conflict analysis until the derived constraint looks “nice,” at which point the solver learns it and backtracks. The standard concept of “niceness” in CDCL is that the constraint should be *asserting*, i.e., that if we remove further literals from the trail in reverse chronological order until the first time when the learned constraint is not falsified, then at this point the constraint propagates some variable that flips an earlier assignment. When we generalized conflict-driven solving to a pseudo-Boolean setting, we would like the conflict analysis to work in the same way.

As a running example, let us consider the pseudo-Boolean formula consisting of the two constraints

$$C_1 \doteq 2x_1 + 2x_2 + 2x_3 + x_4 \geq 4 \quad (7.41a)$$

$$C_2 \doteq 2\bar{x}_1 + 2\bar{x}_2 + 2\bar{x}_3 \geq 3 \quad (7.41b)$$

(which is just an obfuscated way of writing that a majority of the variables $\{x_1, x_2, x_3\}$ have to be true and false at the same time, but it is a simple enough example that we can use it to illustrate our main points). Note that both constraints have slack 3 under the empty assignment, which is larger than all coefficients, so there are no propagations at decision level 0. Suppose that the solver sets x_1 to false to get the trail

$$\rho_1 = (x_1 \stackrel{\text{DEC}}{\leftarrow} 0) . \quad (7.42a)$$

Now $\text{slack}(C_1; \rho_1) = 1$, which is less than the coefficient 2 of x_2 , so C_1 propagates x_2 to true, yielding

$$\rho_2 = (x_1 \stackrel{\text{DEC}}{\leftarrow} 0, x_2 \stackrel{C_1}{\leftarrow} 1) . \quad (7.42b)$$

For the same reason, x_3 is also propagated to true by C_1 (note that, in contrast to CDCL, the same constraint can propagate several times). For this trail

$$\rho_3 = (x_1 \stackrel{\text{DEC}}{\leftarrow} 0, x_2 \stackrel{C_1}{\leftarrow} 1, x_3 \stackrel{C_1}{\leftarrow} 1) \quad (7.42c)$$

the slack of the other constraint C_2 is $\text{slack}(C_2; \rho_3) = -1$, and we have reached a conflict.

Inspired by CDCL conflict analysis, we take the reason constraint $C_1 \doteq \text{reason}(x_3, \rho_2)$ propagating the last literal x_3 under ρ_2 and resolve it over x_3 with the conflicting constraint C_2 , i.e., performing the derivation step

$$\frac{2x_1 + 2x_2 + 2x_3 + x_4 \geq 4 \quad 2\bar{x}_1 + 2\bar{x}_2 + 2\bar{x}_3 \geq 3}{x_4 \geq 1} , \quad (7.43)$$

to obtain the resolvent $x_4 \geq 1 \doteq \text{resolve}(C_1, C_2, x_3)$. But now we have a problem: the slack of the resolvent with respect to what remains on the trail is $\text{slack}(x_4 \geq 1; \rho_2) = 0$. This is no longer negative, so we have lost the invariant from CDCL that the constraint derived on the conflict side should be conflicting!

Taking a step back to analyse what happened, the reason for this failure is that it is in fact possible to satisfy both constraints C_1 and C_2 by extending ρ_2 with the assignment $x_3 = \frac{1}{2}$. Of course, this is not a Boolean assignment. However, taking linear combinations is not a Boolean rule but is sound also over the reals. For this reason, there is no way we can guarantee that the invariant of a conflicting constraint on the conflict side can be maintained if we use only the generalized resolution rule (7.33). Thus, we need to get some Boolean derivation rule into play.

7.6.2.2. Pseudo-Boolean Conflict Analysis Using Saturation

We will now describe how Chai and Kuehlmann [CK05] adapt conflict analysis to a pseudo-Boolean setting using the saturation rule. Saturation in itself cannot help fix our problem, because both constraints resolved in (7.43) are already saturated, as is the resolvent. But if we combine saturation with weakening of the reason constraint, then (perhaps somewhat counter-intuitively) we can get the conflict analysis to work. When resolving a propagating constraint C_{reason} on the reason side with the currently derived constraint C_{confl} on the conflict side (starting with the violated constraint and working our way back along the trail in reverse chronological order, as described above), we will iterate the following procedure:

1. weaken the current reason constraint C_{reason} on some non-falsified literal ℓ' (other than the literal ℓ propagated by C_{reason} , on which we want to apply resolution) to get $\text{weaken}(C_{\text{reason}}, \ell')$;
2. saturate the weakened constraint to obtain $\text{saturate}(\text{weaken}(C_{\text{reason}}, \ell'))$;
3. compute the resolvent $\text{resolve}(C_{\text{confl}}, \text{saturate}(\text{weaken}(C_{\text{reason}}, \ell')), \ell)$ of the weakened reason constraint with the conflicting constraint C_{confl} over the propagated literal ℓ ;

```

while  $slack(resolve(C_{\text{conf}}, C_{\text{reason}}, \ell); \rho) \geq 0$  do
  |  $\ell' \leftarrow$  literal in  $C_{\text{reason}} \setminus \{\ell\}$  not falsified by  $\rho$ ;
  |  $C_{\text{reason}} \leftarrow$  saturate(weaken( $C_{\text{reason}}, \ell'$ ));
end
return  $C_{\text{reason}}$ ;

```

Figure 7.16. Chai-Kuehlmann reason reduction $\text{reduceSat}(C_{\text{conf}}, C_{\text{reason}}, \ell, \rho)$.

until obtaining a resolved constraint that is conflicting. After each step in this iteration C_{reason} is updated to to $\text{weaken}(C_{\text{reason}}, \ell')$, and when we finally get a conflicting resolvent we update C_{conf} to be this new constraint.

Let us first show how this works for our example, and then discuss why this is a correct approach in general. If we weaken $\text{reason}(x_3, \rho_2) \doteq C_1$ on x_2 , which is the first non-falsified literal that is not the one currently propagated, then we get the following derivation:

$$\begin{array}{l}
 \text{Weakening on } x_2 \quad \frac{2x_1 + 2x_2 + 2x_3 + x_4 \geq 4}{2x_1 + 2x_3 + x_4 \geq 2} \\
 \text{Saturation} \quad \frac{2x_1 + 2x_3 + x_4 \geq 2}{2x_1 + 2x_3 + x_4 \geq 2} \qquad 2\bar{x}_1 + 2\bar{x}_2 + 2\bar{x}_3 \geq 3 \\
 \text{Resolution on } x_3 \quad \frac{2x_1 + 2x_3 + x_4 \geq 2}{2\bar{x}_2 + x_4 \geq 1} \qquad 2\bar{x}_1 + 2\bar{x}_2 + 2\bar{x}_3 \geq 3
 \end{array} \tag{7.44}$$

Unfortunately, this does not solve the problem, since $2\bar{x}_2 + x_4 \geq 1$ again has slack 0 with respect to the trail ρ_2 in (7.42b).

We cannot weaken away x_3 , since this is the propagating literal we want to resolve over, but we can weaken C_1 also on x_4 , which is not falsified. This yields

$$\begin{array}{l}
 \text{Weakening on } x_2 \quad \frac{2x_1 + 2x_2 + 2x_3 + x_4 \geq 4}{2x_1 + 2x_3 + x_4 \geq 2} \\
 \text{Weakening on } x_4 \quad \frac{2x_1 + 2x_3 + x_4 \geq 2}{2x_1 + 2x_3 \geq 1} \\
 \text{Saturation} \quad \frac{2x_1 + 2x_3 \geq 1}{x_1 + x_3 \geq 1} \qquad 2\bar{x}_1 + 2\bar{x}_2 + 2\bar{x}_3 \geq 3 \\
 \text{Resolution on } x_3 \quad \frac{x_1 + x_3 \geq 1}{2\bar{x}_2 \geq 1} \qquad 2\bar{x}_1 + 2\bar{x}_2 + 2\bar{x}_3 \geq 3
 \end{array} \tag{7.45}$$

and now we have $slack(2\bar{x}_2 \geq 1; \rho_2) = -1 < 0$, i.e., we have derived a new constraint that maintains the invariant of having negative slack with respect to what remains on the trail. This does not change if we saturate this constraint to get $\bar{x}_2 \geq 1$.

Although we have not formally defined anything like 1UIP pseudo-Boolean constraints — and, indeed, doing so requires some care — it should be clear that $\bar{x}_2 \geq 1$ is asserting. If we undo all decisions on the trail, then at top level we have $slack(\bar{x}_2 \geq 1; \emptyset) = 0$, so x_2 propagates to false yielding $\rho_4 = (x_2 \stackrel{\bar{x}_2 \geq 1}{\leftarrow} 0)$. Looking at $C_1 \doteq 2x_1 + 2x_2 + 2x_3 + x_4 \geq 4$, we have $slack(C_1; \rho_4) = 1$, and since this is smaller than the coefficient 2 of x_1 and x_3 both variables propagate to true. This causes a conflict with $C_2 \doteq 2\bar{x}_1 + 2\bar{x}_2 + 2\bar{x}_3 \geq 3$, and since no decisions have been made the solver can terminate and report that the formula consisting of the constraints (7.41a) and (7.41b) is indeed unsatisfiable.

The key to the pseudo-Boolean conflict analysis just described is that we apply a *reduction algorithm* on the reason constraint, combining weakening and

```

while  $C_{\text{conf}}$  not asserting do
   $\ell \leftarrow$  literal assigned last on trail  $\rho$ ;
  if  $\bar{\ell}$  occurs in  $C_{\text{conf}}$  then
     $C_{\text{reason}} \leftarrow$  reason( $\ell, \rho$ );
     $C_{\text{reason}} \leftarrow$  reduceSat( $C_{\text{reason}}, C_{\text{conf}}, \ell, \rho$ );
     $C_{\text{conf}} \leftarrow$  resolve( $C_{\text{conf}}, C_{\text{reason}}, \ell$ );
     $C_{\text{conf}} \leftarrow$  saturate( $C_{\text{conf}}$ );
  end
   $\rho \leftarrow$  removeLast( $\rho$ );
end
return  $C_{\text{conf}}$ ;

```

Figure 7.17. Pseudo-Boolean conflict analysis $\text{analyzePBconflict}(C_{\text{conf}}, \rho)$.

saturation, to ensure that when the reduced reason constraint is resolved with the currently derived conflict constraint, then the result will be a new conflicting constraint. The pseudo-code for this reduction algorithm from [CK05] is given in Figure 7.16. But how do we know that this procedure is guaranteed to work?

Briefly, the reason is that slack is *subadditive*, i.e., if we take a linear combination of two constraints C and D , then it is not hard to verify that

$$\text{slack}(c \cdot C + d \cdot D; \rho) \leq c \cdot \text{slack}(C; \rho) + d \cdot \text{slack}(D; \rho) \quad (7.46)$$

holds. By the invariant, we know for the currently derived constraint C_{conf} on the conflict side that we have $\text{slack}(C_{\text{conf}}; \rho) < 0$. It is also easy to see directly from the definition (7.38) that weakening the reason constraint C_{reason} leaves $\text{slack}(C_{\text{reason}}; \rho)$ unchanged, since we only weaken on non-falsified literals. But saturation can decrease the slack, and if we have not reached non-positive slack before, then at the very latest this will happen when all non-falsified literals except the propagating one have been weakened away — at this stage the only coefficient contributing to the slack is that of the propagating literal, and since the constraint is saturated this coefficient must be equal to the degree of falsity, so that the whole constraint has slack 0. (This is exactly what happened in our example.) Plugging this into (7.46), we see that a positive linear combination of zero and a negative number will be negative, and the invariant is maintained.

Using this reason reduction method, the whole pseudo-Boolean conflict analysis algorithm will be as in Figure 7.17. The reduction step highlighted in boldface is new compared to CDCL, but everything else is essentially the same (at least at a high level). So how does our conflict analysis compare to CDCL? Let us just point out three important aspects here, which will motivate some of the discussions later.

1. One difference is how much work needs to be performed at each step. When we resolve a new reason with the current conflict clause in CDCL, then we only have to “tag on” the reason clause to the conflict clause, but we do not have to touch the literals already in the conflict clause. Therefore, the total amount of work during CDCL conflict analysis is linear in the sum of the clause sizes. But in pseudo-Boolean analysis we might have to multiply both the reason and the conflict in order to adjust the coefficients so that

the linear combination in (7.33) is cancelling, and this means that we might have to touch all literals in the constraint on the conflict side over and over again. In the worst case, this will incur an extra linear factor in the running time

2. Because of these multiplications, it can also be the case that the coefficients in the constraints grow very large. If this happens, then the integer arithmetic can get hugely expensive. This can become a very serious problem in practice.
3. Perhaps the most serious problem, though, is that for inputs in CNF this procedure described above degenerates to resolution. All that will happen during the conflict analysis is that trivial resolution derivations will produce new clauses, and so the whole algorithm just becomes CDCL but with much more expensive data structures. Hence, if we take the pigeonhole principle formula encoded in CNF and feed it into a pseudo-Boolean solver using this conflict analysis, then although the formula is easy for cutting planes (as shown in [CCT87]) it will be exponentially hard in practice.

The third issue is perhaps the most important one in that it shows how sensitive pseudo-Boolean solvers can be to details of the encoding. We will return to the question of CNF inputs and discuss it in a bit more detail in Section 7.7.

7.6.2.3. Pseudo-Boolean Conflict Analysis Using Division

Motivated by the above discussion, it seems interesting to consider whether the division rule could be a competitive alternative to saturation. It is known that general cutting planes (consisting of the rules (7.27a)–(7.27c) and (7.34)) is *implicationally complete*, meaning that if a pseudo-Boolean formula implies a certain constraint, then there is a way to derive this constraint.³⁸ This is not true for cutting planes with saturation [VEGC⁺18], i.e., when the saturation rule (7.36b) is substituted for the division rule (7.34). For instance, it can be shown that there is no way to derive the cardinality constraint

$$x + y + z \geq 2 \tag{7.47}$$

from the (translation into pseudo-Boolean constraints of the) CNF encoding

$$x + y \geq 1 \tag{7.48a}$$

$$x + z \geq 1 \tag{7.48b}$$

$$y + z \geq 1 \tag{7.48c}$$

using cutting planes with saturation (even with unrestricted linear combinations). In view of this, it is natural to ask whether the use of division could perhaps yield a stronger conflict analysis algorithm. As mentioned above, using division was proposed in the context of general integer linear programming in *CutSat* [JdM13], although it appears that this approach does not work so well in practice. What we will discuss below is a fairly recent variant of pseudo-Boolean conflict analysis

³⁸This is the analogue of Theorem 7.3.1 for resolution saying that of a clause C is implied by a CNF formula F , then there is a resolution derivation of some clause $C' \subseteq C$ from F .

```

c ← coeff(Creason, ℓ);
while slack(resolve(Cconfl, divide(Creason, c), ℓ); ρ) ≥ 0 do
  | ℓ' ← literal in Creason \ {ℓ} such that ℓ̄j ∉ ρ and c † coeff(C, ℓ');
  | Creason ← weaken(Creason, ℓ');
end
return divide(Creason, c);

```

Figure 7.18. Reduction $\text{reduceDiv}(C_{\text{confl}}, C_{\text{reason}}, \ell, \rho)$ using division.

that uses division instead of saturation, and that does seem to perform very well in practice.

In the division-based conflict analysis method, for each step in the conflict analysis we will iterate the following three actions

1. Weaken the reason constraint C_{reason} on some non-falsified literal ℓ' with coefficient not divisible by the coefficient of the propagating literal ℓ to obtain $\text{weaken}(C_{\text{reason}}, \ell')$.
2. Divide the weakened constraint by the coefficient c of the propagating literal, yielding the constraint $\text{divide}(\text{weaken}(C_{\text{reason}}, \ell'), c)$.
3. Compute the resolvent $\text{resolve}(C_{\text{confl}}, \text{divide}(\text{weaken}(C_{\text{reason}}, \ell'), c), \ell)$ of this constraint with the conflicting constraint C_{confl} over the propagated literal ℓ .

These steps are iterated until the resolvent obtained is conflicting. (Again, the constraint C_{reason} is updated to $\text{weaken}(C_{\text{reason}}, \ell')$ after each step.)

Before arguing about correctness, let us do as we did for the saturation-based method and illustrate how this approach works for the constraints C_1 and C_2 from (7.41a)–(7.41b) with the trail $\rho_3 = (x_1 \stackrel{\text{DEC}}{\leftarrow} 0, x_2 \stackrel{C_1}{\leftarrow} 1, x_3 \stackrel{C_1}{\leftarrow} 1)$ in (7.42c), under which C_2 is conflicting. The first attempt to resolve the reason C_1 for x_3 with the conflict constraint C_2 now yields the derivation

$$\begin{array}{l}
 \text{Weakening on } x_4 \quad \frac{2x_1 + 2x_2 + 2x_3 + x_4 \geq 4}{2x_1 + 2x_2 + 2x_3 \geq 3} \\
 \text{Division by 2} \quad \frac{2x_1 + 2x_2 + 2x_3 \geq 3}{x_1 + x_2 + x_3 \geq 2} \\
 \text{Resolution on } x_3 \quad \frac{x_1 + x_2 + x_3 \geq 2 \quad 2\bar{x}_1 + 2\bar{x}_2 + 2\bar{x}_3 \geq 3}{0 \geq 1}
 \end{array} \quad (7.49)$$

so for this particular example the solver immediately derives contradiction and can terminate with a report that the instance is unsatisfiable!

The pseudo-code for the reason reduction algorithm from [EN18] using division is given in Figure 7.18. Let us sketch the argument why this algorithm is guaranteed to return a reduced reason constraint that will maintain our desired invariant, namely that the resolvent of this constraint with the current constraint on the conflict-side has negative slack with respect to the current trail. Just as in the analysis of the reason reduction algorithm reduceSat using saturation in Figure 7.16, it is sufficient to prove that at some point the slack of the constraint on the reason side is guaranteed to become non-positive. This is sufficient to maintain the conflict analysis invariant of negative slack, since the constraint C_{confl} on the conflict side has negative slack by assumption and slack is subadditive (7.46),

```

c ← coeff(C, ℓ);
foreach literal ℓ' in C do
  | if ℓ' ∉ ρ and c ∤ coeff(C, ℓ') then
  |   | C ← weaken(C, ℓ');
  | end
end
return divide(C, c);

```

Figure 7.19. Reason reduction $\text{roundToOne}(C, \ell, \rho)$ used in *RoundingSat*.

meaning that the resolvent of the reason and conflict constraints also has to have negative slack.

Following the notation in Figure 7.18, let c be the coefficient of the literal ℓ propagated by C_{reason} . By the definition of propagation in (7.40) we have

$$0 \leq \text{slack}(C_{\text{reason}}; \rho) < c, \quad (7.50)$$

and since weakening on non-falsified literals does not change the slack these inequalities hold at all times during the execution of `reduceDiv`. Suppose that we have reached the point in the algorithm when all coefficients of non-falsified literals not divisible by c have been weakened away. Consider what contribution the literals in $\text{divide}(C_{\text{reason}}, c)$ give to the slack. Falsified literals in C_{reason} do not contribute at all, and all remaining non-falsified literals have coefficients divisible by c . Therefore, the slack of the reason constraint is divisible by c , i.e., we have

$$\text{slack}(\text{divide}(C_{\text{reason}}, c); \rho) = \frac{\text{slack}(C_{\text{reason}}; \rho)}{c}, \quad (7.51)$$

and it follows from this and (7.50) that

$$0 \leq \text{slack}(\text{divide}(C_{\text{reason}}, c); \rho) < 1, \quad (7.52)$$

i.e., $\text{slack}(\text{divide}(C_{\text{reason}}, c); \rho) = 0$. This proves the correctness of `reduceDiv`.

We remark that the reason reduction method `roundToOne` used in [EN18], and presented in Figure 7.19, does not weaken away literals one by one, but does the maximal amount of weakening right away. This is guaranteed to maintain the invariant by the proof just outlined above. Also, this method is used not only for reason reduction but is applied more aggressively during the conflict analysis. The pseudo-code for the conflict analysis in *RoundingSat* is presented in Figure 7.20.

It is an interesting question how saturation and division compare when used for pseudo-Boolean solving, but this is currently not very well understood. It is clear from our example (7.49) that division can sometimes be more efficient, but one can also construct crafted benchmarks where it seems that saturation should have the potential to work better [GNY19]. Nevertheless, some preliminary conclusions are that for instances where pseudo-Boolean reasoning does not help, so that a competitive approach would have been to translate to CNF and run a CDCL solver, then the conflict speed, and hence the search speed, is orders of magnitude faster in *RoundingSat* than in *Sat4j* [EN18]. For crafted benchmarks where pseudo-Boolean reasoning appears to be crucial, the number of generated

```

while  $C_{\text{conf}}$  contains no or multiple falsified literals on last level do
  if no current solver decisions then
    | output UNSAT and terminate
  end
   $\ell \leftarrow$  literal assigned last on trail  $\rho$ ;
  if  $\bar{\ell}$  occurs in  $C_{\text{conf}}$  then
    |  $C_{\text{conf}} \leftarrow \text{roundToOne}(C_{\text{conf}}, \bar{\ell}, \rho)$ ;
    |  $C_{\text{reason}} \leftarrow \text{roundToOne}(\text{reason}(\ell, \rho), \ell, \rho)$ ;
    |  $C_{\text{conf}} \leftarrow \text{resolve}(C_{\text{conf}}, C_{\text{reason}}, \ell)$ ;
  end
   $\rho \leftarrow \text{removeLast}(\rho)$ ;
end
 $\ell \leftarrow$  literal in  $C_{\text{conf}}$  last falsified by  $\rho$ ;
return  $\text{roundToOne}(C_{\text{conf}}, \ell, \rho)$ ;

```

Figure 7.20. Pseudo-Boolean conflict analysis in *RoundingSat* using `roundToOne`.

conflicts per second in *RoundingSat* goes down significantly, but the performance is still much better than for pseudo-Boolean solvers using saturation [EGCNV18]. One extra bonus is that the frequent use of division helps keep the coefficients small, so that one can use fixed-precision arithmetic (this of course also assumes that there is code for handling overflow, which is an issue we ignore in the pseudo-code presented here). However, the main problem we identified with saturation-based solvers still remains: for CNF inputs, the algorithm degenerates to a CDCL search for resolution proofs.

7.6.3. More Pseudo-Boolean Rules

Before wrapping up our discussion of pseudo-Boolean solving, we wish to mention some other reasoning rules that are relevant to consider in this context. A natural question to ask is whether general linear constraints are needed to harness the full power of pseudo-Boolean solvers, or whether solvers could equally well work with a more limited set of constraints. One particularly interesting class of linear inequalities are cardinality constraints (7.26). Given a general PB constraint such as, for instance,

$$3x_1 + 2x_2 + x_3 + x_4 \geq 4 \quad , \quad (7.53a)$$

one can compute the least number of literals that have to be true, which results in the constraint

$$x_1 + x_2 + x_3 + x_4 \geq 2 \quad . \quad (7.53b)$$

This is used in the solver *Galena* [CK05], which only learns cardinality constraints. The fact that all learned constraints will be of a particular form can also make other aspects of the algorithm easier. Formally, this *cardinality constraint reduction* rule can be written as

$$\frac{\sum_{i \in [n], \sigma \in \{0,1\}} a_i^\sigma x_i^\sigma \geq A}{\sum_{(i,\sigma) : a_i^\sigma > 0} x_i^\sigma \geq T} \quad T = \min\{|I| : I \subseteq [n], \sum_{i \in I, \sigma} a_i^\sigma \geq A\} \quad . \quad (7.54)$$

Another interesting rule is *strengthening*, which we also introduce by giving an example. Consider again the constraints (7.48a)–(7.48c) and suppose that we set

$x \stackrel{\text{DEC}}{\leftarrow} 0$ and propagate. This yields $y \stackrel{x+y \geq 1}{\leftarrow} 1$ and $z \stackrel{x+z \geq 1}{\leftarrow} 1$, meaning that the final constraint $y + z \geq 1$ is “oversatisfied” by a margin of 1. A closer analysis of this situation leads to the conclusion that we can deduce the constraint $x + y + z \geq 2$ in (7.47), since either x is true, in which case the constraint certainly holds, or else $y + z \geq 1$ is oversatisfied as we just saw. Slightly more formally, the *strengthening rule*, which seems to have been imported by [DG02] from operations research, can be described as follows:

- Suppose that assigning $x_j^{\sigma_j} = 0$ implies that the constraint $\sum_{i \neq j, \sigma} a_i x_i^\sigma \geq A$ has to be oversatisfied by an amount of K .
- Then it is sound to deduce the constraint

$$Kx_j^{\sigma_j} + \sum_{i \neq j, \sigma} a_i x_i^\sigma \geq A + K . \quad (7.55)$$

In theory, using strengthening can allow the solver to recover from bad encodings such as CNF (in our example, we recovered the cardinality constraint (7.47) from the CNF encoding (7.48a)–(7.48c)). In practice, however, it seems hard to get this to work in an efficient way.

A final interesting scenario that we want to discuss is the following. If we have the PB constraints

$$2x + 3y + 2z + w \geq 3 \quad (7.56a)$$

$$2\bar{x} + 3y + 2z + w \geq 3 \quad (7.56b)$$

then by eyeballing we can conclude that

$$3y + 2z + w \geq 3 \quad (7.56c)$$

must hold, since x is either true or false and so can contribute to at most one of the constraints (7.56a) and (7.56b). But an application of the generalized resolution rule on these two constraints instead results in the constraint

$$6y + 4z + 2w \geq 4 , \quad (7.56d)$$

reflecting that this rule also takes the possibility $x = \frac{1}{2}$ into consideration. Applying saturation to (7.56d) yields

$$4y + 4z + 2w \geq 4 \quad (7.56e)$$

and division does not help either since it yields the equivalent constraint

$$2y + 2z + w \geq 2 , \quad (7.56f)$$

which is clearly weaker than (7.56c). As observed by [Goc17], it would be quite convenient to have an implementation of what we can call a *fusion resolution* rule

$$\frac{a_j x_j + \sum_{i \neq j, \sigma} b_i^\sigma x_i^\sigma \geq B \quad a_j \bar{x}_j + \sum_{i \neq j, \sigma} b_i^\sigma x_i^\sigma \geq B'}{\sum_{i \neq j, \sigma} b_i^\sigma x_i^\sigma \geq \min\{B, B'\}} . \quad (7.57)$$

The need for such a rule shows up in some tricky benchmarks in [EGCNV18], but we see no obvious way for cutting planes to perform such reasoning in an efficient manner.

7.6.4. Some Challenges for Pseudo-Boolean Solving

We conclude our review of conflict-driven pseudo-Boolean solving with a discussion of some of the challenges that lie ahead. On the theory side, one difficulty is that there seem to be many more degrees of freedom in PB solving compared to conflict-driven clause learning (CDCL). As we have seen above, there are several different ways of generalizing CDCL to a pseudo-Boolean context, and it seems far from obvious what is the best way to do so.

An example of an interesting question concerning the algorithms we have discussed so far is how much the reason should be weakened in the reduction step. Is it better to weaken iteratively, literal by literal, until the first point in time when the resolvent is conflicting? Or is it better to do as in *RoundingSat* and do all the weakening right away? Another curious difference from CDCL is that sometimes the slack on the conflict side can be so negative that it is possible to just skip a resolution step and still maintain that the conflict-side constraint when the last propagated literal is removed from the trail (so that its status changes from falsified to non-falsified and it starts contributing to the slack). In such a scenario, is it better to skip the resolution step, in order to get fewer applications of the resolution rule over all, and get a more “compact explanation” of the conflict, or is it preferable to always resolve? It seems that one can cook up crafted benchmarks supporting both approaches. Different aspects of pseudo-Boolean conflict analysis have been studied in [LMMW20, LMW20], but there is room for much more work in this area.

This leads to the more general question of whether there is a better approach for conflict analysis than generating (the analogue of) trivial resolution derivations. Note that this question also makes sense for CDCL. The main reason in favour of trivial resolution seems to be that it is simple and runs very fast. But perhaps it could sometimes pay off to be slower and do something smarter? Or, in the opposite direction, could it be that one should not try to learn general pseudo-Boolean constraints, as described above, but instead focus on a more limited form such as cardinality constraints, as done in *Galena* [CK05]?

One reason that we do not have any good answers to these questions is that we do not know too much about how the different subsystems of cutting planes described towards the end of Section 7.6.1 relate to each other in terms of theoretical strength. Some progress has been made in recent papers such as [VEGC⁺18, GNY19], but many open problems still remain. A particularly intriguing question is whether cutting planes with division is strictly stronger than cutting planes with saturation when the linear combination rule is limited to generalized resolution. We will discuss this further in Section 7.7.4.

Among the implementation challenges, one of the most important ones is how to achieve efficient propagation for pseudo-Boolean constraints. For CDCL solvers, a simple but crucial observation is that as long as a disjunctive clause contains two non-falsified literals it cannot propagate, and the famous *two-watched-literals scheme* implementing this approach in state-of-the-art solvers is an important part of the explanation how such solvers can run so fast. This is not true in pseudo-Boolean solving — for a constraint like $\sum_{i=1}^n x_i \geq n - 1$ one has to watch all variables in order to detect propagation, since as soon as any single variable

is set to false all others should propagate to true. The recent paper [Dev20] provides what is currently the state of the art in pseudo-Boolean propagations and discusses in more detail the challenges that remain.

A second major challenge is if and how natural and efficient methods can be designed to recover from bad encodings (such as CNF). Although it is hard to make anything like this into a formal claim, it seems that pseudo-Boolean solvers are more sensitive to the exact encoding of a problem, and also to the presence or absence of extra, potentially superfluous constraints, than CDCL solvers. A recent work reporting progress on implementing efficient pseudo-Boolean search for CNF formulas, assuming that these formulas encode cardinality constraints or that such constraints can play an important part in the proofs, is [EN20], but much work still remains.

Another interesting question is how far the solver should backjump once an asserting constraint has been learned. In contrast to CDCL, a learned constraint can be asserting at several levels, and there are even different options in how to define what an asserting constraint should be depending on whether one wants to apply syntactic or (potentially harder to check) semantic criteria. A somewhat related concern is how to assess the “quality” of different constraints, for instance, when the solver has the choice of either performing or skipping a resolution step, and one would like to know which of the two options seems to yield the better constraint.

A puzzling observation, made in, e.g., [EGCNV18], is that sometimes pseudo-Boolean solvers perform extremely poorly on instances which are infeasible even viewed as linear program relaxations without any integrality constraints. Such instances can be trivial for *mixed integer linear programming (MIP)* solvers such as *Gurobi* [Gur], *CPLEX* [CPL], and *SCIP* [SCI], which will detect infeasibility after solving the LP at the root node, while the pseudo-Boolean solvers get completely lost looking for satisfying Boolean assignments in a search space where there are not even any real-valued solutions. On the other hand, it seems that sometimes MIP solvers can fail badly on instances where learning from failed partial assignments to PB constraints appears to be crucial (and where, for this reason, conflict-driven PB solvers can shine). For this reason, a quite tempting proposition would be to borrow techniques from, or merge techniques with, MIP solvers to obtain pseudo-Boolean solvers that could provide the best of both worlds. Some research in this direction has been initiated in [DGN20], but again it seems that most of the work is still ahead.

In order to further develop pseudo-Boolean solving techniques, however, a final challenge that we wish to highlight is that it would be very desirable to develop efficient and concise pseudo-Boolean proof logging techniques. Although the DRAT format employed for CDCL solvers could also be used to log pseudo-Boolean proofs in theory, in practice the required overhead makes this infeasible with current techniques. It seems that the focus on logging only disjunctive clauses mixes very poorly with what is arguably the main advantage of pseudo-Boolean solvers, namely the stronger format of the constraints they derive. There is some recent work on a proof checker *VeriPB* [GMN20b, Ver19] for pseudo-Boolean reasoning, which has been shown to admit efficient proof logging for some constraint programming techniques [EGMN20] and graph solving

algorithms [GMN20a, GMM⁺20], but there is currently no version that would support proof logging for the full range of techniques used by PB solvers in, e.g., the latest pseudo-Boolean solver competition [Pse16].

7.7. Cutting Planes and Proof Complexity

In the previous section we defined different flavours of the cutting planes proof system, and then showed how the conflict-driven SAT solving framework could be lifted from clauses to general 0-1 integer linear constraints. We now wish to proceed to discussing what is known about cutting planes from the point of view of proof complexity.

Before doing so, however, it will be helpful to describe a particular way of constructing crafted benchmarks that has played a crucial role in many of the recent advances on the theoretical side, namely *lifting*. The formal definition of lifted formulas seems to have appeared first in [BHP10], though our discussion below relies heavily on the later paper [HN12]. Readers more interested in seeing statements of concrete proof complexity results can safely skip ahead to Section 7.7.2.

7.7.1. Brief Detour: Lifted CNF Formulas

The idea behind lifting of functions is that we can take a base function f over some domain (which we will choose to be Boolean in this discussion) and extend it to a function over tuples from the same domain by combining it with an *indexing* or *selector* function that determines on which coordinates from the tuples f should be evaluated. More formally, given a positive integer $\ell \geq 2$ and a function $f : \{0, 1\}^m \rightarrow Q$ for some range Q , the *lift of length ℓ of f* is the function $Lift_\ell(f) : \{0, 1\}^{m \times \ell} \times [\ell]^m \rightarrow Q$ such that for any bit-vector $\{x_{i,j}\}_{i \in [m], j \in [\ell]}$ and any $y \in [\ell]^m$ the value of the lifted function is

$$Lift_\ell(f)(x, y) = f(x_{1,y_1}, x_{2,y_2}, \dots, x_{m,y_m}) . \quad (7.58)$$

In words, the y -vector selects which coordinates of the x -vector should be fed to f , as illustrated in Figure 7.21. We refer to the coordinates of the y -vector as *selector variables* and the coordinates of the x -vector as *main variables*, and we write

$$\text{select}_y(x) = (x_{1,y_1}, x_{2,y_2}, \dots, x_{m,y_m}) \quad (7.59)$$

to denote the substring of the x -vector selected by the y -coordinates. (With this notation, we have $\text{select}_y(x) = (x_{1,3}, x_{2,1}, x_{3,2}, x_{4,2})$ in Figure 7.21.)

We next extend this definition from functions to *relations*, or *search problems*. To this end, let S be any search problem defined as a subset of $\{0, 1\}^m \times Q$; that is, on any input $a \in \{0, 1\}^m$, the problem is to find some $q \in Q$ such that $(a, q) \in S$. Then we define the *lift of length ℓ of S* to be a new search problem $Lift_\ell(S) \subseteq \{0, 1\}^{m \times \ell} \times [\ell]^m \times Q$ with input domain $\{0, 1\}^{m \times \ell} \times [\ell]^m$ and output range Q such that for any bit-vector $\{x_{i,j}\}_{i \in [m], j \in [\ell]}$, any $y \in [\ell]^m$, and any $q \in Q$, it holds that

$$(x, y, q) \in Lift_\ell(S) \quad \text{if and only if} \quad (\text{select}_y(x), q) \in S . \quad (7.60)$$

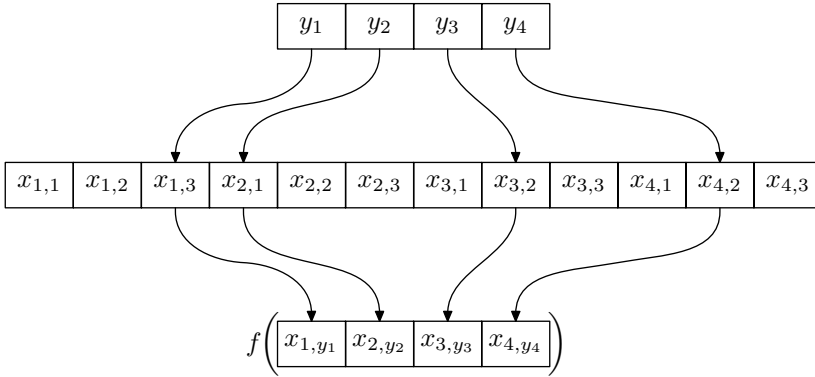

Figure 7.21. Illustration of lifted function (for $\ell = 3$, $m = 4$, and $y = (3, 1, 2, 2)$).

The general paradigm of lifting is to prove that if the function f or the search problem S is hard to compute in some weak computational model, then applying lifting produces a new function $Lift_\ell(f)$ or search problem $Lift_\ell(S)$ that is hard for a much stronger computational models (in which the original problems f or S might be trivial). This is sometimes referred to as *hardness escalation*.

The key behind several recent results establishing lower bounds for the cutting planes proof system has been to study lifted search problems defined in terms of CNF formulas using tools from the area of *communication complexity* [KN97, RY20]. Such lifted search problems are not themselves CNF formulas syntactically speaking, however, and therefore an additional step is needed where these lifted search problems are encoded back into CNF. Such *lifted CNF formulas*, as first introduced in [BHP10], can be constructed in the following way.

Definition 7.7.1 (Lift of CNF formula [BHP10]). Given any CNF formula F with clauses C_1, \dots, C_m over variables u_1, \dots, u_n , and any positive integer $\ell \geq 2$, the *lift of length ℓ* of F is a CNF formula $Lift_\ell(F)$ over $2\ell n$ variables denoted by $\{x_{i,j}\}_{i \in [n], j \in [\ell]}$ (*main variables*) and $\{y_{i,j}\}_{i \in [n], j \in [\ell]}$ (*selector variables*), consisting of the following clauses:

- For every $i \in [n]$, an *auxiliary clause*

$$y_{i,1} \vee y_{i,2} \vee \dots \vee y_{i,\ell} . \quad (7.61a)$$

- For every clause $C_i \in F$, where $C_i = u_{i_1} \vee \dots \vee u_{i_s} \vee \bar{u}_{i_{s+1}} \vee \dots \vee \bar{u}_{i_{s+t}}$ for some $i_1, \dots, i_{s+t} \in [n]$, and for every tuple $(j_1, \dots, j_{s+t}) \in [\ell]^{s+t}$, a *main clause*

$$\bar{y}_{i_1, j_1} \vee x_{i_1, j_1} \vee \dots \vee \bar{y}_{i_s, j_s} \vee x_{i_s, j_s} \vee \bar{y}_{i_{s+1}, j_{s+1}} \vee \bar{x}_{i_{s+1}, j_{s+1}} \vee \dots \vee \bar{y}_{i_{s+t}, j_{s+t}} \vee \bar{x}_{i_{s+t}, j_{s+t}} \quad (7.61b)$$

(where we will refer to C_i as the *original clause* corresponding to the *lifted clause* in (7.61b)).

Let us try to decipher what the notation in Definition 7.7.1 means. The purpose of the auxiliary clauses in (7.61a) is to make sure that in every variable subset $\{y_{i,j} \mid 1 \leq j \leq \ell\}$ at least one of the variables is true. We can think of the selector variables as encoding the vector $y \in [\ell]^m$ in the lifted search problem above. Since every pair $\bar{y}_{i,j} \vee x_{i,j}$ in a main clause (7.61b) is equivalent to an implication $y_{i,j} \rightarrow x_{i,j}$, we can rewrite (7.61b) as

$$(y_{i_1, j_1} \rightarrow x_{i_1, j_1}) \vee \cdots \vee (y_{i_{s+t}, j_{s+t}} \rightarrow \bar{x}_{i_{s+t}, j_{s+t}}) . \quad (7.62)$$

Now we can see that for every clause C_i , the auxiliary clauses encode that there is some choice of selector variables $y_{i,j}$ which are all true, and for this choice of selector variables the $x_{i,j}$ -variables in the lifted clause give us back the original clause C_i . It is easily verified that F is unsatisfiable if and only if $G = \text{Lift}_\ell(F)$ is unsatisfiable, and that if F is a k -CNF formula with m clauses, then G is a $\max(2k, \ell)$ -CNF formula with at most $m\ell^k + n$ clauses. In Figure 7.22 we show the lifted formula $\text{Lift}_2(\text{Peb}_{\Pi_2})$ of length 2 obtained from the pebbling contradiction in Figure 7.11b.³⁹

We remark that there are also other types of lifted CNF formulas in the literature, but Definition 7.7.1 (which, formally speaking, describes lifting using the *indexing gadget*), is the most commonly used version. In the most general sense, though, the pebbling formula with XOR-substitution in Figure 7.12 is also a form of lifted formula.

7.7.2. Cutting Planes Size, Length, and Space

Returning from the detour and focusing again on the cutting planes proof system, the *length* of a cutting planes refutation is the total number of lines/inequalities in it, and the *size* also sums the sizes of all coefficients (i.e., the bit size of representing them). The natural generalization of clause space in resolution is to define (*line*) *space* as the maximal number of linear inequalities needed in memory during a refutation, since every clause is translated into a linear inequality. There is no useful analogue of width/degree known for cutting planes.⁴⁰

Cutting planes can simulate resolution efficiently with respect to length/size and space simultaneously by mimicking the resolution steps one by one. Hence, just as for polynomial calculus we can conclude that the worst-case upper bounds for resolution carry over to cutting planes.

The cutting planes proof system is strictly stronger than resolution with respect to length and size, since cutting planes can refute pigeonhole principle formulas (7.7a)–(7.7b) efficiently [CCT87]. The reason for this is that in contrast to resolution (and polynomial calculus), cutting planes can count. At a high level, pigeonhole principle formulas are refuted simply but summing up the number of

³⁹A very closely related CNF formula, but complemented with clauses $\bar{y}_{i,j} \vee \bar{y}_{i,j'}$ for $1 \leq j < j' \leq \ell$ to enforce that assignments satisfying clauses (7.61a) set only one variable $y_{i,j}$ to true, can be generated in DIMACS format by the tool *CNFgen* [LENV17, CNF] with the command `line cnfgen peb pyramid $\langle h \rangle$ -T lift 2` (for pyramid graphs of height h). Whether these extra clauses are added or not typically does not affect the proof complexity bounds we can obtain for lifted formulas.

⁴⁰That is, one can certainly define width measures, but no such measure is known to have any interesting relation to other complexity measures for cutting planes.

$$\begin{array}{l}
(y_{u,1} \vee y_{u,2}) \\
\wedge (y_{v,1} \vee y_{v,2}) \\
\wedge (y_{w,1} \vee y_{w,2}) \\
\wedge (y_{x,1} \vee y_{x,2}) \\
\wedge (y_{y,1} \vee y_{y,2}) \\
\wedge (y_{z,1} \vee y_{z,2}) \\
\wedge (\bar{y}_{u,1} \vee x_{u,1}) \\
\wedge (\bar{y}_{u,2} \vee x_{u,2}) \\
\wedge (\bar{y}_{v,1} \vee x_{v,1}) \\
\wedge (\bar{y}_{v,2} \vee x_{v,2}) \\
\wedge (\bar{y}_{w,1} \vee x_{w,1}) \\
\wedge (\bar{y}_{w,2} \vee x_{w,2}) \\
\wedge (\bar{y}_{u,1} \vee \bar{x}_{u,1} \vee \bar{y}_{v,1} \vee \bar{x}_{v,1} \vee \bar{y}_{x,1} \vee x_{x,1}) \\
\wedge (\bar{y}_{u,1} \vee \bar{x}_{u,1} \vee \bar{y}_{v,1} \vee \bar{x}_{v,1} \vee \bar{y}_{x,2} \vee x_{x,2}) \\
\wedge (\bar{y}_{u,1} \vee \bar{x}_{u,1} \vee \bar{y}_{v,2} \vee \bar{x}_{v,2} \vee \bar{y}_{x,1} \vee x_{x,1}) \\
\wedge (\bar{y}_{u,1} \vee \bar{x}_{u,1} \vee \bar{y}_{v,2} \vee \bar{x}_{v,2} \vee \bar{y}_{x,2} \vee x_{x,2}) \\
\wedge (\bar{y}_{u,2} \vee \bar{x}_{u,2} \vee \bar{y}_{v,1} \vee \bar{x}_{v,1} \vee \bar{y}_{x,1} \vee x_{x,1}) \\
\wedge (\bar{y}_{u,2} \vee \bar{x}_{u,2} \vee \bar{y}_{v,1} \vee \bar{x}_{v,1} \vee \bar{y}_{x,2} \vee x_{x,2}) \\
\wedge (\bar{y}_{u,2} \vee \bar{x}_{u,2} \vee \bar{y}_{v,2} \vee \bar{x}_{v,2} \vee \bar{y}_{x,1} \vee x_{x,1}) \\
\wedge (\bar{y}_{u,2} \vee \bar{x}_{u,2} \vee \bar{y}_{v,2} \vee \bar{x}_{v,2} \vee \bar{y}_{x,2} \vee x_{x,2}) \\
\wedge (\bar{y}_{v,1} \vee \bar{x}_{v,1} \vee \bar{y}_{w,1} \vee \bar{x}_{w,1} \vee \bar{y}_{y,1} \vee x_{y,1}) \\
\wedge (\bar{y}_{v,1} \vee \bar{x}_{v,1} \vee \bar{y}_{w,1} \vee \bar{x}_{w,1} \vee \bar{y}_{y,2} \vee x_{y,2}) \\
\wedge (\bar{y}_{v,1} \vee \bar{x}_{v,1} \vee \bar{y}_{w,2} \vee \bar{x}_{w,2} \vee \bar{y}_{y,1} \vee x_{y,1}) \\
\wedge (\bar{y}_{v,1} \vee \bar{x}_{v,1} \vee \bar{y}_{w,2} \vee \bar{x}_{w,2} \vee \bar{y}_{y,2} \vee x_{y,2}) \\
\wedge (\bar{y}_{v,2} \vee \bar{x}_{v,2} \vee \bar{y}_{w,1} \vee \bar{x}_{w,1} \vee \bar{y}_{y,1} \vee x_{y,1}) \\
\wedge (\bar{y}_{v,2} \vee \bar{x}_{v,2} \vee \bar{y}_{w,1} \vee \bar{x}_{w,1} \vee \bar{y}_{y,2} \vee x_{y,2}) \\
\wedge (\bar{y}_{v,2} \vee \bar{x}_{v,2} \vee \bar{y}_{w,2} \vee \bar{x}_{w,2} \vee \bar{y}_{y,1} \vee x_{y,1}) \\
\wedge (\bar{y}_{v,2} \vee \bar{x}_{v,2} \vee \bar{y}_{w,2} \vee \bar{x}_{w,2} \vee \bar{y}_{y,2} \vee x_{y,2}) \\
\wedge (\bar{y}_{x,1} \vee \bar{x}_{x,1} \vee \bar{y}_{y,1} \vee \bar{x}_{y,1} \vee \bar{y}_{z,1} \vee x_{z,1}) \\
\wedge (\bar{y}_{x,1} \vee \bar{x}_{x,1} \vee \bar{y}_{y,1} \vee \bar{x}_{y,1} \vee \bar{y}_{z,2} \vee x_{z,2}) \\
\wedge (\bar{y}_{x,1} \vee \bar{x}_{x,1} \vee \bar{y}_{y,2} \vee \bar{x}_{y,2} \vee \bar{y}_{z,1} \vee x_{z,1}) \\
\wedge (\bar{y}_{x,1} \vee \bar{x}_{x,1} \vee \bar{y}_{y,2} \vee \bar{x}_{y,2} \vee \bar{y}_{z,2} \vee x_{z,2}) \\
\wedge (\bar{y}_{x,2} \vee \bar{x}_{x,2} \vee \bar{y}_{y,1} \vee \bar{x}_{y,1} \vee \bar{y}_{z,1} \vee x_{z,1}) \\
\wedge (\bar{y}_{x,2} \vee \bar{x}_{x,2} \vee \bar{y}_{y,1} \vee \bar{x}_{y,1} \vee \bar{y}_{z,2} \vee x_{z,2}) \\
\wedge (\bar{y}_{x,2} \vee \bar{x}_{x,2} \vee \bar{y}_{y,2} \vee \bar{x}_{y,2} \vee \bar{y}_{z,1} \vee x_{z,1}) \\
\wedge (\bar{y}_{x,2} \vee \bar{x}_{x,2} \vee \bar{y}_{y,2} \vee \bar{x}_{y,2} \vee \bar{y}_{z,2} \vee x_{z,2}) \\
\wedge (\bar{y}_{z,1} \vee \bar{x}_{z,1}) \\
\wedge (\bar{y}_{z,2} \vee \bar{x}_{z,2})
\end{array}$$

Figure 7.22. Lifting of the pebbling contradiction in Figure 7.11b.

pigeons and holes, after which the observation can immediately be made that there are too many pigeons to fit into the holes. Cutting planes and polynomial calculus are incomparable with respect to size, i.e., for both proof systems one can find hard formulas that are easy for the other system. PHP formulas are an example of formulas that are hard for polynomial calculus but easy for cutting planes. In the other direction, it was recently shown in [GKRS19] that there are formulas that are easy for polynomial calculus (and even Nullstellensatz) over any field, but are hard for cutting planes. These formulas are obtained by lifting as in Section 7.7.1, but the construction is a bit too involved to describe here.

The length measure in cutting planes does not consider the size of the coefficients. It is natural to ask if, and if so how, the power of cutting planes changes when coefficients are required to be of limited size. In [BC96] it was shown that the size of the coefficients need not be larger than of exponential magnitude if one is willing to tolerate a possible polynomial blow-up in proof length. One can define a subsystem of cutting planes where all inequalities in the proofs have to have coefficients of at most polynomial magnitude measure in the input size (i.e., coefficients should be representable with a logarithmic number of bits), and this subsystem is sometimes denoted CP^* in the literature. Understanding the power of CP^* remains wide open.

Open Problem 7.14. Decide whether cutting planes with coefficients of polynomial magnitude (CP^*) can simulate general cutting planes with at most a polynomial blow-up in proof length, or whether there are formulas for which cutting planes with unbounded coefficients is superpolynomially stronger.

When it comes to space, cutting planes is very much stronger than both resolution and polynomial calculus — it was shown in [GPT15] that any unsatisfiable CNF formula (and, in fact, any set of inconsistent 0-1 linear inequalities) can be refuted in constant line space 5 by cutting planes!⁴¹ This proof works by starting with a linear inequality/hyperplane that cuts away the all-zero point of the Boolean hypercube $\{0, 1\}^n$ from the candidate list of satisfying assignments (there has to exist a clause falsified by this assignment, from which the hyperplane can be obtained), and then uses 4 auxiliary hyperplanes to remove further points $\alpha \in \{0, 1\}^n$ one by one in lexicographical order until all possible assignments have been eliminated, showing that the formulas is unsatisfiable. During the course of this refutation the size of the coefficients of the hyperplanes become exponentially large, however, which the line space measure does not charge for. A very interesting question is what happens if coefficients are limited to be of polynomial magnitude, i.e., if we consider the space complexity of CP^* refutations.

Open Problem 7.15. Determine whether cutting planes with coefficients of polynomial magnitude (CP^*) is as strong as general cutting planes with respect to space, or whether there exist families of formulas that require superconstant space in CP^* .

This question is completely open, and it cannot currently be ruled out that line space 5 would be sufficient. All that is known is that if we restrict the cutting planes proofs to have coefficients of at most constant size, then there are formulas that require $\Omega(\log \log \log n)$ space [GPT15].

If also coefficient sizes are counted, i.e., if one measures the *total space* of cutting planes refutations, then it is not hard to show a linear lower bound (for instance by combining [BSW01] and [BNT13]) and a quadratic worst-case upper bound is immediately implied by resolution. For resolution this quadratic upper bound is known to be tight by [BGT14], but to the best of our knowledge no superlinear lower bounds are known on total space in cutting planes.

Proving space lower bounds, if they exist, seems challenging. It might be worth noting in this context that already cutting planes with coefficients of absolute size 2 (which is the minimum needed to simulate resolution) is quite powerful — this is sufficient to construct space-efficient refutations of pigeonhole principle formulas [GPT15] (when space is measured as the number of inequalities in memory).

For a long time, essentially the only formulas that were known to be hard for the cutting planes proof system with respect to length/size were the *clique-cocklique formulas* (also referred to as *clique-colouring formulas*) claiming (the negation of) that “a graph with an m -clique cannot be $(m - 1)$ -colourable.”

⁴¹Recall that this means that the formula is kept on a read-only input memory, and the working memory never contain more than 5 inequalities at any given time.

The formula consists of clauses

$$q_{k,1} \vee q_{k,2} \vee \cdots \vee q_{k,n} \quad [\text{some vertex is the } k\text{th member of the clique}] \quad (7.63a)$$

$$\bar{q}_{k,i} \vee \bar{q}_{k',i} \quad [\text{clique members are uniquely defined}] \quad (7.63b)$$

$$p_{i,j} \vee \bar{q}_{k,i} \vee \bar{q}_{k',j} \quad [\text{clique members are neighbours}] \quad (7.63c)$$

$$r_{i,1} \vee r_{i,2} \vee \cdots \vee r_{i,m-1} \quad [\text{every vertex } i \text{ has a colour}] \quad (7.63d)$$

$$\bar{p}_{i,j} \vee \bar{r}_{i,\ell} \vee \bar{r}_{j,\ell} \quad [\text{neighbours have distinct colours}] \quad (7.63e)$$

where variables $p_{i,j}$ are indicators of the edges in an n -vertex graph, variables $q_{k,i}$ identify the members of an m -clique in the graph, and variables $r_{i,\ell}$ specify a colouring of the vertices, for indices ranging over $1 \leq i < j \leq n$, $1 \leq k < k' \leq m$, and $1 \leq \ell \leq m - 1$.⁴²

Pudlák [Pud97] proved that these formulas are hard by using a so-called *Craig interpolation* argument, specifically tailored to work for formulas with the right structure. He showed that from any short cutting planes refutation of the formula one can extract a small monotone circuit for clique, which reduces the problem to a question about size lower bounds for monotone circuits. (For completeness, we mention that essentially the same techniques were used in [HC99] to obtain exponential lower bounds for so-called *broken mosquito screen formulas*, but due to space constraints we will not discuss these formulas further here.)

It has been conjectured that Tseitin formulas (as in Figure 7.9) should require long cutting planes refutations, since it should be hard to count mod 2 using linear inequalities. It has seemed even more likely that random k -CNF formulas should be exponentially hard. The last few years have seen some very exciting progress on cutting planes lower bounds. In a breakthrough result, exponential length lower bounds for random CNF formulas of *logarithmic* width were obtained in [HP17, FPPR17]. Unfortunately, currently it does not seem possible to apply the techniques used in these papers to formulas of constant width.

Open Problem 7.16. Prove length lower bounds for cutting planes refutations of random k -CNF formulas for some constant $k \geq 3$.

Another intriguing result established in [GGKS18] is that if one starts with k -CNF formulas (for $k = O(1)$) that require large resolution width, and then applies lifting as described in Section 7.7.1, then this yields formulas which are weakly exponentially hard for cutting planes. Very recently, the cutting planes proof system was shown to be non-automatable, i.e., not to admit efficient proof search, unless $P = NP$ [GKMP20]. As a complement to these results indicating weaknesses of cutting planes, another recent result revealing some of the (quite unexpected) strength of this method of reasoning is that Tseitin formulas have cutting planes refutations of quasipolynomial⁴³ size [DT20]. Interestingly, this

⁴²A closely related version of this formula, but with extra clauses $\bar{q}_{k,i} \vee \bar{q}_{k,j}$ for $1 \leq i < j \leq n$ and $\bar{r}_{i,\ell} \vee \bar{r}_{i,\ell'}$ for $1 \leq \ell < \ell' \leq m - 1$, so that the assignments satisfying the clauses (7.63a) and (7.63d) must set a single variable to true, can be generated by *CNFgen* with the command line `cnfgen cliquecoloring (n) (m) (m-1)` (for the claim that an $(m - 1)$ -colourable n -vertex graph can also have an m -clique). More generally, `cnfgen cliquecoloring (n) (k) (c)` yields a formula claiming that there exists an n -vertex graph that is both c -colourable and has a k -clique. Whether the extra binary clauses discussed above are added or not typically does not affect what proof complexity bounds can be established for these formulas.

⁴³That is, refutations of size $\exp((\log n)^\kappa)$ for some constant κ .

result was obtained by studying the proof system *stabbing planes* [BFI⁺18], which very roughly can be described as an extension of pseudo-Boolean reasoning where one can branch over the truth value not only of variables but of general 0-1 linear inequalities. This proof system is powerful enough to model the kind of reasoning carried out in mixed integer linear programming (MIP) solvers, and appears to be much stronger than cutting planes. However, in some settings it is possible to translate proofs from stabbing planes to cutting planes in a somewhat efficient manner, which is how the result in [DT20] is obtained.

7.7.3. Size-Space Trade-offs for Cutting Planes

Given our very limited understanding of cutting planes, it is perhaps not so surprising that not very much has known about size-space trade-offs for this proof system until quite recently.

It was shown in [GP18a] that short cutting planes refutations of a lifted version of Tseitin formulas on expanders must have large space, but this does not provide a real trade-off since it seems likely that such short refutations do not exist at all, regardless of their space complexity. Earlier, [HN12] proved that short cutting planes refutations of a lifted version of pebbling contradictions (similar to the formula in Figure 7.22) over one particular family of DAGs require large space — a result that was strengthened and generalized by [GP18a] — and for pebbling contradictions such short refutations do exist. Interestingly, and somewhat unexpectedly, all of these results follow from reductions to *communication complexity* [KN97, RY20]. The state of knowledge regarding pebbling contradictions is much worse here than for resolution and polynomial calculus, however — for the latter two proof systems we know of general methods to translate pebbling trade-offs for (essentially) arbitrary graphs into proof complexity size-space trade-offs.

Since [GPT15] established that any unsatisfiable CNF formula has a constant-space refutation, the lower bounds for pebbling contradictions in [HN12, GP18a] yield true size-space trade-off results for cutting planes, with formulas that can be refuted in both small size and small space, but where optimizing both measures simultaneously is impossible. However, the “space-efficient” refutations have coefficients of exponential size. It would be more convincing to obtain trade-offs where the small-space refutations also have small coefficients. Such results would follow if known resolution and polynomial calculus results for pebbling contradictions or Tseitin formulas over long, narrow grids could be extended also to cutting planes, since the resolution refutations establishing the upper bounds in these trade-offs can certainly be simulated by cutting planes with constant-size coefficients. It seems plausible that such trade-off results should hold for these formulas even with respect to cutting planes, but proving this has remained out of reach.

However, using lifted pebbling formulas as in Section 7.7.1, it can be proven that there are formulas which have cutting planes proofs with coefficients of constant size in either small length or small space, but for which any small-space refutation must require superpolynomial length even if the coefficients in the proof are of unbounded size. An example of such a result from [dRNV16] is that there exist CNF formulas $\{F_N\}_{N=1}^{\infty}$ of size $\Theta(N)$ such that:

- F_N can be refuted by cutting planes with constant-size coefficients in size $O(N)$ and (total) space $O(N^{2/5})$.
- F_N can be refuted by cutting planes with constant-size coefficients in (total) space $O(N^{1/40})$ and size $2^{O(N^{1/40})}$.
- Any cutting planes refutation of F_N , even with coefficients of unbounded size, in line space less than $N^{1/20-\epsilon}$ (for some small enough constant $\epsilon > 0$) requires length greater than $2^{\Omega(N^{1/40})}$.

In fact, this trade-off result holds simultaneously for resolution, polynomial calculus, and cutting planes, although for resolution and polynomial calculus the parameters are much worse than in the results surveyed in Sections 7.4.4 and 7.5.6.

As discussed above, determining the precise relation between general cutting planes and the subsystem CP^* with coefficients of at most polynomial magnitude remains open, but what is known regarding Open problems 7.14 and 7.15 can also be stated in the form of a trade-off result. Namely, it was recently shown in [dRMN⁺20] that there are formulas which exhibit strong length-space trade-offs for CP^* but not for general cutting planes. In more detail, it is possible to construct a family of CNF formulas $\{F_n\}_{n=1}^{\infty}$ such that:

- CP^* , and even resolution, can refute F_n in length $\tilde{O}(n)$ (this “big-O-tilde” notation hides polylogarithmic factors in n).
- Cutting planes can refute F_n in length $\tilde{O}(n^2)$ and line space $O(1)$,
- For any CP^* refutation in length L and line space s it must hold that

$$s \cdot \log L = \Omega(n / \log^2 n) . \quad (7.64)$$

In order to make this into a “true trade-off” in the sense of [dRNV16], we would also like to show that CP^* can refute these formulas in small space. This is not known, however, and in fact it is conceivable, or even seems likely, that any CP^* refutation, regardless of the length, would require line space $\Omega(n / \log^2 n)$ for these formulas. Proving such a space lower bound would seem to require new techniques, however.

7.7.4. Subsystems of Cutting Planes

Recall that towards the end of Section 7.6.1 we introduced the following variants of the cutting planes proof system (following [VEGC⁺18]), loosely corresponding to different approaches to pseudo-Boolean solving:

General cutting planes: Rules (7.27a)–(7.27c) and (7.34).

Cutting planes with resolution: As general cutting planes above, except that all applications of (7.27b) and (7.27c) have to be combined into applications of the generalized resolution rule (7.33).

Cutting planes with saturation: Rules (7.27a)–(7.27c) and (7.36b) (with no restrictions on the linear combinations).

Cutting planes with saturation and resolution: As the version of cutting planes with saturation above, except that all applications of the rules (7.27b) and (7.27c) have to be combined instances of generalized resolution (7.33).

As mentioned previously, the general cutting planes proof system is implicationally complete, meaning that if a set of linear inequalities imply some other linear inequality, then the latter inequality can also be derived syntactically. This is *not* true for the other variants of cutting planes listed above. Probably already since [Hoo88, Hoo92] it has been known that cutting planes with division and resolution collapses to the resolution proof system when the input is presented in CNF. It is not hard to show that this holds also if division is replaced by saturation (while restricting linear combinations to general resolution). Thus, subsystems of cutting planes with the generalized resolution rule rather than unrestricted linear combinations can be exponentially weaker than general cutting planes.

However, for cutting planes with saturation it turns out that the generalized resolution rule is not the problem. It was shown in [GNY19], building on [VEGC⁺18], that if the saturation rule is used, then any refutation using unrestricted linear combinations can be transformed into a refutation using only the generalized resolution rule with at most a small polynomial blow-up in the proof length.⁴⁴ Phrased differently, for cutting planes with saturation it is not really a restriction to limit linear combinations to general resolution.

In a pseudo-Boolean solving context it is natural that the generalized resolution rule is used when taking linear combinations of constraints. Such derivation steps arise naturally during conflict analysis, as has been discussed above, and it is hard to see how to devise good heuristics for non-cancelling linear combinations (although it would be very nice if this could be done). A relevant question, therefore, is how the division and saturation rules compare to each other if cutting planes is restricted to generalized resolution. Two results in [GNY19], which we will discuss next, indicate that using division or saturation might lead to incomparable proof systems.

In one direction, there are pseudo-Boolean formulas which have linear-length refutations in cutting planes with division and resolution but require exponential-length refutations in cutting planes with saturation even if there are no restrictions on the linear combinations.

In the other direction, simulating one generalized resolution step followed by a saturation step can take an unbounded number of steps in general cutting planes with division and unrestricted linear combinations. Since the example is simple, we present it here. Let R be a positive integer and consider the two constraints

$$Rx + Ry + \sum_{i=1}^R z_i \geq R \quad (7.65a)$$

and

$$Rx + R\bar{y} + \sum_{i=R+1}^{2R} z_i \geq R . \quad (7.65b)$$

Resolving these two constraints yields

$$2Rx + \sum_{i=1}^{2R} z_i \geq R , \quad (7.66)$$

⁴⁴To be technically precise, note that this is a claim about proof *length* and not about *size*. There is no guarantee in [GNY19] as to what happens to the size of the coefficients.

which after saturation becomes

$$Rx + \sum_{i=1}^{2R} z_i \geq R . \quad (7.67)$$

However, deriving (7.67) from (7.65a) and (7.65b) in general cutting planes (with division and arbitrary linear combinations) can be shown to require $\Omega(\sqrt{R})$ applications of the division rule. Note that this is exponential in the number of bits of the coefficients. It is important to understand that this does *not* show that cutting planes with saturation can be superpolynomially stronger than cutting planes with division — to obtain such a separation, we would need to exhibit a family of pseudo-Boolean formulas for which refutations using division have to be superpolynomially longer than refutations using saturation. What the above example does show, however, is that if CP with division and resolution polynomially simulates CP with saturation and resolution, then such a simulation is unlikely to proceed line by line and instead has to work by some kind of global argument.

Open Problem 7.17. Are there unsatisfiable pseudo-Boolean formulas for which cutting planes with saturation can produce shorter refutations than cutting planes with division?⁴⁵

We can use the above results concerning different versions of cutting planes to understand better the potential and limitations of different approaches to pseudo-Boolean solving.

As we have already discussed, one problem with current pseudo-Boolean solvers is that they perform poorly on CNF inputs. The explanation for this is that if the input is in CNF, then the solvers cannot possibly go beyond resolution, regardless of what heuristics they use. Thus, while solvers that implement native pseudo-Boolean reasoning, such as *Sat4j* [LP10] and *RoundingSat* [EN18], can solve pigeonhole principle formulas very efficiently, they crucially depend on the input being given in pseudo-Boolean form as linear inequalities:

$$p_{i,1} + p_{i,2} + \cdots + p_{i,n} \geq 1 \quad [\text{every pigeon } i \text{ gets a hole}] \quad (7.68a)$$

$$\bar{p}_{1,j} + \bar{p}_{2,j} + \cdots + \bar{p}_{n+1,j} \geq n \quad [\text{no hole } j \text{ gets two pigeons}] \quad (7.68b)$$

If the input is instead presented in CNF, with the cardinality constraints in Equation (7.68b) encoded as the clauses in Equation (7.7b), then the solvers will run in exponential time. The same holds for subset cardinality formulas — if a pseudo-Boolean solver is fed the formula encoded as cardinality constraints, then it runs fast, but on the CNF version in Figure 7.10b it cannot possibly do better than the exponential lower bound on resolution length in [MN14].

An obvious algorithmic challenge is to make pseudo-Boolean solvers reason more efficiently with CNF inputs, so that they could, e.g., detect and use the cardinality constraints hidden in (7.7a)–(7.7b) to get performance comparable to

⁴⁵Here we want the constraints in the pseudo-Boolean formula to be in saturated form, so that the separation would not be a consequence of obfuscated input, but would provide an example where reasoning with saturation during the proof search can be more efficient than reasoning with division, as in the derivation of (7.67) from (7.65a) and (7.65b).

when the input is given as (7.68a)–(7.68b). It is possible to do a preprocessing step to recover cardinality constraints encoded in CNF, and for pigeonhole principle formulas and subset cardinality formulas this works well [BLLM14], but full preprocessing of the input to try to detect cardinality constraints does not seem to be an efficient approach in general. A different idea is to try to perform cardinality constraint detection “on the fly” during the proof search, as proposed in [EN20], but although this seems like a more promising approach it, too, is not yet efficient enough to be used in a general pseudo-Boolean solver. Yet another possibility would be to develop better heuristics for solvers using division and unrestricted linear combinations, since we know that with such rules it is always possible, at least in theory, to rewrite CNF constraints in some other pseudo-Boolean form when this is desirable.

The sensitivity to the input format is not the only challenge in the context of pseudo-Boolean reasoning, however. Another challenging benchmark family are the even colouring (EC) formulas discussed in Section 7.5.4. The pseudo-Boolean encoding of these formulas is obtained by converting every equality constraint to a pair of inequalities, so that, e.g., the first constraint $u + w = 1$ in Figure 7.14b is translated to the inequalities $u + w \geq 1$ and $\bar{u} + \bar{w} \geq 1$, and the second equality $u + z = 1$ is translated to $u + z \geq 1$ and $\bar{u} + \bar{z} \geq 1$, et cetera.

If the number of edges is odd, so that the formula is unsatisfiable, then cutting planes can sum the PB constraints with positive literals over all vertices to derive $2 \cdot \sum_{e \in E(G)} e \geq |E(G)|$ and then divide by 2 and round up to obtain $\sum_{e \in E(G)} e \geq (|E(G)| + 1)/2$. By instead summing up all constraints with negated literals and dividing by 2 one obtains $\sum_{e \in E(G)} \bar{e} \geq (|E(G)| + 1)/2$, and adding these two inequalities cancels all variables and leaves $0 \geq 1$.

One interesting aspect to observe here is that in contrast to pigeonhole principle and subset cardinality formulas, it is essential in the above argument that variables are integer-valued. To see the difference, suppose that we are given a PHP or subset cardinality formula encoded as linear constraints. Then for cutting planes it is sufficient to simply add up the inequalities to derive a contradiction. No integer-based reasoning is needed. Even if we allow putting fractional pigeons into fractional holes, there is no way one can make a pigeon mass of $n + 1$ fit into holes of total capacity n . This set of linear inequalities is unsatisfiable even over the rationals, i.e., the polytope defined by the constraints is empty, and so it is sufficient to just solve the linear programming relaxation. Similarly, for subset cardinality formulas there is no way $4n + 1$ variables could have a total “true mass” of at least $2n + 1$ and a total “false mass” of $2n + 1$ simultaneously. But for collections of linear constraints as in Figure 7.14b, assigning all edges value $\frac{1}{2}$ yields a satisfying fractional solution. The polytope defined by the linear inequalities is *not* empty, but it does not contain any integer points. Hence, refuting EC formulas in cutting planes crucially requires that the solvers use saturation or division (or some other form of integer-based reasoning).

Experiments in [EGCNV18] show that even colouring formulas and some other crafted formulas are much harder for pseudo-Boolean solvers than the cutting planes upper bound would suggest, which seem to indicate that the solvers are still quite far from using the full power of cutting planes reasoning.⁴⁶ It also

⁴⁶To balance this picture somewhat — since this survey chapter might be perceived as taking

seems to be the case that the division-based solver *RoundingSat* performs clearly better than *Sat4j*, and indeed it is not easy to see what a short argument using saturation for the unsatisfiability of even colouring formulas would be. It is tempting to conjecture that EC formulas generated from the right kind of graphs should be exponentially hard for cutting planes with saturation, but proving such a lower bound appears to be beyond current techniques.

Open Problem 7.18. Is it true that even colouring formulas over random 6-regular graphs with an odd number of vertices (so that the formulas are unsatisfiable) are exponentially hard for cutting planes with saturation asymptotically almost surely?

7.7.5. Further Algebraic and Semialgebraic Proof Systems

Nullstellensatz, polynomial calculus, and cutting planes have been generalized to other algebraic and semialgebraic proof systems that are more powerful in several ways. These include the *Lovász-Schrijver* proof system [LS91], the *Sherali-Adams* proof system [SA90], the *Positivstellensatz* proof system [GV01], a system combining Lovász-Schrijver and cutting planes [Pud99], and the *Lasserre* proof system [Las01a]. All of these are methods for reasoning about solutions to polynomial equations. By adapting them to prove the nonexistence of 0-1 solutions for a system of polynomials, they can be used as proof systems for refuting Boolean formulas. There has been extensive work on these systems. For an early expository account of the Positivstellensatz and the Lovász-Schrijver systems, see [GHP02a]. The survey papers [Lau01, CT12] discuss the Lovász-Schrijver, Sherali-Adams, and Lasserre systems.

The *Sum-of-Squares* proof system describes methods for establishing the (non-)existence of general solutions (not just 0-1 solutions) to systems of polynomial equalities over the real numbers. They are similar to the Positivstellensatz system. Sum-of-Squares systems were introduced by [Sho87, Nes00, Par00, Las01b]; see also the survey [BS14]. Other, very strong, algebraic proof systems are the *ideal proof system (IPS)* introduced by Grochow and Pitassi [GP18b] and the noncommutative ideal proof system of [LTW18]. An exposition of these systems is in [PT16].

A recent survey covering proof complexity and Sherali-Adams and Sum-of-Squares is given by [FKP19]. For another survey including the above topics, see [Raz16b]. Not all of the above-discussed systems are propositional proof systems in the sense of Cook and Reckhow; in particular, the validity of IPS proofs can be checked by randomized polynomial time algorithms, but no deterministic polynomial algorithm is known.

An orthogonal family of proof systems — which we mention here anyway because of the connection to cutting planes — are based on *ordered binary decision diagrams (OBDDs)*, which can provide efficient and flexible representations of Boolean functions serving as an alternative to the CNF representation

a rather dim view of the state of the art in pseudo-Boolean solving — we want to stress that there are also applications [LR18, LBD⁺20, SDNS20] where pseudo-Boolean solvers are doing very well, and for some of these applications it seems that the power of the cutting planes proof system is crucial to get better performance than what is offered by CDCL SAT solving, algebraic approaches, constraint programming, and/or mixed integer linear programming.

(see [Bry92]). The paper [AKV04] proposed the use of OBDDs in proof systems, showing they can polynomially simulate resolution and cutting planes with small coefficients. Lower bounds on OBDD-based proof systems were shown in [AKV04], and then by [Kra08, Seg08]. Further lower bounds and simulation results have been obtained in [GZ03, TSZ10, Jĭ1, IKRS17, BIKS18].

7.8. Extended Resolution and DRAT Proof Systems

We now switch our focus to proof systems that are substantially stronger than the earlier considered systems of resolution, Nullstellensatz, polynomial calculus, and cutting planes. Just to give an overview of where we are going, the present section discusses DRAT-style proofs and extended resolution. These systems are directly based on resolution and CDCL solvers, and are intended for use in automated proof systems. Section 7.9 then covers Frege proof systems, which is a generalization of resolution that sits between resolution and extended resolution in proof strength. Extended resolution and Frege proof systems are both stronger than the other proof systems that we have surveyed earlier — in fact, they can give polynomial-size proofs of all the combinatorial principles and counting principles discussed earlier. The only family of formulas discussed so far for which it is not known whether they possess polynomial-size Frege and/or extended resolution proofs are random k -CNF formulas; the usual conjecture is that they do not. Section 7.10 discusses bounded-depth Frege systems, which is a restricted form of Frege systems. Bounded-depth Frege systems are weaker than full Frege systems but stronger than resolution, and are not comparable to cutting planes, in that bounded-depth Frege is more effective on some propositional formulas, but less effective on others.

Our treatment of these topics is theoretical in orientation and relatively brief, partly due to space constraints and partly since these proof systems have yet to be widely used in practical SAT solvers. The exception is that DRAT and similar systems are becoming widely used for proof logging and verification.

Extended resolution (ER) was originally introduced by Tseitin [Tse68] to allow resolution to work with more general formulas than CNFs. The intuition is that an extended resolution refutation should be allowed to introduce proof lines of the form

$$x \leftrightarrow \varphi , \tag{7.69}$$

where x is a *new variable* and φ is an arbitrary propositional formula. The proviso that x is new means that x does not appear in any axiom, in φ , or earlier in the derivation. The extension rule can be used in derivations as well, but then x also must not appear in the formula being derived.

The extension rule (7.69) is stated in the form that will be employed in extended Frege systems, which are defined in Section 7.9. Since resolution systems are constrained to work with clauses, *extended resolution* uses instead a restricted, clausal form of the extension rule. If a and b are literals, and x is a new variable, then the extension rule allows inferring the three clauses

$$\bar{x} \vee a \quad \bar{x} \vee b \quad \bar{a} \vee \bar{b} \vee x \tag{7.70}$$

which express that $x \leftrightarrow (a \wedge b)$. An *extended resolution derivation* is a derivation in which both the resolution rule (7.2) and the extension rule (7.70) are allowed. Using (7.70) multiple times, with multiple new variables, makes it possible to simulate efficiently the action of the full extension inference of (7.69). Consequently, extended resolution simulates (and is simulated by) the extended Frege proof system which uses (7.69).

It is almost immediate that adding the extension rule preserves soundness, since if there is a satisfying assignment to a set of clauses, the satisfying assignment can be extended to give the new variable x the (unique) truth value which satisfies (7.69) or (7.70). Therefore, extended resolution is sound and complete. However, resolution does not polynomially simulate extended resolution. Instead, the addition of extension variables makes the proof system exponentially more powerful. The classic example of this are the pigeonhole principle formulas, which was shown to have polynomial-size extended resolution proofs in [CR79], but to require exponential-size resolution proofs in [Hak85].

The fact that the extension rule is so powerful raises the question of whether practical, CDCL-based, SAT solvers can incorporate the extension rule. If this could be done well, the gains would be enormous, as this would in principle give CDCL the possibility to refute CNFs using the full power of extended resolution. There have been a number of attempts to do so, but the published literature on this is fairly sparse, principally [SB06, AKS10, Hua10, MHB13]. So far, the extension rule has been shown to be useful in limited situations; however, it has not been successful enough to be generally included in SAT solvers. The main bottleneck appears to be that we have no good heuristics for how to choose extension formulas φ for use in the extension rule. A second bottleneck is that even if good choices are made for extension formulas, it appears to be difficult for the CDCL solver to use the new extension variables advantageously for decision literals, unit propagation and clause learning.

In recent years, a new application for the extension rule has appeared, driven by the desire to have SAT solvers output verifiable proofs of correctness of the computations. Section 7.3.1 discussed reverse unit propagation (RUP) proofs as proof traces. RUP proofs, however, are not powerful enough to handle all the preprocessing and inprocessing techniques used by modern SAT solvers. A more powerful *resolution asymmetric tautology* (RAT) inference rule has been developed to supplant RUP, and has later been complemented with a deletion rule in the proof traces to yield the *DRAT* proof system.

The RAT rule differs from RUP rules or resolution in that it does not respect implication. That is to say, it is possible to use a RAT rule to derive a clause C from a set of clauses F even if F does not imply C . Instead, RAT inferences only preserve consistency, in that we are assured $F \cup C$ is consistent if and only if F is. This property is called *equisatisfiability*. As we shall see, examples of this include the pure literal rule and extension axioms. The pure literal rule is used to set a literal that occurs only positively to be set true; the extension axioms are allowed even though they are not true under all truth assignments. Equisatisfiability means that these steps cannot introduce an inconsistency.

Following [HHW13b, HHW13a], a *RAT inference* is formally defined as follows. Let F be the current set of clauses in the clause database. (Recall that

typically the clause database F is repeatedly updated by clause learning and clause deletion.) Let C be a clause $a_1 \vee \cdots \vee a_k \vee b$: here it is permitted, but not required, that the literal b is a new literal not appearing yet in F . Then we may infer C with a *RAT inference* with respect to b , provided that for every clause $D \vee \bar{b}$ in F it holds that the clause

$$a_1 \vee \cdots \vee a_k \vee D \vee b \quad (7.71)$$

either is tautological by virtue of containing clashing literals or is a RUP clause with respect to F . (Recall that a RUP clause is a clause C' which can be inferred by trivial resolution from F , and that this can be checked quickly by adding the negations of the literals in C' to F and using unit propagation to generate a contradiction — see Section 7.3.1 for more details).

The intuition behind a RAT inference is that a clause C of the form $a_1 \vee \cdots \vee a_k \vee b$ can be added to the clause database F without introducing a new inconsistency. One way to justify this is to prove that if the clause C is resolved in all possible ways with clauses of F using the distinguished literal b , then only clauses which are already derivable from F are obtained.

For an example of a RAT inference, let F be the set of clauses

$$\{\bar{b} \vee \bar{a}_1 \vee a_2 \vee a_3, \bar{b} \vee a_4, a_4 \vee \bar{a}_2, a_4 \vee \bar{a}_3, a_2 \vee a_3\} . \quad (7.72)$$

Then the clause $C = a_1 \vee b$ can be inferred by a RAT inference from F with respect to the special variable b . To verify this, note there are two clauses to consider for D by virtue of F containing $D \vee \bar{b}$. The first choice for D is $\bar{a}_1 \vee a_2 \vee a_3$; the resolvent of $D \vee \bar{b}$ with C contains both a_1 and \bar{a}_1 yielding a clause of the form (7.71) that is tautological. The second choice for D is a_4 ; now the resolvent with C is $a_1 \vee a_4$, so the clause (7.71) now becomes $a_1 \vee a_4 \vee b$. This clause is RUP with respect to F since after setting a_1, a_4 and b false in F , we can obtain the empty clause by unit propagation.

Note that the clause C of this example is *not* a consequence of F , since F is satisfied by setting b, a_1, a_4 false and a_2, a_3 true. In particular, RAT can infer C even though $F \not\models C$. Instead, the critical property is that if C can be inferred from F with a RAT inference, then F is satisfiable if and only if $F \cup \{C\}$ is satisfiable. This means that the RAT inference is sound for refutations, but not for derivations. Indeed, the resolution rule is subsumed by the RAT rule, so the RAT rule by itself yields a sound and complete refutation system.

As another example, the RAT inference subsumes the *pure literal rule*. A literal is *pure* if it occurs only positively in the clause database F ; the pure literal rule allows introducing a unit clause asserting the literal is true. Specifically, for the example F of (7.72) the unit clause \bar{a}_1 is trivially RAT with respect to F since there is no clause containing the literal a_1 . Subsequently, the unit clause \bar{b} is RAT as well, for the same reason. In other words, RAT inferences can be used to infer both of the unit clauses \bar{a}_1 and \bar{b} . This is in no way contradicts the previous example, since it is not possible to introduce the clause $b \vee a_1$ at the same time, as the latter clause can no longer be inferred by a RAT inference once \bar{a}_1 and \bar{b} have been introduced. Thus, adding clauses to F may lead to that clauses that were previously RAT clauses are no longer inferable by a RAT inference. Conversely,

deleting clauses from F may cause clauses to become derivable by using the RAT rule.

It is not hard to see that RAT inferences can simulate the extension rule; indeed, the three clauses $\bar{x} \vee a$, $\bar{x} \vee b$, and $\bar{a} \vee \bar{b} \vee x$ of the extension rule (7.70) can be added one at a time by RAT inferences provided F does not contain any clauses containing x or \bar{x} . The first two clauses can be added since F does not contain any clauses involving x ; the third one, because its resolvents with the first two clauses are tautological. Conversely, it is known that extended resolution can simulate the RAT inference [KRPH18]. Therefore, the DRAT proof system and extended resolution polynomially simulate each other.

These simulations between DRAT and extended resolution work because the systems allow introducing arbitrary new variables. Thus, using DRAT for proof search can suffer from the same difficulties as extended resolution; namely, we lack effective methods of deciding what properties the new variables should represent. A different, and very interesting, approach proposed by [HKB17, HKB20] is to consider DRAT without allowing new variables to be introduced. In recent works [HB18, KRPH18, BT19], it has been shown that many of the variants of DRAT are equivalent even when new variables are not allowed to be introduced.

DRAT under the restriction of not introducing new variables is still an area of active research. It is too new to be properly surveyed here, but recent developments include [HHW15, HB18, HKSB17, BT19] and works cited in these papers. An intriguing aspect of DRAT (and related systems) is that, even when no new variables are permitted, it is still unexpectedly strong (see [HKB20, BT19]). It was shown in [BT19, HKB17, HKB20] that even without allowing new variables or clause deletion, a modest extension of the RAT rule called *subset propagation redundancy* (or *SPR* for short), first introduced in [HKB20] is powerful enough to give polynomial-size proofs of many hard examples for bounded-depth Frege proof systems, including pigeonhole principle formulas, clique-colouring formulas, and Tseitin formulas.

The paper [BT19] further showed that when new variables are not allowed, then there is an exponential separation in refutation size between the proof system RAT (the RAT rule without allowing clause deletion) and the proof system DRAT (the RAT rule combined with clause deletion). Clause deletion can give this extra power, since removing clauses permits additional RAT inferences.

An approach to automating the search for DRAT proofs was investigated in the work [HKSB17, HKB19], which used *satisfaction-driven clause learning (SDCL)* to search for short DRAT refutations without new variables. With SDSL, they were able to generate refutations of pigeonhole principle formulas and Tseitin formulas much more quickly than what CDCL can typically accomplish, finding refutations for pigeonhole principle formulas that are close to the optimal polynomial size, although still taking exponential time (at least for PHP formulas). This was accomplished in a very general way without explicitly checking for cardinality constraints. However, so far SDCL has not proved helpful in the general setting of SAT competition problems. As mentioned, there are theoretical results that deletion can exponentially increase the power of (D)RAT; however, there are at present no practical techniques for incorporating this extra power of deletion. In addition, if the deletion rule is not constrained to preserve equisatisfiability,

then deletion may change an unsatisfiable formula into a satisfiable formula. This would be incompatible with present-day CDCL solvers, which search simultaneously for satisfying assignments and proofs of unsatisfiability. For more on DRAT and related systems, see Chapter 15.

7.9. Frege and Extended Frege Proof Systems

Frege proofs are the standard “textbook” propositional proof systems, typically with modus ponens as the sole inference rule, and frequently formulated with connectives \neg , \wedge , \vee , and \rightarrow . In contrast to previous sections, formulas are no longer required to be in CNF, and instead can be formed using arbitrary combinations of Boolean connectives.

Frege systems were first defined in the setting of proof complexity by [CR79, Rec75]). They are axiomatized with a finite set of axiom schemes (for example $F \wedge G \rightarrow F$ is a possible axiom) and a finite set of inference rules (for instance, modus ponens). This allows for many possible Frege systems. Indeed, different sets of connectives, and different axioms and rules of inference can be used. It is required that the connectives of a Frege system can form formulas expressing any Boolean functions (that is that the connectives are “complete”); it is also required that a Frege proof system be implicationaly sound and complete. To explain this last bit, let F be a formula and Γ be a set of formulas; recall that we write $\Gamma \models F$ to indicate that Γ logically implies F . For a Frege system \mathcal{F} to be implicationaly sound and complete, we must have $\Gamma \models F$ if and only if there is an \mathcal{F} -derivation of F from the formulas in Γ . As shown in [CR79, Rec75]), any two Frege systems polynomially simulate each other, so the exact choice of axioms and rules of inference is not particularly important.

We present here an alternative definition of Frege proof systems based on the sequent calculus. This is an elegant and flexible framework for formulating many different proof systems; we describe one particular version, called here *LK*, suitable for propositional logic.⁴⁷ *Propositional formulas* are formed using the propositional connectives \wedge and \vee and variables x and negated variables \bar{x} . Propositional formulas are defined formally by induction: firstly, for x any variable, x and \bar{x} are both propositional formulas and secondly, if φ and ψ are propositional formulas, then their conjunction ($\varphi \wedge \psi$) and their disjunction ($\varphi \vee \psi$) are propositional formulas. Note that propositional formulas allow arbitrary use of conjunctions and disjunctions and consequently are much more general than the CNF formulas considered earlier in this survey.

The lines in an LK proof are sequents. A *sequent* is an expression of the form

$$\varphi_1, \varphi_2, \dots, \varphi_k \Rightarrow \psi_1, \psi_2, \dots, \psi_\ell, \tag{7.73}$$

where the φ_i 's and ψ_i 's are propositional formulas. The intended meaning of this sequent is that the conjunction of the formulas φ_i on the left implies the disjunction of the formulas ψ_j on the right. That is, commas on the left-hand

⁴⁷The name LK is often used instead for a first-order logic, as originally introduced by Gentzen [Gen35]; our propositional system is sometimes called PK in the literature.

side of (7.73) should be understood as if they were \wedge 's, and commas on the right-hand side should be understood as if they were \vee 's. Equivalently, the sequent expresses that the disjunction of the ψ_j 's and the $\neg\varphi_i$'s is true.

It is convenient to use the convention that in the sequent (7.73), the right- and left-hand sides are *multisets*. That is, the order of the formulas $\varphi_1, \dots, \varphi_k$ is unimportant, but the multiplicities of formulas are tracked. We use Γ, Δ, \dots to denote multisets of formulas, and often use commas to denote the union of multisets. The rules of inference for LK are:

Initial sequents: For any variable x , there are three initial sequents (*logical axioms*):

$$x \Rightarrow x \quad \text{and} \quad x, \bar{x} \Rightarrow \quad \text{and} \quad \Rightarrow x, \bar{x} \quad (7.74a)$$

Structural rules:

$$\text{Weak-left: } \frac{\Gamma \Rightarrow \Delta}{\varphi, \Gamma \Rightarrow \Delta} \quad \text{Weak-right: } \frac{\Gamma \Rightarrow \Delta}{\Gamma \Rightarrow \Delta, \varphi} \quad (7.74b)$$

$$\text{Contract-left: } \frac{\varphi, \varphi, \Gamma \Rightarrow \Delta}{\varphi, \Gamma \Rightarrow \Delta} \quad \text{Contract-right: } \frac{\Gamma \Rightarrow \Delta, \varphi, \varphi}{\Gamma \Rightarrow \Delta, \varphi} \quad (7.74c)$$

Cut rule:

$$\text{Cut: } \frac{\Gamma \Rightarrow \Delta, \varphi \quad \varphi, \Gamma \Rightarrow \Delta}{\Gamma \Rightarrow \Delta} \quad (7.74d)$$

Logical rules:

$$\wedge\text{-left: } \frac{\varphi, \psi, \Gamma \Rightarrow \Delta}{\varphi \wedge \psi, \Gamma \Rightarrow \Delta} \quad \wedge\text{-right: } \frac{\Gamma \Rightarrow \Delta, \varphi \quad \Gamma \Rightarrow \Delta, \psi}{\Gamma \Rightarrow \Delta, \varphi \wedge \psi} \quad (7.74e)$$

$$\vee\text{-left: } \frac{\varphi, \Gamma \Rightarrow \Delta \quad \psi, \Gamma \Rightarrow \Delta}{\varphi \vee \psi, \Gamma \Rightarrow \Delta} \quad \vee\text{-right: } \frac{\Gamma \Rightarrow \Delta, \varphi, \psi}{\Gamma \Rightarrow \Delta, \varphi \vee \psi} \quad (7.74f)$$

For extended Frege proofs (but not for Frege or LK), *extension axioms* are also allowed as initial sequents. Extension axioms are specified by a sequence of pairs (x_i, ψ_i) for $i = 1, \dots, k$ so that each ψ_i is a formula and each *extension variable* x_i is a “new” variable that does not appear in the conclusion of the proof and does not appear in any ψ_j for $j \leq i$. Then an extended Frege proof may use the following extension axioms as initial sequents:

Extension axioms:

$$x_i \Rightarrow \psi_i \quad \text{and} \quad \psi_i \Rightarrow x_i \quad (7.75)$$

An LK proof is a sequence of sequents, where each sequent either is a logical axiom or is inferred from earlier sequents by a valid LK rule of inference.⁴⁸ A *Frege proof* of a formula φ is defined to be an LK proof of the sequent $\Rightarrow \varphi$. An *extended Frege*

⁴⁸It is typical in the literature to require LK proofs to be tree-like; we instead allow DAG-like proofs, so as to be consistent with the other systems discussed in this survey. Perhaps confusingly however, Frege proofs based on modus ponens are typically defined to be DAG-like in the literature. This makes no difference for us, as tree-like LK proofs can polynomially simulate (DAG-like) LK proofs [Kra94], so the distinction between tree-like and DAG-like proofs is not important for Frege systems.

proof of φ is defined similarly, but allowing the use of extension axioms (7.75) as initial sequents. Extended Frege is equivalent to extended resolution, in that the two systems polynomially simulate each other.

We can also use LK as a refutation system. For this, let \mathcal{S} be a set of sequents. An LK refutation may use both the logical axioms of (7.74a) and sequents from \mathcal{S} as initial sequents and ends with the empty sequent \Rightarrow . The initial sequents from \mathcal{S} are called *nonlogical axioms*. Since the empty sequent is false under any truth assignment, an LK refutation proves the unsatisfiability of the nonlogical axioms \mathcal{S} .

As already mentioned, Frege systems are strictly stronger than resolution; in fact, even the weaker bounded-depth Frege systems discussed in the next section are more powerful: they can polynomially simulate resolution, but cannot be polynomially simulated by resolution. It was shown in [Bus87] that Frege systems have polynomial-size proofs of the pigeonhole principle formulas, whereas, as already mentioned several times above, the smallest resolution refutations grow exponentially [Hak85].

The polynomial-size Frege proofs of pigeonhole principle formulas can be constructed by showing that Frege systems can define counting, and even define the sum of a vector of integers when the integers are presented as propositional variables representing the integers in binary notation ([Bus87]. This was exploited in [Goe90] to prove that Frege systems can polynomially simulate cutting planes proofs. Furthermore, it is not hard to see that Frege systems can polynomially simulate Nullstellensatz and polynomial calculus over any finite field \mathbb{F} .

Extended Frege systems are conjectured to be yet stronger than Frege systems, but we lack good examples of combinatorial properties that might have short extended Frege proofs but require exponentially long Frege proofs. The paper [BBP95] identified some candidates, but these have largely been ruled out in recent years [HT15, TC17, ABB16, Bus15].

Open Problem 7.19. Find new combinatorial candidates for exponentially separating Frege and extended Frege proofs.

Open Problem 7.20. Give a conditional exponential lower bound for Frege proofs using some assumption weaker than $\text{NP} \neq \text{coNP}$.

7.10. Bounded-Depth Frege Proof System

One important measure of the complexity of general propositional formulas with the connectives \wedge and \vee is the number of alternations of \wedge 's and \vee 's. The *depth* of a propositional formula φ equals the number of levels of disjunctions and conjunctions in φ . More formally, any literal x or \bar{x} is a depth-0 formula, and if $\varphi_1, \dots, \varphi_k$ are all depth strictly smaller than d , then any formula formed by combining those k formulas with only conjunctions, or with only disjunctions, has depth bounded by d . For example, $v \wedge ((x \vee (\bar{y} \vee z)) \wedge \bar{u})$ is a depth-2 formula.

The sequent calculus LK also lends itself to working with Frege proofs with restrictions on formula depth in a natural way. At the bottom level, resolution can be viewed as a depth-0 LK refutation system. In particular, a resolution refutation can be viewed as an LK refutation in which all formulas are merely propositional

variables. To see this, note that if C is a clause containing the variables x_1, \dots, x_k unnegated and the negated literals $\bar{y}_1, \dots, \bar{y}_{k'}$, then the corresponding sequent S_C is $y_1, \dots, y_{k'} \Rightarrow x_1, \dots, x_k$. Under this translation between clauses and sequents of literals, the resolution inference rule corresponds exactly to a cut inference in depth-0 LK. In this way, resolution refutations are essentially identical to depth-0 LK refutations.

The notion of depth-0 LK proof can be generalized to any bounded depth d . For $d \geq 0$, a *depth- d LK proof* is an LK proof in which every formula has depth at most d . We write *d -LK* as a compact notation for the LK proof system restricted to depth- d proofs.

Loosely speaking, the *depth- d Frege system* is the same as the d -LK proof system. However, the notion of depth for Frege proofs is sensitive to issues such as whether proofs are tree-like or DAG-like, and whether proofs are formulated Hilbert-style with modus ponens (say) or with the sequent calculus. Thus, to be formal, we will restrict our attention to the (DAG-like) d -LK proof system.

The *Res(k)* or *k -DNF resolution* proof system is an extension of resolution in which the lines are DNF formulas where the conjunctions have size bounded by k . Note that *Res(1)* is the same as resolution, so *Res(k)* proof systems lie just above resolution in strength. *Res(k)* can also be defined as the subsystem of depth-1 LK in which all formulas are either disjunctions or conjunctions of at most k literals. A number of exponential lower bounds on *Res(k)* refutations of weak pigeonhole principle formulas have been proven in a sequence of papers [ABE02, SBI04, Ale11, AMO15, Raz15] with Razborov [Raz15] establishing exponential lower bounds for $k = \epsilon \log n / \log \log n$. Size-space trade-offs for *Res(k)* were obtained in [BSN11].

There are also exponential lower bounds on the size of depth- d LK proofs for all constant $d > 0$. Haken's exponential lower bound for resolution refutations of pigeonhole principle formulas [Hak85] applies to depth-0 LK. This was substantially extended to give strong lower bounds on the size of bounded-depth LK proofs of the pigeonhole principle formulas by [PBI93, KPW95] who showed that with $m = n + 1$ pigeons and n holes, depth d LK refutations of the PHP formulas require size $\exp(\Omega(n^{5^{1/d}}))$, improving on earlier lower bounds of [Ajt88].

Other known hard principles for bounded-depth LK include the *counting-mod- p principle* formulas.⁴⁹ We define here only the case $p = 2$; this is the *parity principle*. Fix $n > 0$ an odd integer. The parity principle *PARITY $_n$* uses variables $x_{i,j}$ for $1 \leq i < j \leq n$; for convenience of notation, we define $x_{j,i}$ to be the same variable as $x_{i,j}$. The clauses of *PARITY $_n$* consist of the n many totality clauses

$$\bigvee_{j \neq i} x_{i,j} \quad \text{for } 1 \leq i \leq n \quad (7.76a)$$

and the $n \binom{n-1}{2}$ many clauses

$$\bar{x}_{i,j} \vee \bar{x}_{i',j} \quad \text{for } i, i', j \in [n], i \neq i' \neq j \neq i \quad (7.76b)$$

⁴⁹Counting-mod- p principle formulas can be generated in the standard DIMACS format for CNF formulas used by SAT solvers by the tool *CNFgen* [LENV17, CNF] using the command line `cnfgen count <n> <p>` for positive integers n and p such that p does not divide n (in order to get unsatisfiable instances).

claiming that there is a partition of $[n]$ into pairs of elements. These parity principle formulas $PARITY_n$ ⁵⁰ require exponential-size bounded-depth LK refutations; it was established in [BP96a] that depth- d LK refutations of $PARITY_n$ require size $\exp(\Omega(n^{6^{1/(d+1)}}))$. This lower bound holds even if formulas expressing the unsatisfiability of PHP_n^{n+1} are permitted as additional axioms.

The lower bounds for the parity principle refutations can also be generalized to exponential lower bounds for general *counting-mod- p* principles for $p > 2$, as proved by [BIK⁺97] building on work of [BIK⁺96] and [Rii97a, Rii97b].

There are a number of other exponential lower bounds known for bounded-depth LK systems, but these two results are representative of the best known lower bounds. A recent result of [PRST16] has opened up a potential avenue for new lower bounds, by showing a lower bound of $\exp(\Omega((\log n)^2/d^2))$ for the size of d -LK refutations of Tseitin formulas on 3-regular expander graphs where n is the number of vertices in the graph. This result implies a *depth lower bound* of $d = \Omega(\sqrt{\log n})$ for polynomial-size d -LK refutations of these Tseitin formulas. Håstad [Hås17] instead focused on Tseitin formulas defined over grid graphs to obtain an improved size lower bound for d -LK of $\exp(\Omega(n^{1/58(d+1)}))$ and an improved depth lower bound of $\Omega(\log n / \log \log n)$.

The above-discussed results are some of the highlights regarding lower bounds on the size of bounded-depth LK proofs. Along with the lower bounds for polynomial calculus in Section 7.5.2 and cutting planes in Section 7.7.2, these are the state of the art in proving size lower bounds on proof size.

There are also a large number of open problems remaining about the size of bounded-depth LK proofs. Many of these problems lie right at the border of where we expect to be able to prove lower bounds on the complexity of proofs without actually resolving fundamental open questions such as whether $P \neq NP$ or not. One such open problem is to give better separations of depth- d and depth- $(d+1)$ systems.

Open Problem 7.21. Is there an exponential separation between the size of depth- d LK and depth- $(d+1)$ LK refutations of CNF formulas?

So far, only a superpolynomial separation is known for d -LK versus $(d+1)$ -LK proofs when refuting CNF formulas. This separation is obtained by, on the one hand, using the above-discussed lower bounds for d -LK proofs for pigeonhole principle formulas with $n+1$ pigeons and n holes and, on the other hand, constructing small $(d+1)$ -LK proofs of the pigeonhole principle formulas using a speedup technique of Nepomnjaščii [Nep70]. Discussing this in more detail is beyond the scope of this survey; the only proof in the literature is described in [KI02] using formalizations in bounded arithmetic.

One of the reasons that Open Problem 7.21 is so tantalizing is that the Yao-Håstad switching lemmas [Hås86] in circuit complexity tell us that depth- $(d+1)$ propositional formulas can be exponentially more succinct in expressibility than depth- d propositional formulas. This seems like it should give $(d+1)$ -LK proofs more power than d -LK proofs; however, Open Problem 7.21 remains unsolved even though considerable effort has been spent on it.

⁵⁰Parity principle formulas can be generated by *CNFgen* with the command line `cnfgen parity <n>` with the integer n chosen odd (to get unsatisfiable instances).

Another open problem concerns the power of bounded-depth LK when the language is extended to include the parity connective \oplus (exclusive or) in addition to \wedge and \vee . It is straightforward to extend LK to accommodate formulas that use the connectives \wedge , \vee and \oplus ; and the notion of depth extends naturally to the notion of $\{\wedge, \vee, \oplus\}$ -depth. We write $d\text{-LK}(\oplus)$ to denote the depth- d LK system so extended. There are polynomial size, bounded-depth $\text{LK}(\oplus)$ proofs of many principles that depend on only counting mod 2; these include the Tseitin formulas and the onto functional pigeonhole principle formulas for $m = n + 1$ pigeons and n holes. Fundamental results of Razborov [Raz87] and Smolensky [Smo87] in circuit complexity give exponential lower bounds on the expressibility of propositional formulas using the connectives \wedge , \vee and \oplus . For instance the mod-3 summation function cannot be expressed by polynomial-size, bounded-depth propositional formulas with those connectives. Thus, bounded-depth $\text{LK}(\oplus)$ proofs cannot reason directly about mod-3 counting. Nonetheless, it is an open problem to obtain superpolynomial lower bounds for this proof system.

Open Problem 7.22. Let $\text{LK}(\oplus)$ denote LK extended with a parity (exclusive or) logical connective. Are there exponential, or even superpolynomial, lower bounds on the size of bounded-depth $\text{LK}(\oplus)$ proofs? Can bounded-depth $\text{LK}(\oplus)$ be simulated by bounded-depth LK augmented with all instances of formulas expressing the unsatisfiability of the PARITY_n formulas?

Open Problem 7.22 is related to the Nullstellensatz proof system discussed in Section 7.5.1. In fact, the study of proof systems based on counting principles and counting gates was the original impetus for the development of Nullstellensatz [BIK⁺96].

It is interesting to compare the strength of bounded-depth LK proofs to the strengths of the proof systems of resolution, cutting planes, and polynomial calculus. First, as already mentioned, $d\text{-LK}$ polynomially simulates resolution for all $d \geq 0$. However, resolution does not polynomially simulate all the systems $d\text{-LK}$. An example of this are the weak pigeonhole principle formulas PHP_n^{2n} expressing that there is no injection from $2n$ pigeons to n holes. These formulas are known from [PWW88, MPW02] to have quasipolynomial-size 2-LK proofs; but from [Hak85, BT88] to require exponential-size resolution refutations.

Bounded-depth LK systems are not directly comparable to cutting planes. In one direction, there are short cutting planes refutations of PHP and parity principle formulas, for instance. However, these require exponential-size $d\text{-LK}$ proofs for any fixed $d > 0$. For the other direction, an exponential separation can be obtained using a “weak” clique-coclique principle. Recall that the clique-coclique formulas ((7.63a)–(7.63e)) encode that a graph cannot have both a clique of size $m + 1$ and a colouring of size m . By the “weak” clique-coclique formulas we mean an analogous version that states that a graph cannot have clique of size $2m$ and a colouring of size m (this is a weaker claim, and so should be easier to prove). These latter formulas have quasipolynomial-size 3-LK proofs by adapting the quasipolynomial-size 2-LK proofs for weak PHP formulas. On the other hand, the Craig interpolation method of [Pud97], along with lower bounds on monotone real circuits based on [AB87], still work for the weak clique-coclique formulas to show that they require exponential-size cutting planes refutations.

Finally, we can compare bounded-depth Frege to polynomial calculus. In one direction, there are CNF formulas that are easy to refute in polynomial calculus, or even Nullstellensatz, but require exponential-size d -LK proofs for any fixed d , for instance, mod- p counting principles when working over a field of characteristic p . A separation in the other direction follows from [GL10b]. Thus, bounded-depth Frege and polynomial calculus are incomparable proof systems.

7.11. Concluding Remarks

In this chapter we have presented an overview of proof complexity with a focus on connections with SAT solving. On the proof complexity side, one main take-away message is that resolution is fairly well-understood, although substantial important open questions still remain open. There has also been good progress in research on polynomial calculus, cutting planes and bounded-depth Frege systems, but these proof systems are not nearly as well understood as resolution.

When it comes to applied SAT solving (where, as mentioned in the introductory section, we are mostly restricted to studying unsatisfiable formulas, since this is the setting in which the tools from proof complexity can most naturally be brought to bear), there is still lots of room for improvement in our understanding of why different formulas are easy or hard, why different proof systems are better or worse for proof search, and why sometimes seemingly very small differences in algorithms can make big differences in the effectiveness of SAT solvers. It would be interesting to investigate further whether there are relevant connections between proof complexity measures and hardness of SAT, and whether proof complexity can help to shed light on the inner workings on SAT solvers.

We want to stress again that there are many topics in proof complexity that we have not been able to cover in this survey chapter due to the finiteness of time and space, and to a large extent our choice of topics has been guided by considerations as to what should be most relevant in an applied SAT solving context. One major omission from a theoretical point of view is the topic of *bounded arithmetic*. Bounded arithmetic theories are a collection of first-order and second-order theories in formal logic with close connections to both proof complexity and computational complexity theory more broadly. An overview of bounded arithmetic can be found in the books [Bus86, Kra95, CN10] and the final part of [HP93], and the connections to proof complexity are covered in [Kra95, CN10]. The *Paris-Wilkie translation* [PW85] gives a direct connection between bounded arithmetic and quasipolynomial-size, bounded-depth Frege proofs. *Cook translations* [Coo75, Ara00, CM05, CN10, BPT14] relate bounded arithmetic theories to the Frege and extended Frege proof systems.

Another important topic that we have not discussed is *symmetry reasoning* (see Chapter 13). Many of the combinatorial formulas that we have examined in this survey chapter are hard because they contain symmetries that make them hard to deal with for different proof systems — examples include pigeonhole principle formulas for resolution and polynomial calculus, clique-coclique formulas for cutting planes, and (perhaps less obviously) Tseitin formulas for bounded-depth Frege — but these formulas become trivial once reasoning with symmetries is allowed. In practice, different methods of handling symmetries that use static

or dynamic techniques, or combinations thereof, have been developed in, e.g., [DBBD16, DBB17, MBCK18, MBK19, TD19] and have been shown to be quite efficient in many cases, and the question of how to express symmetry reasoning as DRAT proofs has been studied in [HHW15]. It would be very interesting to perform a theoretical study of the strength of the methods of reasoning in the above-mentioned papers. However, we are not aware of any work in proof complexity that focuses on proof systems enhanced with rules for symmetry reasoning apart from a few (by now rather old) papers such as [Kri85, Urq99, AU00, Sze05].

We also want to mention briefly a (somewhat unexpected) connection between SAT solving and MaxSAT solving (discussed in Chapters 23 and 24). In general, it is more difficult to solve MaxSAT problems than SAT problems. However, *dual-rail MaxSAT* has recently been introduced in the papers [IMMS17, BBI⁺18, MIB⁺19] as a method for solving SAT instances. A dual-rail proof system replaces each propositional variable x with two new propositional variables p_x and n_x , for the positive and negative values of x , representing the literals x and \bar{x} . An appropriate dual-rail formulation allows a SAT instance to be reduced to a MaxSAT instance which can be easier in some cases.

Concluding this chapter, the main algorithmic challenge we want to highlight is if and how one can build efficient SAT solvers based on stronger proof systems than resolution. Is it really the case that conflict-driven clause learning (CDCL), originating in the DPLL method from the early 1960s, is the best conceivable paradigm? Or could it be possible that is it now time, over 50 years later, to take the next step and build fundamentally different SAT solvers, perhaps based on some of the algebraic and/or geometric methods discussed in this survey chapter? Is the comparative lack of progress on SAT solvers using such stronger method of reasoning an indication of that there are fundamental limitations to efficient proof search being implemented within stronger proof systems? Or could it be that a sustained long-term effort will yield powerful new SAT solving paradigms, just as the immense work spent on optimizing CDCL solvers over the years have led to improvements in performance of several orders of magnitude?

Acknowledgements

We are most grateful to all our colleagues in the proof complexity and SAT communities, too numerous to list here, with whom we have had stimulating and enlightening discussions over the years. We want to give a special thanks to Paul Beame, Jan Elffers, Stephan Gocht, Massimo Lauria, Gunnar Stålmarck, and Marc Vinyals for answering questions and/or proof-reading different versions of the manuscript, helping to catch many typos and other mistakes, and giving suggestions how to improve the exposition. We are also thankful to Massimo Lauria and Marc Vinyals for providing information on how to generate different crafted proof complexity benchmark formulas using the tool *CNFgen* and finding suitable values for the parameters. Furthermore, we wish to thank Daniel Le Berre, João Marques-Silva, and Dmitry Sokolov for help with literature references, and Armin Biere, Laurent Simon, and Niklas Sörensson for providing empirical data on SAT solver performance. Last, but certainly not least, we are most indebted to Robert Robere for an amazingly thorough review of the first completed version

of the chapter, which further helped to enhance the manuscript. Any remaining errors or deficiencies are certainly the responsibility of the authors only.

Part of this work was carried out while the second author visited the Simons Institute for the Theory of Computing at UC Berkeley in association with the DIMACS/Simons Collaboration on Lower Bounds in Computational Complexity, which is conducted with support from the National Science Foundation. The first author was funded by the Simons Foundation, grant number 578919. The second author was funded by the Swedish Research Council (VR) grants 621-2012-5645 and 2016-00782 as well as by the Independent Research Fund Denmark grant 9040-00389B.

Chapter 8

Fundamentals of Branching Heuristics

Oliver Kullmann

8.1. Introduction

The topic of this chapter is to provide foundations for “branching heuristics”. The whole field of “heuristics” is very diverse, and we will concentrate on a specific part, where developments in the last four decades can be comprised in what actually deserves to be called a “theory”. A full version of this chapter, containing all proofs and extensive examples, is available in [Kul08a].

The notion of a “heuristics” is fundamental for the field of Artificial Intelligence. The (early) history of the notion of “heuristics” is discussed in [BF81], Section II.A, and the usage of this notion in the SAT literature follows their definition of a heuristics as a method using additional information to restrict the search space size, though in this chapter we consider a restricted context, where completeness is not an issue, but the heuristical component of the search process affects only resource usage, not correctness. Furthermore we only study a specific form of search processes here, namely backtracking search. We consider the situation where we have a problem instance F where all direct (“efficient”) methods fail, and so F has to be split into subproblems. In the context of this chapter we basically assume that the method for splitting F is already given, yielding possible “branchings” $F \rightsquigarrow F_1, \dots, F_m$, splitting F into m “subproblems” F_i , and the task of the heuristic is to compare different branchings and to find the “best” branching among them. Let us assume that we have given three branchings to compare:

We see an important aspect of our abstract analysis: Each branch is labelled by a positive real number, which measures the “distance”, that is, how much “simpler” the problem became (w.r.t. a certain aspect). At this level of abstraction not only the branchings but also these distances are given, and the question is what can be done with these numbers, how can they be used to compare these three

branchings? Obviously, all that counts then are the tuples of distances, so-called “branching tuples”. We get $a := (2, 2)$, $b := (3, 3, 4, 9)$, $c := (4, 5, 6, 6, 5, 6)$.

The first part of this chapter is devoted to the combinatorics and analysis of branching tuples. We will see that a canonical value $\tau(t) \in \mathbb{R}_{\geq 1}$ (see Definition 8.3.2) can be computed for each branching tuple, and that these values under fairly general circumstances yield the (only) answer to the problem of comparing branching tuples: The smaller the τ -value the better the tuple. For the above branching tuples the computation yields $\tau(a) = 1.4142\dots$, $\tau(b) = 1.4147\dots$, and $\tau(c) = 1.4082\dots$, and thus the third branching is the best, followed by the first branching, and then the second branching (all under the assumption that all that is given are these numbers). The τ -function arises naturally from standard techniques from difference equations, and for example $\tau(b)$ is the (unique) positive solution of $x^{-3} + x^{-3} + x^{-4} + x^{-9} = 1$. Using an appropriate scaling, the τ -function yields a (generalised) mean \mathfrak{T} (in a precise sense), and the task of evaluating branchings can be understood as extracting a generalised mean-value from each tuple (where in this interpretation the tuple is the better the larger the mean). It is worth mentioning here that branching tuples are arbitrary tuples of positive *real* numbers, and thus are amenable to optimisation techniques.

After having developed a reasonable understanding of branching tuples, based on the analysis of *rooted trees* which consist of these branching tuples w.r.t. a run of the given backtracking solver, we then turn to the question of how actually to compute “good” distances. At this time the general theory can only give rough guidelines, which however suffices to *compare* different distance functions w.r.t. their appropriateness. So we can compare distance functions, and we can also optimise them. But finally we have to come up with some concrete distance, and fortunately, in the second part of this chapter, at least for CNF in the context of so-called “look-ahead” solvers a reasonable answer can be given, obtained by a remarkable convergence of theoretical and empirical studies. We need to remark here that heuristics for so-called “conflict-driven” solvers cannot be fully handled here, basically since these solvers are not really based on backtracking anymore, that is, we cannot speak of *independent* branches anymore, but rather an iterative process is taking place.

In more details, the content of this chapter is as follows:

1. The general framework and its assumptions are discussed in Section 8.2. First we discuss the focus of our approach, and which questions are excluded by this theory, which is based on comparing branchings by condensing them into branching tuples. The way these tuples arise is based on “measures” (of approximated problem complexity) or more generally on “distances”, and we discuss the meaning of this process of extracting branching tuples. Alternative branchings are represented by alternative branching tuples, and so we need to order branching tuples by some linear quasi-order (smaller is better), choosing then a branching with smallest associated branching tuple. This order on the set of branching tuples is given by applying a “projection function”, and by an introductory example

- we motivate the “canonical projection”, the τ -function.
2. The combinatorics of branching tuples and the fundamental properties of the τ -function are the subject of Section 8.3. In particular we consider bounds on the τ -function (resp. on the associated mean \mathfrak{T}). These bounds are important to derive upper and lower bounds on tree sizes. And under special circumstances one might wish to consider alternatives to the τ -function as a “projection” (comprising a branching tuple to one number), and then these bounds provide first alternatives. Section 8.3 is concluded by introducing the fundamental association of probabilities with branching tuples.
 3. Then in Section 8.4 we discuss the fundamental method of estimating tree sizes, first for trees with given probability distributions, and then for trees where the probability distribution is derived from a given distance by means of the τ -function.
 4. The τ -function is “in general” the only way to comprise branching tuples into a single number, however the precise value of the τ -function is not of importance, only the linear quasi-order it induces on the set of all branching tuples; this is proven in Section 8.5.
 5. Though the τ -function is the canonical projection in general, there might be reasons to deviate from it under special circumstances. The known facts are presented in Section 8.6. For binary branching tuples (t_1, t_2) (dominant for practical SAT solving) we relate the projections $t_1 + t_2$ and $t_1 \cdot t_2$ to the τ -function, yielding a strong analytical argument why the “product rule” is better than the “sum rule”, complementing the experimental evidence.
 6. With Section 8.7 we enter the second part of this chapter, and we discuss the known distances w.r.t. practical SAT solving.
 7. As already mentioned, at present there is no theory for choosing a “good” distance for a particular class of problem instances (other than the trivial choice of the optimal distance), but from the general theory developed in the first part of this chapter we obtain methods for improving distance functions, and this is discussed in Section 8.8.
 8. Our approach on branching is based on a two-phase model, where first the branching itself is chosen, and then, in a second step, the order of the branches. Methods for finding good orders (for SAT problems) are discussed in Section 8.9.
 9. The ideas for concrete distances, as presented in Section 8.7, also have bearings on more general situations than just boolean CNF-SAT, and especially our general theory is applicable in a much larger context. A quick outlook on this topic is given in Section 8.10.

8.2. A general framework for branching algorithms

A general framework for heuristics for branching algorithms is as follows: Consider a non-deterministic machine \mathcal{M} for solving some problem, where the computation terminates and is correct on *each* possible branch, and thus the decisions made

during the run of the machine only influence resource consumption. The task for a heuristics \mathcal{H} is to make the machine deterministic, that is, at each choice point to choose one of the possible branches, obtaining a deterministic machine $\mathcal{M}_{\mathcal{H}}$, where typically time and/or space usage is to be minimised. Likely not much can be said about the choice-problem in this generality, since no information is given about the choices. The focus of this article is on the problem of good choices between different possibilities of splitting problems into (similar) *subproblems*, where for each possible choice (i.e., for each possible splitting) we have (reasonable) information about the subproblems created. Not all relevant information usable to gauge branching processes for SAT solving can be represented (well) in this way, for example non-local information is hard to integrate into this “recursive” picture, but we consider the splitting-information as the central piece, while other aspects are treated as “add-ons”.

8.2.1. Evaluating branchings

The basic scenario is that at the current node v of the backtracking tree we have a selection $\mathcal{B}(v) = (B_1, \dots, B_m)$ of branchings given, and the heuristic chooses one. Each branching is (in this abstract framework) considered as a tuple $B_i = (b_1, \dots, b_k)$ of branches, where each b_i is a “smaller” problem instance, and k is the width of the branching. If the determination of the order of branches is part of the heuristics, then all $k!$ permutations of a branching are included in the list $\mathcal{B}(v)$, otherwise a standard ordering of branches is chosen. If we consider branching on a boolean variable, where the problem instance contains n variables, and all of them are considered by the heuristics, then the selection $\mathcal{B}(v)$ contains $2n$ branchings if the order of the two branches is taken into account, and only n branchings otherwise.

The problem is solved in principle, if we have precise (or “good”) knowledge about the resource consumption of the subproblems b_i (in the order they are processed, where the running time of b_i might depend on the running time of b_j for $j < i$), since then for every possible branching we sum up the running times of the branches (which might be 0 if the branch is not executed) to get the total running time for this branching, and we choose a branching with minimal running time. If ordinary backtracking order is not followed (e.g., using restarts, or some form of evaluating the backtracking tree in some other order), or branches influence other branches (e.g., due to learning), then this might be included in this picture by the assumption of “complete clairvoyance”.

Though this picture is appealing, I am not aware of any circumstances in (general) SAT solving where we actually have good enough knowledge about the resource consumption of the subproblems b_i to apply this approach successfully. Even in the probabilistically well-defined and rather restricted setting of random 3-SAT problems, a considerable effort in [Ouy99] (Chapter 5) to construct such a “rational branching rule” did not yield the expected results. The first step towards a practical solution is to use (rough) estimates of problem complexity, captured by a measure $\mu(F)$ of “problem complexity”. We view $\mu(F)$ as a kind of

logarithm of the true complexity. For example, the trivial SAT algorithm has the bound $2^{n(F)}$, and taking the logarithm (base 2) we obtain the most basic measure of problem complexity here, the number $n(F)$ of variables. This “logarithmic” point of view is motivated by the optimality result Lemma 8.4.9. Progress in one branch $F \rightsquigarrow F'$ then can be measured by $\Delta\mu(F, F') = \mu(F) - \mu(F') > 0$. However, since at this time the practical measures $\mu(F)$ are too rough for good results, instead of the difference $\Delta\mu(F, F')$ a more general “distance” $d(F, F') > 0$ needs to be involved, which estimates, in some heuristic way, the prospects F' offers to actually be useful in the (near) future (relative to F , for the special methods of the algorithm considered). Before outlining the framework for this kind of analysis, two basic assumptions need to be discussed:

- A basic assumption about the estimation of branching quality is *homogeneity*: The branching situation might occur, appropriately “relocated”, at many other places in the search tree, and is not just a “one-off” situation. If we have a “special situation” at hand (and we are aware of it), then, in this theoretical framework, handling of this special situation is not the task of the heuristics, but of the “reduction” for the currently given problem (compare Subsection 8.7.2).
- Another abstraction is, that as for theoretical upper-bounds, a “mathematical running time” is considered: The essential abstraction is given by the *search tree*, where we ignore what happens “inside a node”, and then the mathematical running time is the number of nodes in this tree. Real running times (on real machines) are not considered by (current, abstract) heuristics. In the literature (for example in [Ouy99]) one finds the attempt of taking the different workloads at different nodes into account by measuring the (total) number of assignments to variables, but this works only for special situations, and cannot be used in general. Furthermore, practice shows that typically, given the number of nodes in the search tree and some basic parameters about the problem size, curve-fitting methods yield good results on predicting the actual running time of a solver.¹

8.2.2. Enumeration trees

We focus on algorithms where an enumeration tree is built, and where the main heuristical problem is how to control the growth of the tree.

1. We do not consider “restarts” here, that is, rebuilding the tree, possibly learning from prior experiences. In the previous phase of SAT-usage, emphasise was put on *random* restarts, with the aim of undoing bad choices, while in the current phase randomness seems no longer important, but the effects of *learning* are emphasised. In this sense, as remarked by John Franco, restarts can be seen as a kind of “look-ahead”.

¹The framework we develop here actually is able to handle different run times at different nodes by attaching different weights to nodes. However in this chapter, where the emphasise is on setting up the basic framework, we do not consider this; see [Kul08a] for how to generalise the framework.

2. We assume mostly a depth-first strategy.
3. “Intelligent backtracking” (that is, not investigating the second branch in the case of an unsatisfiable first branch where the conflict does not depend on the branching) is considered as accidental (not predictable), and thus not included in heuristical considerations.
4. “Jumping around” in the search tree in order to prioritise nodes with higher probability of finding a satisfying assignment (like in [Hv08]) is considered as a layer on top of the heuristics (a kind of control layer), and is not considered by the core heuristics (given the current state of research).
5. The effect one branch might have on others (via “global learning”) is also considered a secondary effect, out of our control and thus not directly covered by the heuristics.
6. As discussed in [Kul08b], conflict-driven solvers actually tend to choose an iterative approach, not creating independent sub-problems for branching, but just choosing one branch and leaving it to learning to cater for completeness. Such a process seems currently unanalysable.

After having outlined what is to be included in our analysis, and what is to be left out, we now give a first sketch of the framework to be developed in this article.

8.2.3. A theoretical framework

For the author of this chapter, the theory developed here originated in the theoretical considerations for proving upper bounds on SAT decision (see Section 8.7.3 for further comments), and so the underlying “driving force” of the heuristics is the minimisation of an upper bound on the search tree size. Only later did I see that in [Knu75] actually the same situation is considered, only from a different point of view, a probabilistic one where a path through the search tree is chosen by randomly selecting one successor at each inner node.²

Example 8.2.1. An instructive example is the first non-trivial 3-SAT bound ([Luc84, MS85]), where via the autarky argument it can be assumed that a binary clause is always present, and then splitting on a variable in this binary clauses eliminates one variable in one branch and two variables in the other (due to unit-clause elimination). “Traditionally” this is handled by considering the worst case and using a difference equation $f_n = f_{n-1} + f_{n-2}$ (n is the number of variables, while f_n is the number of leaves in the search tree). Reasonably we assume $f_0 = 0$ and $f_1 = 1$, and then $(f_n)_{n \in \mathbb{N}_0}$ is the Fibonacci sequence with $f_n = \frac{1}{\sqrt{5}} \left(\left(\frac{1+\sqrt{5}}{2} \right)^n - \left(\frac{1-\sqrt{5}}{2} \right)^n \right)$, and using $r : \mathbb{R} \setminus \left(\frac{1}{2} + \mathbb{Z} \right) \rightarrow \mathbb{Z}$ for rounding to the nearest integer, we have $f_n = r \left(\frac{1}{\sqrt{5}} \left(\frac{1+\sqrt{5}}{2} \right)^n \right)$ (see Chapter 1 in [CFR05] for an introduction into these considerations). Whatever the initial values f_0, f_1 are, we always have $f_n = \Theta \left(\left(\frac{1+\sqrt{5}}{2} \right)^n \right) = O(1.619^n)$. The fundamental approach is the Ansatz $f_n = \lambda^n$, which leads to the equation $\lambda^n = \lambda^{n-1} + \lambda^{n-2}$, which is equivalent to $\lambda^2 = \lambda + 1$.

²In fact, the proof of the central “ τ -lemma” in [Kul99b] used already the probabilistic interpretation, but [Knu75] was not known to me at this time.

We do not follow the general theory of difference equations any further, since the initial conditions are of no relevance, and we also want to allow descents in arbitrary positive *real* numbers, in order to allow optimisations. The computation of the root λ from Example 8.2.1 will be generalised in Definition 8.3.2, while Theorem 8.4.8 yields a general method for computing bounds on tree sizes. Regarding our main purpose, the evaluation of branchings, we can show (in Section 8.5) that this generalised λ -calculation is the only “general” way of projecting a branching tuple to a single number.

As we have already mentioned, the first step is to move from branchings to branching tuples. For Example 8.2.1 this means extracting the branching tuple $(1, 2)$ as the essential piece of information. Now an important aspect of the theory developed in this chapter is that branching tuples are not only considered in isolation, but in connection with the (search) trees (in abstracted form). This “emancipation” of search trees, which in the form of worst-case analysis based on recurrence equations are factually suppressed, is also important for practical applications, as demonstrated in Section 8.8, since it allows to consider the real computations going on, not just their shadows in the form of worst-case considerations, which must deliver some interpretable bound at the end. And furthermore the study of probability distributions on the leaves of the tree combine the worst-case upper bounds with the probabilistic considerations from [Knu75] — the λ -calculation associates, in a canonical way, a probability distribution to the branches of a branching tuple (see Subsection 8.3.4).

So a main part of the theory is concerned with estimating sizes of trees in connection with branching tuples associated with them, based on simple probability considerations. For this task, the above λ -calculation takes on the more general form of evaluating a branching tuple by a real number. We call such evaluations *evaluation projection*, but actually, since the only form of projections used in this paper are such evaluation projections, we just call them “projections”. The general study of projections yields the underlying theory to answer questions like “Why is the product-rule for SAT heuristics better than the sum-rule?” (see Section 8.6). We begin the development of the theoretical framework by taking a closer look at branching tuples and the “ λ -calculation”.

8.3. Branching tuples and the canonical projection

The subject of this section is the theory of “branching tuples” and their evaluation. The theory shows its full strength when considering branchings of arbitrary width, which at this time is of importance for theoretical upper bounds (see Section 8.7.3) and for constraint satisfaction (see Section 8.10.2), and which might become more important for practical SAT solving when for example considering deeper look-aheads at the root of the search tree.

8.3.1. Branching tuples and their operations

One single (potential) branching consisting of $k \in \mathbb{N}$ branches is evaluated by a “branching tuple” a of length k , attaching to each branch i a positive real num-

ber a_i , which is intended to measure the progress achieved in reducing problem complexity in this branch (thus the larger a_i , the better is branch i).

Definition 8.3.1. $\mathcal{BT} := \bigcup_{k \in \mathbb{N}} (\mathbb{R}_{>0})^k$ denotes the set of **branching tuples**.

Remarks:

1. Basic measurements for branching tuples are minimum $\min : \mathcal{BT} \rightarrow \mathbb{R}_{>0}$, maximum $\max : \mathcal{BT} \rightarrow \mathbb{R}_{>0}$, sum $\Sigma : \mathcal{BT} \rightarrow \mathbb{R}_{>0}$, and width $\| : \mathcal{BT} \rightarrow \mathbb{N}$. The minimum $\min(a)$ of a branching tuple is a “worst-case view”, while $\max(a)$ is a “best-case view”. In general, disregarding the values, the larger $|a|$, i.e., the wider the branching is, the worse it is.
2. The set of branching tuples of width k is $\mathcal{BT}^{(k)} := \{t \in \mathcal{BT} : |t| = k\}$, which is a *cone*, that is for $a \in \mathcal{BT}^{(k)}$ and $\lambda \in \mathbb{R}_{>0}$ we have $\lambda \cdot t \in \mathcal{BT}^{(k)}$, and for $a, b \in \mathcal{BT}^{(k)}$ we have $a + b \in \mathcal{BT}^{(k)}$.
3. Branching tuples of width 1, which do not represent “real branchings” but “reductions”, are convenient to allow.
4. One could also allow the empty branching tuple as well as the zero branching tuple (0) (of width 1), but for the sake of simplicity we abstain from such systematic extensions here.

Concatenation of branching tuples a, b is denoted by “ $a ; b$ ”, and yields the semigroup $(\mathcal{BT}, ;)$ (the empty branching tuple would be the neutral element here). The width function $\|$ now becomes a homomorphism from $(\mathcal{BT}, ;)$ to $(\mathbb{N}, +)$. Concatenation allows us to define the strict prefix order $a \sqsubset b \Leftrightarrow \exists x \in \mathcal{BT} : a ; x = b$ (that is, b is obtained from a by adding further positive numbers to the end of a) for $a, b \in \mathcal{BT}$, while $a \sqsubseteq b \Leftrightarrow a \sqsubset b \vee a = b$. A further basic operation for a branching tuple a of width k is to apply a *permutation* $\pi \in S_k$, which we denote by $\pi * a := (a_{\pi(1)}, \dots, a_{\pi(k)})$. Finally we have **composition of branching tuples** a, b at position i of a , that is, branching b is attached to branch i of a ; since we allow permutation of branching tuples, it suffices to set $i = 1$ here, and the resulting composition is denoted by $\mathbf{a} \mathbb{M} \mathbf{b}$, defined as

$$(a_1, \dots, a_p) \mathbb{M} (b_1, \dots, b_q) := (a_1 + b_1, \dots, a_1 + b_q, a_2, \dots, a_p)$$

$$=$$

We obtain a semigroup $(\mathcal{BT}, \mathbb{M})$ (non-commutative; the zero branching tuple (0) would be the neutral element). It is important to realise that it makes a difference where to attach the branching b , that is in our setting, the branching tuples $a \mathbb{M} b$ and $(\pi * a) \mathbb{M} b$ are in general qualitatively different:

- (i) if b is better than a , then attaching b to a smaller component of a yields a better tuple than when attaching it to a larger component;
- (ii) if b is worse than a , then attaching b to a smaller component of a yields a worse tuple than when attaching it to a larger component.

The intuitive reason is that “more balanced tuples are better”, and so in the first case it is a greater improvement to a when improving its weak parts than when improving its strong parts, while in the second case making a weak part worse means a greater impairment than making a strong part worse.

8.3.2. The tau-function

In this section we introduce formally the τ -function as discussed in Example 8.2.1, and show its main properties.

Definition 8.3.2. Define $\chi_k : \mathcal{BT} \times \mathbb{R}_{>0} \rightarrow \mathbb{R}_{>0}$ by $\chi(t, x) := \sum_{i=1}^{|t|} x^{-t_i}$. Observe that for each $t \in \mathcal{BT}$ the map $\chi(t, -) : \mathbb{R}_{>0} \rightarrow \mathbb{R}_{>0}$ is strictly decreasing with $\chi(t, 1) = |t| \geq 1$ and $\lim_{x \rightarrow \infty} \chi(t, x) = 0$. Now $\tau : \mathcal{BT} \rightarrow \mathbb{R}_{\geq 1}$ is defined as the unique $\tau(t) := x_0 \in \mathbb{R}_{\geq 1}$ such that $\chi(t)(x_0) = 1$ holds.

By definition we have $\tau(t) \geq 1$, with $\tau(t) = 1 \Leftrightarrow |t| = 1$. For $k \in \mathbb{N}$ we denote by $\tau_k : \mathcal{BT}^{(k)} \rightarrow \mathbb{R}_{\geq 1}$ the τ -function restricted to branching tuples of width k .

Example 8.3.1. The computation of $\tau(1, 2)$ (recall Example 8.2.1) leads to the equation $x^{-1} + x^{-2} = 1$, which is equivalent to $x^2 - x - 1 = 0$, which has the two solutions $\frac{1 \pm \sqrt{5}}{2}$, and thus $\tau(1, 2) = \frac{1 + \sqrt{5}}{2} = 1.6180\dots$ Only very few τ -values can be expressed by analytical formulas, and most of the time numerical computations have to be used (see Remark 2 to Corollary 8.3.5), so for example $\tau(2, 3, 5) = 1.4291\dots$

Simple properties can be proven directly:

Lemma 8.3.1. *For every $a \in \mathcal{BT}$, $k \in \mathbb{N}$ and $\lambda \in \mathbb{R}_{>0}$ we have:*

1. $\tau(\lambda \cdot a) = \tau(a)^{1/\lambda}$.
2. $\tau_k(\vec{1}) = k$.
3. τ_k for $k \geq 2$ is strictly decreasing in each component.
4. τ_k is symmetric, that is, invariant under permutation of branching tuples.
5. $\tau(a)^{\min(a)} \leq |a| \leq \tau(a)^{\max(a)}$, that is, $|a|^{1/\max(a)} \leq \tau(a) \leq |a|^{1/\min(a)}$.
6. $\lim_{\lambda \rightarrow 0} \tau(a; (\lambda)) = \infty$ and $\lim_{\lambda \rightarrow \infty} \tau(a; (\lambda)) = \tau(a)$.

The τ -function fulfils powerful convexity properties, from which non-trivial further properties will follow. A function $f : C \rightarrow \mathbb{R}$ defined on some convex subset $C \subseteq \mathbb{R}^k$ is called “strictly convex” if for all $x, y \in C$ and $0 < \lambda < 1$ holds $f(\lambda x + (1 - \lambda)y) < \lambda f(x) + (1 - \lambda)f(y)$; furthermore f is called “strictly concave” if $-f$ is strictly convex. By definition τ_1 is just the constant function with value 1, and so doesn’t need to be considered here.

Lemma 8.3.2. *For $k \geq 2$ the function τ_k is strictly convex.*

Lemma 8.3.2 strengthens considerably the quasi-convexity of τ_k as shown in Lemma 4.1 of [Epp06]; in Corollary 8.3.5 we shall prove a further strengthening.

8.3.3. Bounds on the tau-function

Just from being symmetric and strictly convex it follows, that $\tau_k(a)$ for tuples a with a given fixed sum $\Sigma(a) = s$ attains its strict minimum for the constant tuple (with entries $\frac{s}{k}$); see Lemma 8.3.3 below for a proof. Thus, using $\mathfrak{A}(t) := \Sigma(t)/|t|$ for the arithmetic mean of a branching tuple, we have $\tau(\mathfrak{A}(t) \cdot \vec{1}) \leq \tau(t)$ (with strict inequality iff t is not constant). In the remainder of this subsection we will be concerned with further estimations on the τ -functions, and for that purpose we use the following well-known means (see [HLP99, Bul03]):

1. The *arithmetic mean*, the *geometric mean*, and the *harmonic mean* of branching tuples t are denoted respectively by $\mathfrak{A}(t) := \frac{1}{|t|}\Sigma(t) = \frac{1}{|t|} \sum_{i=1}^{|t|} t_i$, $\mathfrak{G}(t) := \sqrt[|t|]{\prod_{i=1}^{|t|} t_i}$ and $\mathfrak{H}(t) := |t| / (\sum_{i=1}^{|t|} \frac{1}{t_i})$. We recall the well-known fundamental inequality between these means: $\mathfrak{H}(t) \leq \mathfrak{G}(t) \leq \mathfrak{A}(t)$ (where strict inequalities hold iff t is not constant).
2. More generally we have the *power means* for $\alpha \in \overline{\mathbb{R}}$ given by $\mathfrak{M}_\alpha(t) := (\frac{1}{|t|} \sum_{i=1}^{|t|} t_i^\alpha)^{1/\alpha}$ for $\alpha \notin \{-\infty, 0, +\infty\}$, while we set $\mathfrak{M}_{-\infty}(t) := \min(t)$, $\mathfrak{M}_0(t) := \mathfrak{G}(t)$ and $\mathfrak{M}_{+\infty}(t) := \max(t)$. By definition we have $\mathfrak{M}_{-1}(t) = \mathfrak{H}(t)$ and $\mathfrak{M}_1(t) = \mathfrak{A}(t)$. In generalisation of the above fundamental inequality we have for $\alpha, \alpha' \in \overline{\mathbb{R}}$ with $\alpha < \alpha'$ the inequality $\mathfrak{M}_\alpha(t) \leq \mathfrak{M}_{\alpha'}(t)$, which is strict iff t is not constant.

We want to establish a variation of the τ -function as a “mean”, comparable to the above means. In the literature there are no standard axiomatic notions about “means”, only collections of relevant properties, and we condense the relevant notion here as follows:

Definition 8.3.3. Consider $k \in \mathbb{N}$. A **mean** is a map $M : \mathcal{BT}^{(k)} \rightarrow \mathbb{R}_{>0}$ which is continuous, strictly monotonic increasing in each coordinate, symmetric (i.e., invariant under permutation of the arguments) and “consistent”, that is, $\min(a) \leq M(a) \leq \max(a)$ for $a \in \mathcal{BT}^{(k)}$. A mean M is **homogeneous** if M is positive homogeneous, i.e., for $\lambda \in \mathbb{R}_{>0}$ and $a \in \mathcal{BT}^{(k)}$ we have $M(\lambda \cdot a) = \lambda \cdot M(a)$.

All power means are homogeneous means. Yet k -ary means M are only defined for tuples of positive real numbers $a \in \mathbb{R}_{>0}^k$, and we extend this as follows to allow arguments 0 or $+\infty$, using the extended real line $\overline{\mathbb{R}} = \mathbb{R} \cup \{\pm\infty\}$. We say that M is defined for $a \in \overline{\mathbb{R}}_{\geq 0}^k$ (allowing positions to be 0 or $+\infty$) if the limit $\lim_{a' \rightarrow a, a' \in \mathbb{R}_{>0}^k} M(a')$ exists in $\overline{\mathbb{R}}$, and we denote this limit by $M(a)$ (if the limit exists, then it is unique). Power means $\mathfrak{M}_\lambda(a)$ for $\lambda \neq 0$ are defined for all $a \in \overline{\mathbb{R}}_{\geq 0}^k$, while $\mathfrak{M}_0(a) = \mathfrak{G}(a)$ is defined iff there are no indices i, j with $a_i = 0$ and $a_j = \infty$.

Definition 8.3.4. Consider a mean $M : \mathcal{BT}^{(k)} \rightarrow \mathbb{R}_{>0}$. We say that M is **∞ -dominated** resp. **0-dominated** if for every $a \in \overline{\mathbb{R}}_{\geq 0}^k$, such that an index i with $a_i = \infty$ resp. $a_i = 0$ exists, $M(a)$ is defined with $M(a) = \infty$ resp. $M(a) = 0$. On the other hand, M **ignores ∞** resp. **ignores 0** if $M(a; (\infty))$ resp. $M(a; (0))$ is defined iff $M(a)$ is defined with $M(a; (\infty)) = M(a)$ resp. $M(a; (0)) = M(a)$.

Power means \mathfrak{M}_λ with $\lambda > 0$ are ∞ -dominated and ignore 0, while for $\lambda < 0$ they are 0-dominated and ignore ∞ . The borderline case $\mathfrak{M}_0 = \mathfrak{G}$ is ∞ -dominated as well as 0-dominated if only tuples are considered for which \mathfrak{G} is defined (and thus we do not have to evaluate “ $0 \cdot \infty$ ”).

Another important properties of means is convexity resp. concavity. Power means \mathfrak{M}_α with $\alpha > 1$ are strictly convex, while power means \mathfrak{M}_α with $\alpha < 1$ are strictly concave; the borderline case $\mathfrak{M}_1 = \mathfrak{A}$ is linear (convex and concave).

Lemma 8.3.3. *For every concave mean M we have $M \leq \mathfrak{A}$.*

Proof. By Jensen’s inequality (see [HUL04]) we have $M(a) = \sum_{\pi \in S_k} \frac{1}{k!} M(\pi * a) \leq M(\sum_{\pi \in S_k} \frac{1}{k!} \cdot (\pi * a)) = M(\mathfrak{A}(a) \cdot \vec{1}) = \mathfrak{A}(a)$. \square

We now consider the means associated with the τ -function. In the following $\log = \log_e$ denotes the natural logarithm (to base e).

Definition 8.3.5. For $k \geq 2$ the map $\mathfrak{T}_k : \mathcal{BT}^{(k)} \rightarrow \mathbb{R}_{>0}$ is defined by

$$\mathfrak{T}_k(t) := \frac{\log(k)}{\log(\tau(t))} = \log_{\tau(t)}(k).$$

Note that while a smaller $\tau(t)$ indicates a better t , for the τ -mean \mathfrak{T} the larger $\mathfrak{T}_k(t)$ is the better t is, but this only holds for fixed k , and due to the normalisation the τ -means of tuples of different lengths cannot be compared.

Theorem 8.3.4. *Consider $k \geq 2$.*

1. \mathfrak{T}_k is a strictly concave homogeneous mean.
2. We have $\mathfrak{M}_{2-k}(t) \leq \mathfrak{T}_k(t) \leq \mathfrak{A}(t)$, with equalities iff t is constant. Especially we have $\mathfrak{G}(t) \leq \mathfrak{T}_2(t) \leq \mathfrak{A}(t)$.
3. For $k \geq 3$ it is \mathfrak{T}_k 0-dominated and ∞ -ignoring, while \mathfrak{T}_2 is 0-dominated as well as ∞ -dominated, whence only defined for $t \in \overline{\mathbb{R}}_{\geq 0}^2 \setminus \{(0, \inf), (\inf, 0)\}$.

In general we have that if a positive function $f : C \rightarrow \mathbb{R}_{>0}$ is “reciprocal-concave”, that is, $1/f$ is concave, then f is log-convex (but not vice versa), that is, $\log \circ f$ is convex. Furthermore, if f is log-convex then f is convex (but not vice versa).

Corollary 8.3.5. *Consider $k \geq 2$.*

1. τ_k is strictly reciprocal-log-concave for $k \geq 2$, that is, the map $t \in \mathcal{BT}^{(k)} \mapsto 1/\log(\tau(t)) \in \mathbb{R}_{>0}$ is strictly concave. Thus τ is strictly log-log-convex.
2. For $t \in \mathcal{BT}^{(k)}$ we have $\tau(\mathfrak{A}(t) \cdot \vec{1}) = k^{1/\mathfrak{A}(t)} \leq \tau(t) \leq k^{1/\mathfrak{M}_{2-k}(t)} = \tau(\mathfrak{M}_{2-k}(t) \cdot \vec{1})$.

Remarks:

1. Part 2 says that replacing all entries in a branching tuple by the arithmetic mean of the branching tuple improves (decreases) the τ -value, while replacing all entries by the geometric mean ($k = 2$) resp. harmonic mean

($k = 3$) impairs (increases) the τ -value. The case $k = 2$ of this inequality was shown in [KL98] (Lemma 5.6). For the use of the lower and upper bounds in heuristics see Subsection 8.6.

2. Computation of $\tau(t)$ can only be accomplished numerically (except of a few special cases), and a suitable method is the Newton-method (for computing the root of $\chi(t)(x) - 1$), where using the lower bound $|t|^{1/\mathfrak{A}(t)}$ as initial value performs very well (guaranteeing monotonic convergence to $\tau(t)$).

8.3.4. Associating probability distributions with branching tuples

Definition 8.3.6. Given a branching tuple $a = (a_1, \dots, a_k)$, the branching tuple $\tau^P(a) \in \mathcal{BT}^{(k)}$ is defined by $\tau^P(a)_i := \tau(a)^{-a_i}$ for $i \in \{1, \dots, k\}$.

Remarks:

1. By definition we have $\Sigma(\tau^P(a)) = 1$, and thus $\tau^P(a)$ represents a probability distribution (on $\{1, \dots, k\}$).
2. For $\lambda \in \mathbb{R}_{>0}$ we have $\tau^P(\lambda \cdot a) = \tau^P(a)$, and thus $\tau^P(a)$ only depends on the relative sizes of the entries a_i , and not on their absolute sizes.
3. For fixed k we have the map $\tau_k^P : \mathcal{BT}^{(k)} \rightarrow \text{int}(\sigma_{k-1}) \subset \mathcal{BT}^{(k)}$ from the set of branching tuples (a_1, \dots, a_k) of length k to the interior of the $(k - 1)$ -dimensional standard simplex σ_{k-1} , that is, to the set of all branching tuples $(p_1, \dots, p_k) \in \mathcal{BT}^{(k)}$ with $p_1 + \dots + p_k = 1$. We have already seen that $\tau_k^P(\lambda \cdot a) = \tau_k^P(a)$ holds. Furthermore τ_k^P is surjective, i.e., every probability distribution of size k with only nonzero probabilities is obtained, with $(\tau_k^P)^{-1}((p_1, \dots, p_k)) = \mathbb{R}_{>0} \cdot (-\log(p_1), \dots, -\log(p_k))$.

8.4. Estimating tree sizes

Now we turn to the main application of branching tuples and the τ -function, the estimation of tree sizes. We consider rooted trees (T, r) , where T is an acyclic connected (undirected) graph and r , the root, is a distinguished vertex of T . Since we are considering only rooted trees here, we speak in the sequel just of “trees” T with root $\text{rt}(T)$ and vertex set $V(T)$. We use $\#\text{nds}(T) := |V(T)|$ for the number of nodes of T , while $\#\text{lvs}(T) := |\text{lvs}(T)|$ denotes the number of leaves of T .

8.4.1. Notions for trees

For a node $v \in V(T)$ let $d_T(v)$ be the *depth* of v (the length of the path from the root to v), and for $i \in \{0, \dots, d(v)\}$ let $T(i, v)$ be the vertex with depth i on the path from the root to v (so that $T(0, v) = \text{rt}(T)$ and $T(d(v), v) = v$). For a node $v \in V(T)$ we denote by T_v the subtree of T with root v . Before turning to our main subject, measuring the size of trees, some basic strategic ideas should be pointed out:

- Trees are considered as “static”, that is, as given, not as evolving; the main advantage of this position is that it enables us to consider the “real”

backtracking trees, in contrast to the standard method of ignoring the real object and only to consider approximations given by recursion equations.

- The number of leaves is a measure easier to handle than the number of nodes: When combining trees under a new root, the number of leaves behaves additively, while the number of nodes is bigger by one node (the new root) than the sum. Reductions, which correspond to nodes with only a single successor, are being ignored in this way. For binary trees (every inner node as exactly two children) we have $\#nds(T) = 2\#lvs(T) - 1$. And finally, heuristics in a SAT solver aim at reducing the number of conflicts found, that is, the number of leaves.
- All leaves are treated equal (again, this corresponds to the point of view of the heuristics).

8.4.2. Adorning trees with probability distributions

Consider a finite probability space (Ω, P) , i.e., a finite set Ω of “outcomes” together with a probability assignment $P : \Omega \rightarrow [0, 1]$ such that $\sum_{\omega \in \Omega} P(\omega) = 1$; we assume furthermore that no element has zero probability ($\forall \omega \in \Omega : P(\omega) > 0$). The random variable P^{-1} on the probability space (Ω, P) assigns to every outcome ω the value $P(\omega)^{-1}$, and a trivial calculation shows that the expected value of P is the number of outcomes:

$$E(P^{-1}) = \sum_{\omega \in \Omega} P(\omega)P(\omega)^{-1} = |\Omega|. \quad (8.1)$$

So the random variable P^{-1} associates to every outcome ω a guess $P^{-1}(\omega)$ on the (total) number of outcomes, and the expected value of these guesses is the true total number of all outcomes. Thus, via sampling of P^{-1} we obtain an estimation on $|\Omega|$. In the general context this seems absurd, since the probabilities of outcomes are normally not given a priori, however in our application, where the outcomes of the probability experiment are the leaves of the search tree, we have natural ways at hand to calculate for each outcome its probability. We remark that for $r \in \mathbb{R}_{\geq 1}$ from (8.1) we get for the r -th moment the lower bound $E((P^{-1})^r) = E((P^{-r})) \geq |\Omega|^r$ (by Jensen’s inequality).

Definition 8.4.1. For trees T we consider *tree probability distributions* \mathfrak{P} , which assign to every edge (v, w) in T a probability $\mathfrak{P}((v, w)) \in [0, 1]$ such that for all inner nodes v we have $\sum_{w \in ds_T(v)} \mathfrak{P}((v, w)) = 1$, that is, the sum of outgoing probabilities is 1; we assume furthermore, that no edge gets a zero probability. We obtain the associated probability space (Ω_T, P) , where $\Omega_T := lvs(T)$, that is, the outcomes are the leaves of T , which have probability

$$P(v) := \prod_{i=0}^{d(v)-1} \mathfrak{P}((T(i, v), T(i+1, v))). \quad (8.2)$$

The edge-probabilities being non-zero just means that no outcome in this probability space has zero probability (which would mean it would be ignored).

Equation (8.2) makes sense for any vertex $v \in V(T)$, and $P(v)$ is then to be interpreted as the event that an outcome is a leaf in the subtree of T with root v (that is, $P(v) = \sum_{w \in \text{lvs}(T_v)} P_T(w)$); however we emphasise that the values $P(v)$ for inner nodes v are only auxiliary values. From (8.1) we obtain:

Lemma 8.4.1. *For every finite rooted tree T and every tree probability distribution \mathfrak{P} for T we have for the associated probability space Ω_T and the random variable $P^{-1} : \Omega_T \rightarrow]0, 1]$:*

$$\min P^{-1} = \min_{v \in \text{lvs}(T)} P(v)^{-1} \leq \#\text{lvs}(T) = E(P^{-1}) \leq \max_{v \in \text{lvs}(T)} P(v)^{-1} = \max P^{-1}.$$

Corollary 8.4.2. *Under the assumptions of Lemma 8.4.1 the following assertions are equivalent:*

1. $\min P^{-1} = \#\text{lvs}(T)$.
2. $\#\text{lvs}(T) = \max P^{-1}$.
3. P is a uniform distribution (all leaves have the same probability).

Lemma 8.4.1 opens up the following possibilities for estimating the size of a tree T , given a tree probability distribution \mathfrak{P} :

1. Upper bounding $\max P^{-1}$ we obtain an upper bound on $\#\text{lvs}(T)$, while lower bounding $\min P^{-1}$ we obtain a lower bound on $\#\text{lvs}(T)$.
2. Estimating $E(P^{-1})$ by sampling we obtain an estimation of $\#\text{lvs}(T)$.

By Corollary 8.4.2, in each case a tree probability distribution \mathfrak{P} yielding a uniform distribution p on the leaves is the most desirable distribution (the lower and upper bounds coincide with the true value, and only one path needs to be sampled). It is easy to see that each tree has exactly one such “optimal tree probability distribution”:

Lemma 8.4.3. *Every finite rooted tree T has exactly one tree probability distribution \mathfrak{P} which induces a uniform probability distribution P on the leaves, and this canonical tree probability distribution \mathfrak{CP}_T is given by*

$$\mathfrak{CP}_T((v, w)) = \frac{\#\text{lvs}(T_w)}{\#\text{lvs}(T_v)}$$

for $v \in V(T)$ and $w \in \text{ds}_T(v)$.

The canonical tree probability distribution \mathfrak{CP}_{T_v} on a subtree T_v of T (for $v \in V(T)$) is simply obtained by restricting \mathfrak{CP}_T to the edges of T_v (without change).

8.4.3. The variance of the estimation of the number of leaves

If the leaf probabilities vary strongly, then the variance of the random variable P^{-1} will be very high, and a large number of samples is needed to obtain a reasonable estimate on the number of leaves. So we should consider more closely the variance

$\text{Var}(P^{-1}) = E((P^{-1} - \#\text{lvs}(T))^2) = E(P^{-2}) - \#\text{lvs}(T)^2 \in \mathbb{R}_{\geq 0}$ of the random variable P^{-1} . By definition, the variance is 0 if and only if the probability distribution is uniform, that is, iff \mathfrak{P} is the canonical tree probability distribution on T . To estimate $\text{Var}(P^{-1})$ one needs to estimate $E(P^{-2})$, that is, the second moment of P^{-1} . By definition we have $E(P^{-2}) = \sum_{v \in \text{lvs}(T)} P(v) \cdot P(v)^{-2} = \sum_{v \in \text{lvs}(T)} P(v)^{-1}$. So $E(P^{-2})$ is just the sum over all estimations on $\#\text{lvs}(T)$ we obtain from the probability distribution P . Somewhat more efficiently, we can calculate all moments of P^{-1} recursively (using a number of arithmetical operations which is linear in $\#\text{nds}(T)$) as follows, where we use \mathfrak{P}_{T_v} for the restriction of the tree probability distribution $\mathfrak{P} = \mathfrak{P}_T$ to subtree T_v (unchanged), while P_{T_v} is the probability distribution induced by \mathfrak{P}_{T_v} (which is not the restriction of P_T ; for $w \in \text{lvs}(T_v)$ we have $P_{T_v}(w) = P_T(v)^{-1} \cdot P_T(w)$). Trivial calculations show:

Lemma 8.4.4. *For a finite rooted tree T , a tree probability distribution \mathfrak{P} on T and $r \in \mathbb{R}_{\geq 0}$ we can recursively compute the r -th moment $E(P^{-r})$ of P^{-1} by*

- If T is trivial (i.e., $\#\text{nds}(T) = 1$), then we have $E(P_T^{-r}) = 1$.
- Otherwise $E(P_T^{-r}) = \sum_{v \in \text{ds}(\text{rt}(T))} \mathfrak{P}_T(\text{rt}(T), v)^{1-r} \cdot E(P_{T_v}^{-r})$.

Following [Knu75] (Theorem 3), we give an estimation on the variance of P^{-1} if the derived transition probabilities on the edges are within a factor α of the canonical tree probability distribution (recall Lemma 8.4.3).

Lemma 8.4.5. *For a finite rooted tree T and a tree probability distribution \mathfrak{P} on T , which fulfils $\mathfrak{P}_T^{-1} \leq \alpha \cdot \mathfrak{C}\mathfrak{P}_T^{-1}$ for some $\alpha \in \mathbb{R}_{\geq 1}$, we have $E(P_T^{-r}) \leq \alpha^{(r-1) \cdot \text{ht}(T)} \cdot \#\text{lvs}(T)^r$ for all $r \in \mathbb{R}_{\geq 1}$.*

Corollary 8.4.6. *Under the same assumptions as in Lemma 8.4.5 we have*

$$\text{Var}(P_T^{-1}) \leq (\alpha^{\text{ht}(T)} - 1) \cdot \#\text{lvs}(T)^2.$$

All the considerations of this section can be generalised to the case, where we also take inner nodes of the tree into account, and where we have an arbitrary cost function which assigns to every node of the tree its cost (in this section we considered the cost function which assigns every leaf the cost 1, while every inner node gets assigned cost 0). See [Kul08a] for details.

8.4.4. The tau-method

In the previous subsection we developed a method of estimating tree sizes, assuming a given tree probability distribution which assigns to every edge a transition probability. Now in this subsection we discuss how to obtain such transition probabilities via the help of “distances” and “measures”. The basic idea is to attach a distance $d((u, v))$ to the edge (u, v) , measuring how much “progress” was achieved via the transition from u to v , and where a standard method for obtaining such distances is to use a measure μ of “complexity” via $d((u, v)) := \mu(u) - \mu(v)$.

Definition 8.4.2. A *distance* d on a finite rooted tree T is a map $d : E(T) \rightarrow \mathbb{R}_{>0}$ which assigns to every edge (v, w) in T a positive real number, while a *measure* is a map $\mu : V(T) \rightarrow \mathbb{R}$ such that $\Delta\mu$ is a distance, where $\Delta\mu((v, w)) := \mu(v) - \mu(w)$. For a distance d we define the measures $\min \Sigma d$ and $\max \Sigma d$ on T , which assign to every vertex $v \in V(T)$ the minimal resp. maximal sum of d -distances over all paths from v to some leaf.

The τ -function yields a canonical method to associate a tree probability distribution to a distance on a tree as follows.

Definition 8.4.3. Consider a rooted tree T together with a distance d . For an inner node v of T we obtain an associated branching tuple $d(v)$ modulo permutation; assuming that T is ordered, i.e., we have a sorting $\text{ds}_T(v) = \{v_1, \dots, v_k\}$, we obtain a concrete branching tuple $d(v) := (d(v, v_1), \dots, d(v, v_k))$. The associated tree probability distribution \mathfrak{P}_d is given by

$$\mathfrak{P}_d((v, v_i)) := \tau^P(d(v))_i$$

(recall Definition 8.3.6).

By definition we have for $\lambda \in \mathbb{R}_{>0}$ that $\mathfrak{P}_{\lambda \cdot d} = \mathfrak{P}_d$. By Remark 3 to Definition 8.3.6 for every tree probability distribution \mathfrak{P} for T there exist distances d on T with $\mathfrak{P} = \mathfrak{P}_d$, and d is unique up to scaling of the branching tuples at each inner node (but each inner node can be scaled differently).

Given a distance d on a tree T , in order to apply Lemma 8.4.1 we need to estimate $\min P_d^{-1}$ and $\max P_d^{-1}$, where P_d is the probability distribution induced by \mathfrak{P}_d on the leaves of T according to Definition 8.4.1.

Definition 8.4.4. For a rooted tree (T, r) with a distance d let $\min \tau(d) := +\infty$ and $\max \tau(d) := 1$ in case T is trivial (consists just of r), while otherwise $\min \tau(d) := \min_{v \in V(T) \setminus \text{lvs}(T)} \tau(d(v))$ and $\max \tau(d) := \max_{v \in V(T) \setminus \text{lvs}(T)} \tau(d(v))$.

Lemma 8.4.7. Consider a rooted tree (T, r) together with a distance d . For the induced probability distribution P_d on the leaves of T we have:

1. $(\min \tau(d))^{\min \Sigma d(r)} \leq \min P_d^{-1}$.
2. $\max P_d^{-1} \leq (\max \tau(d))^{\max \Sigma d(r)}$.

Proof. We prove Part 1 (the proof for Part 2 is analogous). If T is trivial then the assertion is trivial, so assume that T is non-trivial. Let $\tau_0 := \min \tau(d)$.

$$\begin{aligned} \min P_d^{-1} &= \min_{v \in \text{lvs}(T)} P_d(v)^{-1} = \min_{v \in \text{lvs}(T)} \prod_{i=0}^{d(v)-1} \mathfrak{P}_d(T(i, v), T(i+1, v))^{-1} = \\ &= \min_{v \in \text{lvs}(T)} \prod_{i=0}^{d(v)-1} \tau(d(T(i, v)))^{d(T(i, v), T(i+1, v))} \leq \\ &= \min_{v \in \text{lvs}(T)} \prod_{i=0}^{d(v)-1} \tau_0^{d(T(i, v), T(i+1, v))} = \min_{v \in \text{lvs}(T)} \tau_0^{\sum_{i=0}^{d(v)-1} d(T(i, v), T(i+1, v))} = \tau_0^{\min \Sigma d(r)}. \end{aligned}$$

□

Lemma 8.4.1 together with Lemma 8.4.7 yields immediately the following fundamental method for estimating tree sizes.

Theorem 8.4.8. *Consider a rooted tree (T, r) . For a distance d on (T, r) we have*

$$(\min \tau(d))^{\min \Sigma d(r)} \leq \#\text{lvs}(T) \leq (\max \tau(d))^{\max \Sigma d(r)}.$$

And for a measure μ on (T, r) which is 0 on the leaves we have

$$(\min \tau(\Delta\mu))^{\mu(r)} \leq \#\text{lvs}(T) \leq (\max \tau(\Delta\mu))^{\mu(r)}.$$

Remarks:

1. So upper bounds on tree sizes are obtained by Theorem 8.4.8 through

- upper bounds on the τ -values on the branching tuples at each inner node of the tree
- and upper bounds on the maximal sum of distances amongst paths in the tree,

where the latter can be obtained via the root-measure in case the distances are measure-differences.

2. The general method of Theorem 8.4.8 was introduced by [Kul99b] (Lemma 8.2 there; see Section 8.7.3 here for more on the topic of theoretical upper bounds), while in [KL97, KL98] one finds direct (inductive) proofs.

The ideal measure on a tree makes the bounds from Theorem 8.4.8 becoming equal:

Lemma 8.4.9. *Consider a non-trivial rooted tree (T, r) . Then the following assertions are equivalent for a measure μ on (T, r) which is 0 on the leaves:*

1. *There exists $\lambda \in \mathbb{R}_{>0}$ with $\forall v \in V(T) : \mu = \lambda \cdot \log(\#\text{lvs}(T_v))$.*
2. $(\min \tau(\Delta\mu))^{\mu(r)} = \#\text{lvs}(T)$.
3. $(\max \tau(\Delta\mu))^{\mu(r)} = \#\text{lvs}(T)$.
4. $\min \tau(\Delta\mu) = \max \tau(\Delta\mu)$.

If one of these (equivalent) conditions are fulfilled then $\mathfrak{P}_{\Delta\mu} = \mathfrak{CP}_T$ (the canonical tree probability distribution; recall Lemma 8.4.3).

So a good distance d on a rooted tree T has to achieve two goals:

1. Locally, for each inner node v with direct successors $\text{ds}(v) = \{v_1, \dots, v_k\}$ the relative proportions of the distances $d(v, v_i)$ must mirror the sizes of the subtrees hanging at v_i (the larger the subtree the smaller the distance).
2. Globally, the scaling of the different τ -values at inner nodes must be similar.

As we have seen in Lemma 8.4.9, if the second condition is fulfilled perfectly, then also the first condition is fulfilled (perfectly), while the other direction does not hold (the first condition can be achieved with arbitrary scaling of single branching

tuples). The problem of constructing good distance functions (from a general point of view) is further discussed in Section 8.8.

After having seen that the τ -function can be put to good use, in the following section we show that at least the linear quasi-order induced on branching tuples by the τ -function (the smaller the τ -value the “better” the tuple) follows from very fundamental requirements on the evaluation of branchings.

8.5. Axiomatising the canonical order on branching tuples

On \mathcal{BT} we have a natural linear quasi-order given by $a \leq b \Leftrightarrow \tau(a) \leq \tau(b)$ for $a, b \in \mathcal{BT}$. Here we show how this order follows from simple intuitive axioms (extending [Kul98]).

Definition 8.5.1. A relation \leq on \mathcal{BT} is called a **canonical branching order** if it fulfils the six properties (TQO), (CMP), (P), (W), (M) and (Con), which are the following conditions (for all branching tuples a, b, c and all permutations π), where the induced equivalence relation $a \sim b :\Leftrightarrow a \leq b \wedge b \leq a$ and the induced strict order $a < b :\Leftrightarrow a \leq b \wedge a \not\sim b$ are used. First the five elementary conditions are stated:

- (TQO) (“Total Quasi-order”) \leq is a total quasi-order on \mathcal{BT} , that is, $a \leq a$, $a \leq b \wedge b \leq c \Rightarrow a \leq c$ and $a \leq b \vee b \leq a$ for all branching tuples a, b, c .
- (CMP) (“Composition”) $a \leq b \Rightarrow (a \leq a \wedge b \leq b) \wedge (a \leq b \wedge a \leq b)$.
- (P) (“Permutation”) $\pi * a \sim a$.
- (W) (“Widening”) $a \sqsubset b \Rightarrow a < b$.
- (M) (“Monotonicity”) If $k := |a| = |b| \geq 2$, $\forall i \in \{1, \dots, k\} : a_i \leq b_i$ and $\exists i \in \{1, \dots, k\} : a_i > b_i$, then $a < b$.

Now for $a \in \mathcal{BT}$ let $\gamma_a : \mathbb{R}_{>0} \rightarrow \mathcal{BT}$ be defined by $\gamma_a(x) := a;(x)$ (“left translation”). So (M) just expresses that for $a \in \mathcal{BT}$ the map γ_a is strictly decreasing. And extend $\gamma_a : \mathbb{R}_{>0} \rightarrow \mathcal{BT}$ to $\gamma_a : \overline{\mathbb{R}}_{>0} \rightarrow \mathcal{BT}$ by $\gamma(+\infty) := a$. The remaining condition is:

- (Con) (“Continuity”) For $a \in \mathcal{BT}$ the map $\gamma_a : \overline{\mathbb{R}}_{>0} \rightarrow \mathcal{BT}$ is continuous with regard to the natural topology on $\overline{\mathbb{R}}_{>0}$ and the order topology on \mathcal{BT} , i.e.:
 - (Con1) For $x \in \mathbb{R}_{>0}$ and $b, c \in \mathcal{BT}$ with $b < \gamma_a(x) < c$ there is $\delta \in \mathbb{R}_{>0}$ such that for $x' \in \mathbb{R}_{>0}$ with $|x - x'| < \delta$ we have $b < \gamma_a(x') < c$.
 - (Con2) For $b \in \mathcal{BT}$ with $b > a$ there is $x_0 \in \mathbb{R}_{>0}$ such that for $x' \in \mathbb{R}_{>x_0}$ we have $b > \gamma_a(x')$.

Remarks:

1. The intuitive meaning of “ $a \leq b$ ” is that “in general”, that is, “if nothing else is known”, branching tuple a is at least as good as b (doesn’t lead to larger branching trees). The main result of this section is that actually there is exactly one canonical branching order.

2. (TQO) expresses the comparability of branching tuples; the order does not fulfil antisymmetry (i.e., $a \leq b \wedge b \leq a \Rightarrow a = b$), since for example, as stated in (P), permutation doesn't change the value of a branching, and via (CMP) also composition of a branching tuple with itself doesn't change its value.
3. (CMP) states that if a is at least as good as b , then $a \mathbb{M} b$ as well as $b \mathbb{M} a$ are "compromises", improving b and impairing a .
4. (P) says permutation does not change anything essential.
5. (W) requires that adding branches to a branching impairs the branching.
6. (M) states that increasing some component of a branching tuple of width at least two strictly improves the branching tuple.
7. Finally (Con) states that sufficiently small changes in one component yield only small changes in the "value" of the tuple.

Lemma 8.5.1. *The linear quasi-order on \mathcal{BT} given by $a \leq b \Leftrightarrow \tau(a) \leq \tau(b)$ for $a, b \in \mathcal{BT}$ is a canonical branching order.*

Lemma 8.5.2. *Consider a canonical branching order \leq on \mathcal{BT} . Then for $a, b \in \mathcal{BT}$ with $\tau(a) < \tau(b)$ we have $a < b$.*

Theorem 8.5.3. *There is exactly one canonical branching order on branching tuples, given by $a \leq b \Leftrightarrow \tau(a) \leq \tau(b)$ for all $a, b \in \mathcal{BT}$.*

Proof. Consider a canonical branching order \leq . We have to show that for all $a, b \in \mathcal{BT}$ we have $a \leq b \Leftrightarrow \tau(a) \leq \tau(b)$. By Lemma 8.5.1 we know the direction from right to left. So assume that \leq is a canonical branching order, and consider $a, b \in \mathcal{BT}$. If $a \leq b$ holds, then $\tau(a) > \tau(b)$ by Lemma 8.5.2 would imply $a > b$ contradicting the assumption. So assume now (finally) $\tau(a) \leq \tau(b)$, and we have to show that $a \leq b$ holds. If $a > b$ would be the case, then by (Con1) there exists $\varepsilon \in \mathbb{R}_{>0}$ with $a \mathbb{M}(\varepsilon) > b$, however we have $\tau(a \mathbb{M}(\varepsilon)) < \tau(a) \leq \tau(b)$, and thus by Lemma 8.5.2 it would hold $a \mathbb{M}(\varepsilon) < b$. \square

For branching tuples with rational entries the canonical branching order can be decided in polynomial time (in the binary representation) by using the decidability of the first-order theory of the real numbers ([Ren92]). The approach of this section can be generalised by considering only tuples of length at most k resp. of length equal k , and formulating the axioms in such a way that all occurring branching tuples are in the restricted set. In the light of the questions arising in the subsequent Section 8.6 about projections for branching tuples of restricted width such generalisations seem to be worth to study.

8.6. Alternative projections for restricted branching width

The argumentation of Subsection 8.5 depends on considering branching tuples of arbitrary length. The strength of the τ -function is that it imposes a consistent scaling for tuples of different sizes, and Theorem 8.5.3 shows that the order induced by the τ -function (the canonical order) is the only reasonable order if

branching tuples of arbitrary width are considered. Now if we consider only branching tuples of some constant length, then other choices are possible. Practical experience has shown that for a binary branching tuple (a_1, a_2) maximising the product $a_1 \cdot a_2$ yields good results, and this projection is universally used now (ignoring tie-breaking aspects here), while maximising the sum $a_1 + a_2$ has been shown by all experiments to perform badly. We are now in a position to give theoretically founded explanations:

1. The general rule is that $\tau(a_1, a_2)$ should be minimised.
2. If computation of $\tau(a_1, a_2)$ is considered to be too expensive, then the approximations from Corollary 1, Part 2 could be used, which amount here to either maximise the arithmetic mean $\mathfrak{A}(a_1, a_2)$ or to maximise the geometric mean $\mathfrak{G}(a_1, a_2)$. Now maximising $\mathfrak{A}(a_1, a_2)$ is equivalent to maximising the sum $a_1 + a_2$, while maximising the geometric mean $\mathfrak{G}(a_1, a_2)$ is equivalent to maximising the product $a_1 \cdot a_2$.
3. So maximising the sum $a_1 + a_2$ means to minimise a lower bound on the τ -value, while maximising the product $a_1 \cdot a_2$ means minimising an upper bound on the τ -value — it appears now that the second choice is more meaningful, since it amounts to minimise an upper bound on the tree size, while minimising a lower bound on the tree size leads to nowhere.

A more quantitative explanation is given by the following lemma, which shows that the product yields a better approximation to the τ -mean than the sum.

Lemma 8.6.1. *We have $\mathfrak{A}(a_1, a_2) - \mathfrak{T}(a_1, a_2) \geq \mathfrak{T}(a_1, a_2) - \mathfrak{G}(a_1, a_2)$ for all $a_1, a_2 \in \mathbb{R}_{>0}$, with equality iff $a_1 = a_2$ (and in this case both sides are zero).*

Especially for branching tuples with more than two entries the τ -function appears as the canonical choice; if approximations are sought then the product (corresponding to the geometrical mean) can no longer be used, but the general upper bound from Corollary 1, Part 2 is a candidate.³ It is not clear whether for branching tuples of constant width the canonical order is always the superior choice (and using for example the product-rule for binary branches is just a reasonable approximation), or whether there might be special (but still “general”) circumstances under which other orders are preferable. Considering again binary branchings, for the canonical order the branching tuples $(1, 5)$ and $(2, 3)$ are equivalent, but they are distinguished by the product rule which favours $(2, 3)$. This is in fact a general property of the product rule (which, as already said, is only sensible for binary tuples) that it favours more symmetric tuples (compared to the canonical order).

³The unsuitability of the product for branching widths at least 3 can be seen for example by the fact that the product is ∞ -dominated (i.e., if one component goes to infinity, so does the product), while the τ -function is ∞ -ignorant — if one branch is very good, then this does not mean that the whole branching is very good, but only that this branch doesn’t contribute to the overall cost.

8.7. How to select distances and measures

After having laid the foundations, in this section we consider now the basic “branching schemes” used by such (practical) SAT solvers employing branching algorithms. The essential ingredient of these “schemes” (made more precise in Subsection 8.7.2) is the underlying distance function, however obviously the whole of the algorithm is important, and the aspects related to the branching heuristics are condensed in these “schemes”.⁴ The main purpose is to give an overview on the relevant measures $\mu(F)$ of “absolute problem complexity” or of distances $d(F, F')$ as measurements of “relative problem complexity”, as core ingredients of the heuristical melange found in a SAT solver. This is intertwined with especially the reduction process, and we discuss this aspect further in Subsection 8.7.2. A potential source for future heuristics is the literature on worst-case upper bounds, and we make some comments in Subsection 8.7.3. Then in Subsection 8.7.4 we give a “rational reconstruction” of the branching schemes currently used in practice, which actually all can be explained as “maximising the number of new clauses” — this branching rule in its pure form was implemented by the `OKsolver-2002` (see [Kul02]), and is presented in Subsection 8.7.4.1, while the historical development in practical SAT solving leading to this rule is discussed in Subsection 8.7.4.2. For background on “look-ahead SAT solvers” in general see Chapter 5 of this handbook.

8.7.1. Some basic notations for clause-sets

Applying the abstract ideas and notions to concrete problems, now we need to consider more closely actual problem instances. In the sequel we use the following notations for (multi-)clause-sets F :

- $n(F) := |\text{var}(F)|$ is the number of variables (actually occurring in F).
- $c(F) := |F|$ is the number of clauses, and more specifically $c_k(F)$ for $k \in \mathbb{N}_0$ is the number of clauses of length (exactly) k .
- $\ell(F) = \sum_{C \in F} |C| = \sum_{k \in \mathbb{N}_0} c_k(F) \cdot k$ is the number of literal occurrences.
- The maximal clause-length is denoted by $\text{rank}(F)$.
- For a partial assignment φ the result of applying φ to F is denoted by $\varphi * F$ (eliminating satisfied clauses, and removing falsified literals from the remaining clauses).
- The partial assignment (just) assigning value ε to variable v is denoted by $\langle v \rightarrow \varepsilon \rangle$.
- $r_k(F)$ denotes generalised unit-clause propagation (see [Kul99a]), i.e., r_0 just reduces F to $\{\perp\}$ iff $\perp \in F$, r_1 is unit-clause propagation, r_2 is failed-literal propagation etc.

⁴As remarked earlier, yet heuristics for conflict-driven solvers are mainly “purely heuristical”, and no theoretical foundation exists, whence we do not consider them here. Some general remarks on heuristics in this context are in [Kul08b]. From a theoretical angle, in [BKS04] guidance by structure has been considered (on an example), while [BKD⁺04] considered the relation between tree decompositions and learning.

8.7.2. On the notion of “look-ahead”

An important concept in this context is the notion of “look-ahead”, which is used in the literature in different ways, and so needs some discussion. A *reduction* is typically a function $r(F)$ for problem instances F , computable in polynomial time such that problem instance $r(F)$ is satisfiability equivalent to F . Now for example in [Fre95] “look-ahead” is used mainly instead of “reduction” (actually framed in the language of constraint satisfaction, as “constraint propagator”), and this reduction process can actually be integrated into the heuristics for choosing the branching variable. This integration of reduction and heuristics seems to be rather popular amongst current look-ahead architectures, however in this article, with its foundational emphasis, we need clean and precise distinctions, and so we use the following architecture of a recursive backtracking SAT solver:

1. The input is a problem instance F .
2. Via the *reduction* r the instance is reduced to $F' := r(F)$, including at least unit-clause propagation (iterated elimination of (all) unit-clauses).
3. If now F' is trivially satisfiable or unsatisfiable, as established by the *immediate-decision oracle*, then the result is returned (more complex tests for satisfiability or unsatisfiability can be integrated into the reduction).
4. The purpose of the *branching scheme* (for standard SAT solvers) is now to select a *branching variable* $v \in \text{var}(F')$ such that branching using the two branches

yields the “fastest” decision (applying the algorithm recursively to the branches). Note that from this point of view branching considers only reduced instances. For sequential execution the ordering of the branches is important, and is accomplished by the *branching ordering heuristics*. The tasks of the branching scheme and the branching ordering heuristics are accomplished as follows:

- (a) For each variable $v \in \text{var}(F')$ and value $\varepsilon \in \{0, 1\}$ the *look-ahead reduction* r' computes an approximation of $r(\langle v \rightarrow \varepsilon \rangle * F')$ as $F_v^\varepsilon := r'(\langle v \rightarrow \varepsilon \rangle * F')$, where r' is a weaker form of r .
- (b) Via the *distance function* d for each variable v the branching tuple $t_v := (d(F', F_v^0), d(F', F_v^1)) \in \mathbb{R}_{>0}^2$ is computed.
- (c) Via the *projection* ρ each branching tuple t_v is projected to a single real number $\rho(t_v)$, and the branching scheme selects a variable v_0 with minimal $\rho(t_{v_0})$ (possibly using additional distance functions to break ties).
- (d) The branching order finally is established by a *satisfiability estimator* $P(F_{v_0}^\varepsilon)$, a function which computes for each branch $F_{v_0}^\varepsilon$ an “approximation” of the chance of being satisfiable, and the branch with higher P -value is chosen first.

In order to separate reduction and branching scheme we require here that no reduction takes place in Step 4 (where the branching scheme performs its work), that is, no F_v^ε is trivially decidable (according to Step 3), and thus r must actually be stronger than r' . Often r is the “look-ahead version” of r' , that is, if r' is the identity, then r is just unit-clause propagation, and if r' is unit-clause propagation then r is failed-literal elimination; in general, if $r' = r_k$ then often $r = r_{k+1}$. In practice typically the separation between reduction and heuristic is blurred, and the choice of the “branching heuristics” involves a mixture of choices for reduction, look-ahead reduction, distances, projections and satisfiability estimator, typically applied in an entangled way to improve efficiency, but for the correct understanding the above distinctions seem essential.

8.7.3. Branching schemes in theoretical algorithms

[Kul92, Kul99b] introduced the now dominant technique for proving worst-case upper bounds on NP-hard problems, called “measure-and-conquer” in [FGK05], which is based on Theorem 8.4.8 and the use of an appropriate “interesting” distance d or measure μ . For a recent work on upper bounds and measures see [Wah07], and Chapter 16 of this handbook for worst-case upper bounds in general, while in this chapter we only consider the particular strand of work in this area which influenced heuristics for SAT solving.

In [KL97, KL98] the basic measures n , c , ℓ for SAT decision have been considered for the first time systematically. [Kul99b], motivated by [Sch92], based his analysis on the (measure-based) distance $d^2 = \Delta m_k = \Delta n - \alpha \Delta z_k$, where z_k is a capped version of c_2 (in order to make c_2 and n comparable), and $\alpha \in \mathbb{R}_{>0}$ is to be optimised. Note that a *decrease* in n is favourable, while an *increase* in the number of binary clauses is favourable. An important refinement then replaces the distance d^2 by the distance d^3 , which takes (depending on the parameter k) a fixed amount of *new* binary clauses into account (as improvement), while “ignoring” the number of eliminated binary clauses. Starting from this measure, by extensive experimentation the heuristic for the `OKsolver-2002` was empirically “derived” ([Kul98]), arriving for 3-CNF at a distance function without magic numbers, which is just the number of *new binary clauses*.

That the distance Δn vanished finally in this development can be motivated as follows: Δn was used in [Kul99b] since an upper bound in the measure n was to be derived. But “heuristic” versions, which just care about making the tree smaller, without caring about accompanying (interpretable) upper bounds, can remove the factor n which imposed, due to the positivity requirement $d^3 > 0$, a cap on the number k of binary clauses to be taken into account — now arbitrary amounts of new binary clauses count! This branching scheme, generalised to arbitrary CNF will be further discussed in Subsection 8.7.4.1. It seems to be at this time the strongest “pure” heuristics known (for look-ahead solver, and used as basis for further heuristical extensions). And, by “magic coincidence”, its basic content is closely related to the emerging heuristics from practical SAT solving, as explained in Subsection 8.7.4.2.

8.7.4. Branching schemes in practical algorithms

Now we turn to branching schemes as proposed (and used) in the realm of “practical SAT solving”. First a few comments on very simple underlying distances, which might be useful for comparisons (or perhaps in the context of optimising combinations of distances, as considered in Section 8.8):

1. The trivial choice, an “arbitrary variable”, is reflected by choosing a constant distance function. Here the “tie-breaking rule” becomes decisive, and choosing a random variable, which for random instances is the same as choosing the first variable in a fixed (instance-independent) order, is considerably worse than choosing the first occurring variable in the clause-set, which for random instances in the average will choose the variable occurring most often.
2. Δn is perhaps the most basic non-trivial choice. This distance gets stronger with look-ahead, but for practical SAT solving it never played a role yet (different from the theoretical upper bounds as mentioned in Subsection 8.7.3). Δc and $\Delta \ell$ are more sensitive to the input⁵, but still these distances appear as not suitable for practical SAT solving in general. Likely the basic problem with these measures is that they do not provide any guidance towards increased efficiency of the reduction process (unit-clause propagation and beyond).

We present the branching scheme of the `OKsolver-2002` in Subsection 8.7.4.1 as the core rule: It represents a certain convergence of theoretical considerations coming from worst-case upper bounds (see Subsection 8.7.3) with practical developments (see Subsection 8.7.4.2), it has been deliberately kept free from purely heuristical considerations (as much as possible — only the clause-weights appear to be unavoidably of heuristical nature), and this one rule actually represents the core of modern branching rules for look-ahead solvers. As explained in Subsection 8.7.3, the underlying distance started from a combination of Δn and the number of new 2-clauses (for inputs in 3-CNF), but experimental results forced Δn to leave, and the result is close to the rule `dsj` as a result of the development starting with the Jeroslow-Wang rule — however the novelty is, and this came from the theoretical investigations in worst-case analysis, to view the whole process as applying a distance function, with the aim of maximising the number of *new clauses*.⁶ In the literature on practical SAT solving, this target (creating as many strong constraints as possible) has been first discussed in [Li99].

There have been a few attempts of going beyond the underlying distance:

1. In [Ouy99], Chapter 3, we find a scheme to dynamically adjust the weights of clauses of length 2, leading to branching rule “B”. However, since this considers the “old” clauses, it really means new clauses of length 1, i.e.,

⁵where for $c \geq n$ to hold, reduction by matching autarkies is needed (see [KL98, Kul03])

⁶The explanations in [HV95] for the first time concentrated on the role of unit-clause propagations, however from the point of view of simplifying the current formula, not, as the distance functions emphasises, from the point of view of the emergence of *future reductions*.

unit-clauses, which from our point of view shouldn't be considered in this form by the branching rule, but it should be considered by the (r_1) look-ahead. So this scheme seems only to be another approximation of the look-ahead, where at least for "look-ahead solvers" the r_1 -look-ahead seems mandatory now.

2. Van Maaren et al considered non-linear approximations of CNF in order to gain a deeper, geometrical understanding of the problem instance. These efforts culminated in the branchings rule discussed in [vW00], where branching rule "MAR" is presented. The main idea is to derive for the residual clause-set in a natural way an n -dimensional ellipsoid (where n is the number of variables of the current clause-set), where each variable corresponds to one axis of the ellipsoid, and then the geometry of the ellipsoid can tell us which variable might have the biggest influence. Again the problem is that it seems impossible to include into this picture the logical inferences, i.e., the look-ahead. The fundamental problem is that this point of view doesn't seem to deliver a measure or a distance, and thus it cannot be used to compare arbitrary problem instances. Perhaps this restriction can be overcome in the future.

The most promising direction at this time for strengthened distances is presented in Section 8.8, where, based on our general understanding of the interplay between distances and trees, possibilities are discussed to optimise distance functions, even online, so that one can start with a reasonable distance, as presented in the subsequent Subsection 8.7.4.1, and then adapt it to the problem at hand.

8.7.4.1. Maximise the number of new clauses

We start with presenting the current state-of-the-art, which in its pure form is the branching rule "MNC" ("maximise new clauses") used by the `OKsolver-2002`, and from this we make a "rational reconstruction" of earlier rules (in Subsection 8.7.4.2), which can well be understood as approximations of MNC.

MNC for a branching variable v and the residual clause-set F considers the two branches F_0, F_1 , where for a standard look-ahead solver we have $F_\varepsilon = \varphi_\varepsilon * F$, where φ_ε is the extension of $\langle v \rightarrow \varepsilon \rangle$ by unit-clause propagation, and uses as distance the weighted number of new clauses

$$d_{\text{MNC}}(F, F') = \sum_{k=2}^{\text{rank}(F)-1} w_k \cdot c_k(F' \setminus F).$$

More precisely, multi-clause-sets should be used here, since typically in practice multiple occurrences of the same new clause are counted, and no contraction with existing clauses takes place. By optimisation on random 3-CNF at the (approximated) threshold, optimal weights could be established as approximately $w_2 := 1$, $w_3 := 0.2$, $w_4 := 0.05$, $w_5 := 0.01$, $w_6 := 0.003$ and $w_k = 20.45 \cdot 0.2187^k$ for $k \geq 7$, where these weights also work quite well on other problem instances. The "precise" combination of the two distances $d_{\text{MNC}}(F, F_0), d_{\text{MNC}}(F, F_1)$ into

one number happens via the τ -function, while in practice the product-rule is sufficient (as discussed in Subsection 8.6). After the best variable has been chosen, the first branch is selected as will be discussed in Section 8.9, where in practical applications currently the scheme discussed in Subsection 8.9.1 seems to yield the best results. A few remarks:

1. We have $d_{\text{MNC}}(F, F_\varepsilon) = 0$ iff $F_\varepsilon \subseteq F$, in which case φ_ε is a “weak autarky” for F , and thus F_ε is satisfiability equivalent to F , so no branching is needed.
2. The more new clauses the better, and the better the shorter they are.
3. New clauses result from falsifying literal occurrences in (old) clauses which are not satisfied — satisfied clauses are ignored by the distance (but will be taken into account when choosing the first branch).
4. When performing look-ahead the behaviour of d_{MNC} seems counterintuitive: Consider two variables v, w , where for v we have in both branches many inferred assignments (by unit-clause propagation), but it happens that they both result in just, say, one new clause each; on the other hand, assume that for w in both branches there aren’t many inferred assignments (possibly none at all), but more new clauses. Then w will be preferred over v . Such examples can be constructed, but in practice it turned out that attempts at balancing d_{MNC} , by for example the number of inferred assignments, performed worse in almost all cases (which is also confirmed by the historical development, as outlined in the subsequent subsection).⁷

Instead of clauses also more general “conditions” (“constraints”) can be treated, if partial assignments can be applied to them, and instead of new clauses we then need to consider conditions whose domains have been restricted. Since conditions can show much more variety in their behaviour, the problem of the choice of weights for the “new conditions” becomes more pronounced; a first approximation is to replace the length k of clauses by the size of the domain of the condition, but in general one needs to keep in mind that the reason why shorter clauses are preferred over longer ones is that they are *more constrained*, i.e., will easier yield inferred assignments in the future. One can measure the ratio of falsifying assignments for the new conditions (the higher the better), but according to current knowledge extensive experimentation to find good weighting schemes seems unavoidable. One also needs to take into account that while clauses can only yield a single inferred assignment, other constraints can yields more inferred assignments (at once; and potentially also other types of information might be inferred, for example equality between variables). See Subsection 8.10.1 for some examples.

⁷The extreme case of zero new clauses needs to be handled (since distances need to be positive), and for this case we have the autarky-reduction above; in [Kul99b] also the case of an arbitrary number of new clauses is treated via the addition of “autarky clauses” (which actually goes beyond resolution), and the `OKsolver-2002` contains (deactivated) code for handling the case of exactly one new clause. The future has to show whether this scheme is of value.

8.7.4.2. The historical development (for practical SAT solving)

An early branching scheme is presented in [JW90], and is known as the “Jeroslow-Wang rule”. Since it is a rather confused rule, of weak efficiency and mixing up several aspects, we do not further comment on this scheme. However this scheme was at least historically of importance, since it allowed [HV95] to state an improved branching scheme, with improved (though still confused) reasoning: The Jeroslow-Wang rule is replaced by the “two-sided Jeroslow-Wang rule”, rejecting the idea that branching schemes are “satisfiability driven”, and replacing this paradigm by the “simplification paradigm”. We can interpret this rule by the underlying distance $d_{2JW}(F, F') := \sum_{k=1}^{\text{rank}(F)-1} w_k \cdot c_k(F' \setminus F)$ where $w_k := 2^{-k}$ (strictly following [HV95] it would be $w_k = 2^{-(k+1)}$, but obviously the factor $\frac{1}{2}$ doesn’t matter here). Reduction is unit-clause propagation and pure literal elimination. No look-ahead is used (fitting with the choice of reduction(!)), and as projection the sum is used. The choice of the first branch happens by the Johnson-rule (see Subsection 8.9.2). We see that d_{MNC} improves d_{2JW} by

1. using the product as projection;
2. discriminating sharper between different clause-length;
3. using r_1 -look-ahead (instead of r_0);
4. choosing of the first branch by the Franco-rule (see Subsection 8.9.1).

These shortcomings have been addressed piecewise by later developments as outlined below. Regarding our interpretation, we need to stress that the understanding of the “two-sided Jeroslow-Wang rule” as based on the distance of counting *new* clauses is a rational reconstruction, while the argumentation in [HV95] tries to argue in the direction of “simplification”. However this is not really what d_{2JW} is aiming at, namely increasing the number of future forced assignments (by unit-clause propagation or stronger means). In [HV95] we find a misleading understanding of the sum $d_{2JW}(F, \langle v \rightarrow 0 \rangle * F) + d_{2JW}(F, \langle v \rightarrow 1 \rangle * F)$ (maximised by the heuristics), which is there understood as estimating the simplification (as a kind of average over both branches), and so the real target of the rule, creating many new short clauses (for both branches(!)), where then the sum only acts as a (bad) projection, remained hidden.

[VT96] improves upon this branching scheme by using the product as projection (incorporated in the branching rule **dsj**), apparently for the first time, while still not using look-ahead. [DABC96] (the **C-SAT** solver) did not yet use the product-projection, but introduced certain aspects of look-ahead (incorporating the first round of unit-clause propagation) and also a steeper decline for the weights w_k (close to the weights used by the **OKsolver-2002** scheme), namely now $w_k = -\log(1 - (2^{k+1} - 1)^{-2})$, where the quotient $\frac{w_k}{w_{k+1}}$ is monotonically decreasing, with limit 4. In Section 3.1 of [Ouy99] a possible derivation of this rule is offered. A similar approach (but already using the product-projection, and partially using r_2 as reduction), improving the **Satz** solver, is discussed in [Li99]. While these heuristics aimed at “doing a thorough job”, there is also the direction of “cheaper heuristics”, mostly focusing on efficient implementations. The basic idea is “MOM”, i.e., “maximum occurrences in clauses of minimum size”,

and all these heuristics can be understood as approximations of “maximise the number of new clauses”, driven by the kind of available data which happens to be supported by the data structures. The solver `Posit` ([Fre95]) introduced efficient data structures and an efficient implementation of r_2 -reduction (which altogether made it very competitive), but regarding heuristics no progress over [VT96] took place. Once the efficiency of r_2 -reduction (“failed literal eliminations”) for this type of solvers (the “look-ahead solvers”) became apparent, the cost of measurements needed to evaluate d_{MNC} and variations as well as the cost of look-aheads diminishes (relatively), and the branching scheme as embodied in its pure form by the `OKsolver-2002` (as discussed in Subsection 8.7.4.1) is now the common standard of look-ahead solvers. The `march`-solvers extended the scheme in various ways (see [Heu08]), considering only a subset of variables for the look-ahead, as pioneered by [LA97], but the core rule has been left unchanged.

8.8. Optimising distance functions

Now we turn to the topic of improving distance functions by evaluating how good they actually predict progress as given by the real branching trees. The possibility of evaluating distances leads to the possibility of actually optimising distances, and the two basic approaches are considered in Subsections 8.8.2, based on the evaluation techniques discussed in Subsection 8.8.1. The subject of optimising distances has been studied in the context of theoretical upper bounds (see Subsection 8.7.3). For practical SAT solving however there seems to be no general attempt (considering arbitrary distances) in the literature. The notion of “adaptive heuristics” as used in [Hv07] is based on a broad view of “heuristics”, and actually only concerns the reduction process (see Subsection 8.7.2), by dynamically adapting the set of variables eligible for reduction considerations, thus weakening the reduction by excluding variables, and also adapting the set of variables for a strengthened reduction.

8.8.1. Evaluating distance functions

The “relative” effectiveness of the distance function d used in a solver on one particular instance (with medium-size branching tree) can be gauged (that is, regarding its “relative values”) as follows: Compute the distribution of the random variable P^{-1} induced by \mathfrak{P}_d (see Definition 8.4.3) — a good distance function yields a centred distribution (around $E(P^{-1}) = \#lvs(T)$), while a bad distance function is more similar to the uniform distribution.

This evaluation is also computationally not very expensive: At each node along the current path the probabilities of the branches are computed, and once a leaf is found, then the product of these probabilities along the whole path is dumped to a file; viewing the distribution of the random variable P with a statistical tool kit (like R) might reveal interesting phenomena.⁸ That we consider only “relative values” of d here means that an “optimal distance” d (with constant

⁸Handling the logarithms of the probabilities is likely advantageous. And one should keep

$P^{-1} = \#\text{lvs}(T)$) is derived from a canonical distance $\Delta\mu$ with $\mu(v) = \log \#\text{lvs}(T_v)$ (recall Lemma 8.4.9) by multiplying the branching tuple at each inner node with an *individual* positive real number (possibly different for each node).

Care is needed with the interpretation of such evaluations: Comparing different distance functions can be misleading (even on the same tree), since, metaphorically speaking, to make some interesting predictions something needs to be risked, and a thumb heuristic can have a smaller variance than a more powerful heuristic.

A weakness in using the variance for evaluating distance functions is that the absolute values of the distances at different nodes are ignored. The second basic possibility for evaluating distances on (given) trees is to use the upper bound from Theorem 8.4.8, which on the other hand has the disadvantage that only the worst nodes are considered (while the variance includes all nodes).

8.8.2. Minimising the variance or minimising the tau-upper-bound

A numerical value for the quality of the distance function d is given by the variance $\text{Var}(P^{-1})$ (the smaller the better, and the optimal value is 0); for convenience the standard deviation $\sqrt{\text{Var}(P^{-1})}$ might be used, and for comparing different trees the normalised standard deviation $\frac{\sqrt{\text{Var}(P^{-1})}}{\#\text{lvs}(T)}$ is appropriate, however these quantities only serve as a “user interface” in our context, and are not considered furthermore. By Lemma 8.4.4 we have an efficient recursive method for computing the variance, which also does not cause space overhead since no additional storage is required (if we do not want to visually inspect the spread of P^{-1}). If we have given several distance functions d_1, \dots, d_k , then we can choose the best one (on average) as the one with minimal $\text{Var}(P_{d_i}^{-1})$. This method can also be used “on the fly”, during the execution of a backtracking solver, with negligible overhead, to dynamically adapt the solver to the problem at hand. Of course, measuring the quality of a distance function by the variance $\text{Var}(P_d^{-1})$ enables not only comparison of different distance functions, but if d depends on parameter α (possibly a vector), then we can also optimise d_α by minimising $\text{Var}(P_{d_\alpha}^{-1})$ (for the given tree). A special (interesting) case is where d is given as a convex linear combination of distances d_1, \dots, d_k (that is, $d = \sum_{i=1}^k \lambda_i \cdot d_i$ for $\lambda_i \geq 0$ and $\sum_{i=1}^k \lambda_i = 1$). Actually, here the d_i do not need to be distances, but could even assume negative values, if only we take care to restrict the λ_i accordingly to avoid non-positive values of d . These optimisations could be also performed “online”.

Instead of minimising $\text{Var}(P_{d_\alpha}^{-1})$ one could consider minimising $\max(P_{d_\alpha}^{-1}) = \max_{v \in \text{lvs}(T)} P_{d_\alpha}(v)^{-1}$, i.e., minimising the worst-case upper bound from Lemma 8.4.1. This task is considerably simplified by applying logarithms. However this optimisation is much rougher, since it only cares about getting rid off the most extreme cases (this is the worst-case perspective), which might be weak since the worst case might occur only rarely. So the only real alternative seems to minimise the upper bound $(\max \tau(d))^{\max \Sigma(d)}$, or better $\log((\max \tau(d))^{\max \Sigma(d)}) =$

in mind that on the leaves we do not consider the uniform probability distribution, and so just plotting the “observations “ is not meaningful.

$(\max \Sigma(d)) \cdot \log(\max \tau(d))$, which still suffers from considering only the worst case, but has the advantage that scaling of the distances is taken into account.

8.9. The order of branches

After having chosen the branching variable, the next step then is to order the branches, which according to Subsection 8.7.2 is the task of the *branching ordering heuristics* (thus ordering of branches is not integrated into the τ -method, but is an additional step).⁹ We extract an approximated “probability” that we have a favourable situation, like finding a satisfying assignment for look-ahead solvers, or “learning a lot” for conflict-driven solvers, and order the branches according to this approximation (in descending order). Unfortunately yet not much theoretically founded is known about clause-learning, and the question here is only how to compute “approximations” of some form of probability that a clause-set F is satisfiable. Such “approximations” are achieved by *satisfiability estimators* P .

For unsatisfiable problem instances the order doesn’t matter (without learning), while for satisfiable instances, whatever the branching is, finding the right first branch actually would solve the problem quickly (when ignoring the time for choosing the first branch). While in previous sections often the problem representation was not of importance, and very general satisfiability problems over non-boolean variables could be handled, now the approaches are combinatorially in nature and thus are more specific to (boolean) clause-sets. In Subsections 8.9.1 and 8.9.2 we consider the two schemes currently used in practice¹⁰. A difficulty is that these two satisfiability estimators for choosing the first branch do not have standard names; for ease of reference we propose the following names:

1. Since apparently the first approach has first been mentioned by John Franco, we call it the “Franco heuristics” or “Franco estimator”.
2. The second approach was apparently first mentioned in [Joh74] in the context of “straight-line programs”, which is close to our usage, while the “Jeroslow-Wang heuristics” from [JW90] misuses the heuristics to actually choose the branching *variable* (as discussed in Subsection 8.7.4.2), so it seems sensible to call the heuristics the “Johnson heuristics” (or the “Johnson estimator”).

8.9.1. The Franco estimator: Considering random clause-sets

This approach, apparently first mentioned in the literature in [GPFW97] (in the context of backtrack-free algorithms for random formulas), considers F as a

⁹In [Hv08] this is called “direction heuristics”. We prefer to speak of the ordering of branches since our methods work for arbitrarily wide branchings, and they consider not just the first branch.

¹⁰The *OKsolver-2002* uses the first scheme, and on random 3-CNF this scheme appears to be slightly stronger than the second one, an observation already made 1986 by John Franco in the context of (incomplete) “straight-line SAT algorithms” (which do not backtrack but abort in case of a failure).

random element $F \in \Omega(p_1(F), \dots, p_k(F))$ of some probability space Ω depending on parameters p_i . So now we can speak of the probability $P_\Omega(F \in \mathcal{SAT})$ that F is satisfiable. Yet this approach has not been applied in this form, and one does not consider the (complicated) probability $P_\Omega(F \in \mathcal{SAT})$ of “absolute” satisfiability, but instead the probability $P_\Omega(\varphi * F \in \mathcal{SAT})$ that a random (total) assignment φ satisfies a random $F \in \Omega$. Most natural is to consider the constant density model (with mixed densities), that is one considers all clause-sequences F as equally likely which have $n(F)$ many (formal) variables and $c(F)$ many clauses in total, where for clause-length k we have $c_k(F)$ many clauses. Then actually the random assignment φ_0 can be fixed, say to the all-zero assignment, and due to the independence of the clause-choices we have $P(\varphi_0 * F \in \mathcal{SAT}) = \prod_{C \in F} (1 - 2^{-|C|})$. For efficiency reasons the use of the logarithm $L(F) := \log \prod_{C \in F} (1 - 2^{-|C|}) = \sum_{C \in F} \log(1 - 2^{-|C|})$ is preferable, where furthermore the factors $\log(1 - 2^{-k})$ for relevant clause-lengths $k = 1, 2, 3, \dots$ can be precomputed. So the first approach yields the rule to order a given branching (F_1, \dots, F_m) by descending $L(F_i) = \sum_{k \in \mathbb{N}_0} c_k(F_i) \cdot \log(1 - 2^{-k})$.

8.9.2. The Johnson estimator: Considering random assignments

The second approach considers the specific F equipped with the probability space of all total assignments, and the task is to approximate the probability $\#\text{sat}(F)/2^{n(F)}$ that a random assignments satisfies F , where $\#\text{sat}(F)$ is the number of satisfying (total) assignment. Since for conjunctive normal forms falsifying assignments are easier to handle than satisfying assignments, we switch to the consideration of the probability $P_0(F) := \#\text{usat}(F)/2^{n(F)} = 1 - \#\text{sat}(F)/2^{n(F)}$ that a total assignment falsifies F (where $\#\text{usat}(F)$ is the number of total assignments falsifying F). We have the obvious upper bound $P_0(F) \leq \#\text{usat}(F)/2^{n(F)} \leq P_0^1(F) := \sum_{C \in F} 2^{-|C|}$, which is derived from considering the case that no total assignment falsifies two (different) clauses of F at the same time. The lower index “0” in $P_0^1(F)$ shall remind of “unsatisfiability”, while the upper index indicates that it is the first approximation given by the “inclusion-exclusion” scheme. Using P_0^1 as approximation to P_0 , we obtain the rule to order a branching (F_1, \dots, F_m) by ascending $\sum_{k \in \mathbb{N}_0} c_k(F_i) \cdot 2^{-k}$. We see that this method in principle is very similar to the first method, in both cases one minimises (for the first branch) the weighted number $c^w(F) = \sum_{k=0}^{\infty} w(k) \cdot c_k(F)$ of clauses of F , where the weights $w(k)$ depend only on the length k of the clauses. The only difference between these two methods are the weights chosen: for the first method we have $w_1(k) = -\log(1 - 2^{-k})$, for the second $w_2(k) = 2^{-k}$. Asymptotically we have $\lim_{k \rightarrow \infty} \frac{w_1(k)}{w_2(k)} = 1$, since for small x we have $-\log(1 - x) \approx x$. So the second method can also be understood as an approximation of the first method.

Another understanding of this heuristic comes from [Joh74]: $P_0^1(F)$ is the (exact) expected number of falsified clauses for a random assignment (this follows immediately by linearity of expectation). We remark that thus by Markov’s inequality we obtain again $P_0(F) \leq P_0^1(F)$. And finally we mention that if $P_0^1(F) < 1$ holds, then F is satisfiable, and the Johnson heuristic, used either without look-

ahead or with look-ahead involving unit-clause-propagation, will actually find a satisfying assignment without backtracking, since in case of $P_0^1(F) < 1$ for every variable $v \in \text{var}(F)$ there exists $\varepsilon \in \{0, 1\}$ with $P_0^1((v \rightarrow \varepsilon) * F) < 1$. We also see that using the Johnson heuristic without backtracking and without look-ahead yields an assignment which falsifies at most $P_0^1(F)$ many clauses of F . For fixed uniform clause-length k we get at most $P_0^1(F) = c(F) \cdot 2^{-k}$ falsified clauses, that is at least $c(F) \cdot (1 - 2^{-k})$ satisfied clauses, which actually has been shown in [Hås01] to be the optimal approximation factor ($\frac{1}{1-2^{-k}}$) for the maximal number of satisfied clauses which can be achieved in polynomial time (unless $P = NP$).

8.9.3. Alternative points of view

It appears to be reasonable that when comparing different branchings (for SAT this typically means different branching variables) where one branching has a branch with a very high associated probability of satisfiability, that then we take the satisfiability-aspect more important than the reduction-aspect, since we could be quite sure here. Yet it seems that due to the crudeness of the current schemes such considerations are not very successful with the methods discussed above, however they are applied in the context of a different paradigm, which does not use approximated satisfiability probabilities of problem instances for the ordering of branches, but uses approximations of *marginal probabilities* for single variables as follows: Consider a satisfiable problem instance F (for unsatisfiable instances the order of branches does not matter in our context) and a variable $v \in \text{var}(F)$. If we can compute reasonable approximations $\tilde{p}_v(\varepsilon)$ for values $\varepsilon \in \{0, 1\}$ of the ratio $p_v(\varepsilon)$ of satisfying (total) assignments f with $f(v) = \varepsilon$, then we choose first the branch ε with higher $\tilde{p}_v(\varepsilon)$. The main structural problem of this approach is that it focuses on single variables and cannot take further inferences into account, while when having a satisfiability probability estimator $P(F)$ at hand, then we can improve the accuracy of the approximation by not just considering $P(\langle v \rightarrow \varepsilon \rangle * F)$ but applying further inferences to $\langle v \rightarrow \varepsilon \rangle * F$. However especially for random problems this approach shows considerable success, and so we conclude this section by some pointers to the relevant literature.¹¹

The basic algorithm for computing the marginalised number of satisfying assignments (i.e., conditional on setting a variable to some given value) is the “sum-product algorithm” (see [KFL01]), also known as “belief propagation”. This algorithm is exact if the “factor graph”, better known to the SAT community as “clause-variable graph” (for clause-sets; a bipartite graph with variables and clauses as the two parts), is a tree. Considering the variable-interaction graph $\text{vig}(F)$ (nodes are variables, joined by an edge if occurring together in some constraint), in [KDG04] approximations $p_v^k(\varepsilon)$ of $p_v(\varepsilon)$ for a parameter $k \in \mathbb{N}_0$

¹¹Another problem with this approach is that for good predictions variables v with “strong bias”, i.e., with large $|\tilde{p}_v(0) - \tilde{p}_v(1)|$ are preferred, which interferes with the branching heuristics (for example on unsatisfiable instances preferring such variables seems rather senseless). This is somewhat similar to preferring a variable v with one especially high value $P(\langle v \rightarrow \varepsilon \rangle * F)$, but now the problem is even more pronounced, since a “confident” estimation $\tilde{p}_v(\varepsilon)$ requires $\tilde{p}_v(1 - \varepsilon)$ to be low, and such biased variables might not exist (even when using precise values).

are studied (for the purpose of value ordering) where the approximation is precise if $k \leq \text{tw}(\text{vig}(F))$, the treewidth of the variable-interaction graph. A recent enhancement of belief propagation is “survey propagation”; see [BMZ05] for the original algorithm, and [Man06, HM06] for further generalisations.

Finally, to conclude this section on the order of branches, some aspect is worth to mention which indicates that the order of branches should also take the (expected) complexity of the branches into account. Say we have a branching variable v , where branch $v \rightarrow 0$ has approximated SAT probability 0.7 and expected run time 1000s, while branch $r \rightarrow 1$ has approximated SAT probability 0.3 and expected run time 1s. Then obviously branch $v \rightarrow 1$ should be tried first. Apparently this approach has not been transformed yet into something really workable, likely for the same reason as with the “rational branching rule” mentioned in Subsection 8.2.1, namely that the estimations for running times are far too rough, but it explains the erratic success of methods for choosing the branching order according to ascending expected complexity (easiest problem first) in practice on selected benchmarks.

8.10. Beyond clause-sets

The general theory of branching heuristics, developed in Section 8.2 to Section 8.6, is applicable to any backtracking algorithm, including constraint satisfaction problems (with non-boolean variables), and also the methods discussed in Section 8.8 are applicable in general. However the special heuristics discussed in Section 8.7 and Section 8.9 focused on SAT for boolean CNF. In this section we give an outlook on heuristics using more general “constraints” than clauses, considering “generalised clauses” in Subsection 8.10.1 (for examples BDD’s), which support generic SAT solving (via the application of partial assignments), and considering representations from constraint programming in Subsection 8.10.2.

8.10.1. Stronger inference due to more powerful “clauses”

Staying with boolean variables, a natural candidate for strengthened clauses are OBDDs. [FKS⁺04] is a good example for this direction, which also contains an overview on other approaches. Actually, OBDDs are only a stepping stone for [FKS⁺04], and the form of of generalised clauses actually used are “OBDDs on steroids”, called “smurf’s”, which store for every partial assignment (in the respective scope) all inferred assignments. In accordance with the general scheme MNC from Subsection 8.7.4.1, but without (i.e., with trivial) look-ahead¹², [FKS⁺04] define for each smurf a weight after the branching assignment, which reflects the reduction in the number of variables of the smurf due to inferred assignments, directly and with exponential decay also for the possible futures. More lightweight approaches include equivalence reasoning; see [Li03] for heuristical approaches to include the strengthened reasoning efficiently into the look-ahead of the heuristics.

¹²likely due to the fact that standard clause-learning is used, whose standard data structures are incompatible with stronger reductions and look-aheads

8.10.2. Branching schemes for constraint satisfaction

While the previous Subsection 8.10.1 considered “generalised SAT” in the sense that, though more general “constraints” are used, they are very “structured” w.r.t. allowing efficient inspection of the effects of (arbitrary) partial assignments. The field of constraint satisfaction on the other side tends to take a black-box point of view of constraints. The theory developed in this chapter yields a straightforward canonical basic heuristics for this environment, and we present these considerations below. First however some general comments on the discussion of branching heuristics for constraint satisfaction problems (CSPs) in [van06].

The *branching strategy* (see Section 4.2 in [van06]) selects the way in which to split the problem. For SAT solving binary branching on a variable is absolutely dominant (only in theoretical investigations more complex branchings are used), and thus for practical SAT solving the problem of the choice of branching strategy does not exist (at this time): An essential feature of SAT solving (compared for example with CSP solving) is that problems are “shredded” into tiny pieces so that the “global intelligence” of a SAT solver can be applied, and only “micro decisions” are made (via *boolean* variables), always on the outlook for a better opportunity (which might arise later, while by a more complex branching we might have made choices too early). Translating a problem with non-boolean variables to SAT (with boolean variables) typically increases the search space. On the other hand, [MH05] showed that this increased search space also contains better branching possibilities: A d -way branching for a variable v with domain D_v of size d (i.e., $v = \varepsilon_1, v = \varepsilon_2, \dots, v = \varepsilon_d$ for $D_v = \{\varepsilon_1, \dots, \varepsilon_d\}$) can always be efficiently simulated by a 2-way branching (corresponding to $v = \varepsilon, v \neq \varepsilon$ for some $\varepsilon \in D_v$), but not vice versa.

The *variable ordering heuristics* (see Section 4.6.1 in [van06]) is responsible for choosing the branching variable (given that only branching on a single variable is considered), which for SAT solving is typically just called the “branching heuristics”. The general tendency seems to be also to choose a variable minimising the expected workload, but surprisingly the integration of the information on the single branches (for the different values in the domain of the variable) into one single number, i.e., the task of the evaluation projection, has apparently never been systematically considered, and consequently the handling of projection is weak. Thus, though 2-way branching can have an edge, as mentioned above, there seems to be some scope of improvement for existing d -way branching (and other schemes yielding non-binary branching) by using the τ -projection (which plays out its strength in a context where various branching widths occur!).

The *value ordering heuristics* (see Section 4.6.2 in [van06]) is responsible for choosing the order of the branches (compare Section 8.9 in this chapter). In (standard, i.e., binary) SAT branching this just means the choice of the first branch.

Now to the most basic measures and distances. The basic estimation for problem complexity for boolean problems F is $2^{n(F)}$, the size of the search tree, from which we derive the measure $\mu(F) = n(F) = \log_2 2^{n(F)}$ (motivated by Lemma

8.4.9). As already mentioned at several places, using the distance Δn is rather weak for general SAT solving. However this measure can be strengthened by either strengthening the look-ahead, or by differentiating more between variables. The latter is possible for CSP problems, where variables v have domains D_v , and then $\mu(F) = \log \prod_{v \in \text{var}(F)} |D_v| = \sum_{v \in \text{var}(F)} \log(|D_v|)$ becomes a “more informed” measure of problem complexity (note that $\mu(F) = n(F)$ if all variables are binary). When considering arbitrary branching width, usage of the τ -function becomes compulsory, and comparing different branchings $F \rightsquigarrow (F_1^i, \dots, F_{p_i}^i)$ is then done by choosing the branching i with minimal $\tau(\Delta\mu(F, F_1^i), \dots, \Delta\mu(F, F_{p_i}^i))$. When combined with look-ahead (recall, this always refers to the branching heuristics (alone), that is, the F_j^i are better approximations of the reduced formula computed when actually choosing this branch), this yields decent basic performance. However if more information on the constraints is available, then the approach as discussed at the end of Subsection 8.7.4.1 likely will yield stronger results.

8.11. Conclusion and outlook

Regarding branching heuristics (the main topic of this chapter), one could say that historically the first phase has been finished by now, laying the foundations by constructing basic heuristics, as outlined in Subsection 8.7.4, and developing the basic theory as outlined in Sections 8.3 to 8.5. Now a much stronger emphasise should be put on precise quantitative analysis, as discussed in Section 8.8 on optimising (and measuring) the quality of heuristics, including the consideration of specialised branching projections as discussed in Section 8.6. Case studies on classes of problems should be valuable here. When saying that for branching heuristics the initial phase of theory building and systematic experimentation is finished, then actually this can only be said about finding the branchings, while regarding ordering the branches (as surveyed in Section 8.9) we are lacking a good theoretical foundation, and likely also much further experimentation is needed.

The general theory (on finding good branchings and ordering them) is applicable also beyond clause-sets (as discussed in Section 8.10), and while for clause-sets we have at least reasonable intuitions what might be good measures (distances) and ordering heuristics, here the situation is much more complicated. Combining the theory developed in this chapter with the different approaches from the field of constraint satisfaction (which in my opinion lacks the general theory, but has a lot to say on specific classes of constraints) should be a good starting point.

Finally, a major enterprise lies still ahead of us: theoretical foundations for heuristics for conflict-driven SAT solvers. In the introductions to Sections 8.7 and 8.9 we made a few remarks on conflict-driven solvers, but mostly we did not cover them in this chapter due to their non-tree-based approach and the lack of a theoretical foundation. See Chapter 4 of this handbook for more information on these solvers and the underlying ideas, where the basic references are as follows: With the solver **GRASP** ([MSS99]) the basic ideas got rolling, then **Chaff** ([MMZ⁺01, ZMMM01]) was considered by many as a breakthrough, while further progress was obtained by the solvers **BerkMin** ([GN02]) and **MiniSat** ([ES04]).

Chapter 9

Preprocessing in SAT Solving

Armin Biere, Matti Järvisalo, and Benjamin Kiesl

Preprocessing has become a key component of the Boolean satisfiability (SAT) solving workflow. In practice, preprocessing is situated between the encoding phase and the solving phase, with the aim of decreasing the total solving time by applying efficient simplification techniques on SAT instances to speed up the search subsequently performed by a SAT solver. In this chapter, we overview key preprocessing techniques proposed in the literature. While the main focus is on techniques applicable to formulas in conjunctive normal form (CNF), we also selectively cover main ideas for preprocessing structural and higher-level SAT instance representations.

9.1. Introduction

One of the main reasons for the success of SAT solving is the ability of modern conflict-driven clause-learning solvers (described in Chapter 4 on CDCL) to search over large CNF formulas with millions of variables and clauses. Nevertheless, real-world applications such as model checking (Chapter 18) and software verification (Chapter 20) often yield formulas that are still too large for state-of-the-art solvers, which in turn can limit the applicability of SAT solving as the solution method of choice. The immense size of formulas is often caused by a combination of the complex nature of the problems themselves, the propositional encodings available, and the automated encoding techniques that generate the formulas in practice.

Automated encoding techniques in particular can deteriorate solver performance by introducing redundancies in the form of unnecessary clauses and variables. Moreover, one and the same problem can often be encoded in various different ways, meaning that SAT solvers are at the mercy of the user in terms of how a problem instance is actually encoded. This calls for *preprocessing*, that is, the application of automated techniques that simplify formulas before passing them to solvers in order to improve the efficiency of the whole solving pipeline. Preprocessing not only improves efficiency in general, it also takes the burden of crafting complex problem encodings from the user, thus allowing non-expert users to leverage the power of modern SAT solvers.

Preprocessing has within recent years become a key component of the SAT solving workflow. A landmark in the history of preprocessing is the technique of *bounded variable elimination* (BVE) [EB05], as implemented in the SATELITE preprocessor [EB05] and later integrated in version 2.0 [ES06] of MINISAT [ES03].¹ In 2005 and 2006 it contributed to the largest improvement of solver performance witnessed in the history of the SAT competitions. Even today, bounded variable elimination is still arguably the most important practical preprocessing technique.

In the SAT solving workflow, preprocessing is situated between the encoding phase, during which a user or a dedicated tool encodes a problem as a formula of propositional logic, and the solving phase, during which a SAT solver tries to determine the satisfiability of a formula. The distinction between these phases, however, is not straightforward: on the one hand, preprocessing can be viewed as an automated re-encoding of a formula, which would make it part of the encoding phase; on the other hand, it can also be viewed as a form of reasoning itself, which would make it part of the solving phase. The latter view is emphasized by the recent rise of so-called *inprocessing* SAT solvers [JHB12, FBS19], which interleave search with phases during which typical preprocessing techniques are applied. In fact, since 2013 the SAT competitions have been dominated by CDCL solvers that utilize inprocessing. However, combining incremental SAT solving [Hoo93, KWS00, WKS01, ES03, ALS13, BBIS16] with preprocessing and inprocessing still poses a challenge in practice [KNPH05, KN11, NRS12, NR12, NRS14, FBS19] and will not be considered much further in this chapter.

From an abstract point of view, preprocessing techniques can be seen as implementations of inference rules that, when applied to formulas arising from real-world problem domains, yield equisatisfiable formulas that are easier to solve. Most preprocessing techniques are designed to simplify CNF formulas on the syntactic level by reducing the number of variables and the number of clauses. A popular example of this is again the method of bounded variable elimination, which uses Davis-Putnam resolution [DP60] and other techniques to eliminate variables without increasing the number of clauses.

Reducing the size of formulas, however, does not always improve the efficiency of the solving process. Sometimes SAT solvers actually benefit from redundant formula parts, which makes the search for effective preprocessing more complex than the search for methods that just yield equisatisfiable formulas of smaller size. The most evident example of this is the clause learning mechanism at the heart of CDCL solvers (Chapter 4 on CDCL): clause learning drastically improves the solving process by adding clauses that are logically entailed by the input formula and thus, by definition, redundant. Additionally, binary clauses (i.e., clauses with only two literals) are often considered special and thus not removed by SAT solvers due to their high potential for enabling more propagation.

A drastic example illustrating the worst-case impact of preprocessing techniques that *remove* clauses comes from the theoretical study of proof systems (Chapter 7): In 1985, Haken proved that a natural SAT encoding of the pigeon-hole principle (PHP) admits only resolution proofs of exponential size [Hak85], meaning that CDCL solvers—which are based on resolution—require exponential

¹While tight integration of preprocessing with search is now more common there also exist stand-alone preprocessing tools [Man12, WvdGS13] in the spirit of SATELITE [EB05].

time to solve this encoding [BKS04, PD11]. But, as shown by Cook [Coo76], if we add specific clauses (so-called *definition clauses*) to the PHP encoding, the resulting CNF formulas have polynomial-size resolution proofs, meaning that CDCL solvers can, at least in theory, solve them in polynomial time.

Unfortunately, popular preprocessing techniques such as *bounded variable elimination*, *blocked clause elimination* [JBH10], and *cone-of-influence reduction* (a circuit-preprocessing technique described in Chapter 27) remove these definition clauses, turning an instance that is tractable for CDCL solvers into an intractable one. In practice, some of the most effective preprocessing techniques still aim at removing formula parts, but others also add strong redundant clauses such as binary or even unit clauses.

Another approach to analyze the effects and limits of preprocessing is offered by *kernelization* as studied in the area of fixed-parameter complexity, the topic of Chapter 17. However, while kernelization is an important theoretical concept in the context of SAT, it has—unlike the other techniques discussed in this chapter—so far not been used effectively in practical preprocessing.

Classifying practical preprocessing techniques in terms of their underlying inference rules is difficult, but we can identify two main categories: The first category consists of techniques that employ the resolution rule and its variations; examples are *unit propagation*, *bounded variable elimination* [SP04, Bie04, EB05], *hyper binary resolution* [Bac02, BW03, GS05, HJB13], and other advanced probing techniques such as *distillation* [HS07] and *vivification* [PHS08].

The second category consists of preprocessing techniques that identify literals or clauses that are redundant under different notions of redundancy; examples of such techniques are *clause subsumption*, *hidden literal elimination* [HJB11], *equivalent-literal substitution* (called *equivalence reduction* in [Bac02, BW03]), and *blocked clause elimination* [JBH10] together with its generalizations [HJL⁺15, KSTB16, KSTB18, KSS⁺17, HKB17, HKB20].

Preprocessing techniques also vary in the ways in which they analyze formulas. Most techniques are applied syntactically on CNF formulas, but some utilize graph representations of implication chains and other types of functional dependencies, or even higher-level constraints—implicitly represented by clauses—to preprocess a formula.

Although many individual preprocessing techniques are by themselves quite simple, the potential of preprocessing and inprocessing lies in combining different preprocessing techniques in such a way that they benefit from each other. For instance, at points where one technique is unable to make further progress, another technique might be applicable, and might even modify the formula in ways that trigger the first technique again.

In practice, however, running a specific preprocessing technique until completion is often only feasible for techniques that are computationally inexpensive. Because of this, even stand-alone preprocessors such as SATELITE [EB05] rely on limits that bound the maximum number of occurrences of a candidate variable to be eliminated. Without such limits they would not be beneficial and run out of time on many instances. Moreover, scheduling the effort spent on individual preprocessing techniques is not trivial and has not seen much published research to date [Bie14]. Different preprocessing techniques can also have similar effects

in the sense that they perform the same modifications; for instance, both blocked clause elimination and bounded variable elimination have been shown to simulate cone-of-influence reduction on the CNF-level [JBH12].

Finally, the naive incorporation of preprocessing and inprocessing into the solving pipeline can potentially lead to unexpected outcomes, including incorrect solving results. Especially in inprocessing SAT solvers, a lot of care [JHB12] is required to ensure that simplification techniques interact in a sound way with both clause learning and *clause forgetting* (learned clauses are *deleted* quite frequently during the *reduce* phase of a SAT solver to improve memory usage and speed up propagation). Additionally, since many preprocessing techniques only maintain equisatisfiability but not logical equivalence, solution-reconstruction methods are sometimes required to transform a satisfying assignment of a preprocessed formula into a satisfying assignment of the original formula.

Most techniques described in this chapter are also available in the SAT solver CADICAL [Bie17]. The goal of developing CADICAL was to produce a SAT solver that is thoroughly documented, easy to understand and modify, and in the end still comparable to the state of the art (in the SAT Race 2019 it actually solved the largest number of instances). Therefore, consulting the CADICAL source code and its (inlined) documentation at <https://github.com/arminbiere/cadical> in parallel to reading this chapter is highly recommended. As CADICAL has been participating in the SAT competition since 2017, its solver descriptions [Bie17, Bie18, Bie19, BFFH20] provide additional technical details.

In the rest of this chapter, we give an overview of key preprocessing techniques proposed in the literature. Although our main focus is on CNF-level preprocessing, we will also briefly discuss main ideas proposed for structure-based preprocessing on the level of Boolean circuit representations of propositional formulas. The chapter is organized into sections describing CNF-level techniques, from basic concepts such as unit propagation (Section 9.2), over more advanced resolution-based preprocessing such as bounded variable elimination (Section 9.3), to preprocessing beyond resolution-based techniques, such as clause elimination (Section 9.4), as well as how to reconstruct solutions to original input CNF formulas after preprocessing (Section 9.5). Beyond CNF-level techniques we provide an additional shorter overview of preprocessing techniques applicable on higher-level propositional representations (Section 9.6), and conclude the chapter with a short summary and future work (Section 9.7).

9.2. Classical Preprocessing Techniques

We begin by discussing various classical CNF-level preprocessing techniques: unit propagation (the main propagation mechanism in complete SAT solvers), pure literal elimination, basic clause elimination techniques, and the detection of connected components in a graph representation of formulas to identify formula parts that can be solved independently of each other.

9.2.1. Unit Propagation

Unit propagation is a straightforward technique that has been common in SAT solving for many decades [DP60]; it is based on the *unit-clause rule*: Given a

formula in conjunctive normal form, the unit-clause rule checks if the formula contains a *unit clause*, i.e., a clause that contains only a single literal. If so, it removes all clauses that contain the literal from the formula (this step can be seen as an instance of subsumed-clause removal) and it removes the negation of the literal from the other clauses. Unit propagation repeatedly applies the unit-clause rule until either it derives the empty clause or there are no more unit clauses left. In the former case, we say that unit propagation derives a *conflict*.

Example 1. Consider the formula $(x) \wedge (\bar{x} \vee y) \wedge (\bar{y} \vee z \vee v)$. The unit-clause rule takes the unit clause (x) and first removes it from the formula. It then removes the literal \bar{x} from the clause $(\bar{x} \vee y)$, resulting in the formula $(y) \wedge (\bar{y} \vee z \vee v)$. Another application of the unit-clause rule first removes the unit clause (y) and then removes the literal \bar{y} from $(\bar{y} \vee z \vee v)$. We end up with the formula $(z \vee v)$.

Clearly, whenever a formula contains a unit clause, the formula can only be satisfied by assignments that make the literal of the unit clause true. The application of unit propagation during preprocessing is therefore safe insofar as the resulting formula and the original formula are equisatisfiable. If unit propagation derives a conflict, we can conclude that the formula must be unsatisfiable. The converse, however, is not true. For example, the formula $(x \vee y) \wedge (\bar{x} \vee y) \wedge (x \vee \bar{y}) \wedge (\bar{x} \vee \bar{y})$ is unsatisfiable, but since it does not contain any unit clauses, unit propagation cannot derive a conflict.

Unit propagation (as well as several other preprocessing techniques we discuss later on) can be seen as the repeated application of the classical *resolution* rule [Rob65]. Given two clauses $(c_1 \vee \dots \vee c_m \vee l)$ and $(d_1 \vee \dots \vee d_n \vee \bar{l})$, the resolution rule allows us to derive the clause $(c_1 \vee \dots \vee c_m \vee d_1 \vee \dots \vee d_n)$, which is called the *resolvent* of the two clauses upon l . In case of unit propagation, the removal of the literal \bar{l} from a clause can be seen as a resolution step with the clause (l) and thus is also often called *unit resolution*. In the context of constraint programming, unit propagation is also called *Boolean constraint propagation* (BCP). Unit propagation is essential for the original search-based D(P)LL algorithm [DLL62] as well as for the CDCL procedure described in Chapter 4.

9.2.2. Failed Literals

The notion of a *failed literal* [LB01, LaPMS03] forms the basis of a preprocessing technique known as *failed-literal probing*, which is an integral part of look-ahead solving (see Chapter 5). The origin of failed literals dates back to Zabih and McAllester [ZM88], and is featured in the thesis of Freeman [Fre95]. The related SLUR algorithm by Schlipf et. al. [SAFS95] has been used to characterize a class of polynomially solvable formulas (see also [dV00] for a related line of work).

A literal l is a failed literal with respect to a formula F if unit propagation derives a conflict on $F \wedge (l)$. Clearly, if unit propagation derives a conflict on $F \wedge (l)$, then $F \wedge (l)$ is unsatisfiable and therefore F implies \bar{l} . The addition of the unit clause (\bar{l}) to F thus preserves equivalence, and the corresponding preprocessing technique that adds the negations of failed literals to a formula is called failed-literal probing.

Example 2. Let $F = (x \vee u) \wedge (\bar{x} \vee u) \wedge (\bar{u} \vee z \vee y) \wedge (\bar{u} \vee z \vee \bar{y})$. Since F does not contain any unit clauses, it cannot be simplified by unit propagation alone. However, \bar{u} is a failed literal because unit propagation derives a conflict on $F \wedge (\bar{u})$, caused by the first two clauses. The unit clause (u) is therefore implied by F and so we can add it to F . If we then perform unit propagation on $F \wedge (u)$, we obtain the simplified formula $G = (z \vee y) \wedge (z \vee \bar{y})$.

In practical preprocessing, a list of candidate literals is considered, and for all the candidate literals it is checked whether or not they are failed literals. It is generally not clear how to order the candidate literals to minimize the number of required decisions. For instance, in Example 2, the literal \bar{u} is the only failed literal with respect to F . In the worst case, we would thus have tested all other literals before (\bar{u}) . After simplifying F , which yields G , we can see that \bar{z} becomes a failed literal, but z , y , and \bar{y} are still no failed literals. Simplifying a formula until there are no more failed literals can thus require us to test quadratically many literals (with respect to the number of variables) in the worst case. Assuming the strong exponential-time hypothesis (ETH), the quadratic upper bound is tight in terms of both the number of variables and the number of clauses, even for Horn-3-CNF formulas [JK14]. As each test performs unit propagation, this results in cubic accumulated complexity in the worst case.

The cubic complexity can be reduced by marking the literals that were implied by unit propagation in tests since the last time a failed literal has been detected. These literals do not have to be tested until another failed literal is found, since their propagation did not lead to a conflict. As soon as a test yields a conflict—meaning that a new failed literal is found—all the marked literals have to be unmarked again (it is more efficient to use time-stamping techniques though). This optimization was independently discovered and described in [ABS99] and [SNS02].

Another optimization consists of testing only literals that do not occur in binary clauses themselves (but their negation does), thus effectively only testing the roots of the binary implication graph [GS05, Bie17].² With these techniques, failed-literal probing can run until completion even on large industrial SAT instances or can be used as preprocessing for splitting and partitioning in distributed SAT solving [HJN10]. Later in this chapter we will discuss an extension, based on look-ahead (see also Chapter 5), that learns binary clauses on the fly by combining *hyper binary resolution* with equivalent-literal reasoning.

9.2.3. Pure Literals

A pure literal is a literal whose negation does not occur in the formula. The corresponding technique of pure-literal elimination removes all clauses that contain a pure literal, because these clauses can be trivially satisfied by making the pure literal true without falsifying any other clauses.

Example 3. Consider the formula $(\bar{x} \vee y \vee z) \wedge (\bar{y} \vee \bar{z})$. The literal \bar{x} is a pure literal in this formula whereas all the other literals are not pure.

²When focusing on roots, cyclic literal dependencies, as in $(a \vee \bar{b}) \wedge (\bar{a} \vee b) \wedge (a \vee b)$, might prevent detection of some failed literals though. This can be avoided by computing strongly connected components and, for instance, equivalent-literal substitution as discussed in Section 9.3.2.

Pure-literal elimination was introduced independently both by Davis and Putnam [DP60] and by Dunham, Fridshal, and Sward [DFS59]. While a failed literal can be seen as a literal which we make false because making it true would lead to a conflict, a pure literal can be seen as a literal which we make true because making it true cannot lead to a conflict. Moreover, if a formula is unsatisfiable, clauses containing a pure literal cannot be used productively in a resolution proof because pure literals can never be resolved away.

An alternative to removing clauses that contain pure literals is to add the pure literals as unit clauses. The addition of these unit clauses, however, does not always preserve logical equivalence, because it could remove potential models in which a pure literal is false. Nevertheless, adding pure literals as unit clauses does not change the satisfiability status of a formula. This idea of performing transformations that yield equisatisfiable—but not necessarily logically equivalent—formulas is the corner stone of more advanced preprocessing techniques, such as blocked clause addition, which we discuss later.

9.2.4. Subsumption

A clause C is *subsumed* by a clause D if the set of literals in C is a superset of the literals in D . Analogously, a clause is subsumed by a formula if it is subsumed by some clause in the formula. The removal of subsumed clauses is an important technique that is often referred to as *subsumption*. The idea behind subsumption is to eliminate clauses that are redundant in the sense that their removal does not affect the satisfiability of a formula: if a formula contains two clauses C and D , where D subsumes C , the removal of C yields a logically equivalent formula since every assignment that satisfies D must also satisfy C .

Example 4. The clause $(\bar{x} \vee y \vee z)$ is subsumed by the clause $(\bar{x} \vee z)$ since the set $\{\bar{x}, y, z\}$ is a superset of the set $\{\bar{x}, z\}$. Whenever $(\bar{x} \vee z)$ is true, $(\bar{x} \vee y \vee z)$ must also be true.

We have already seen an application of subsumption earlier: During unit propagation, when a unit clause (l) is found, all the clauses containing the literal l are removed from the formula. A corner case is the empty clause, which subsumes all other clauses in a formula.

9.2.4.1. Forward Subsumption

Forward subsumption starts with a given clause C and a formula F , and checks if C is subsumed by F . A simple technique to check if a clause is forward subsumed by a formula F temporarily marks all literals of C as false and then checks whether there is another (usually smaller) clause D in F with only false literals.

In order to find all potential candidates D without iterating over F , at least one literal of every clause in F needs to be “watched”. Two-watched literal schemes [ZS00, MMZ⁺01], as commonly used in CDCL solvers (see Chapter 4), suffice too, while *occurrence lists* (an occurrence list contains *all* the clauses in which a literal occurs) are not necessary. A similar technique has been described in [Bra04] and refined in [Zha05].

9.2.4.2. Backward Subsumption

In contrast to forward subsumption, which checks if a clause C is subsumed by a clause D in F , backward subsumption checks if F contains clauses C that are subsumed by a given clause D , and if so, removes them. Backward subsumption is actually more common in practice; for example, in SAT solvers using clause learning, learned clauses are never forward subsumed, but they might subsume other clauses of the formula, in particular clauses that were learned recently.

As described in Exercise 271 of [Knu15] and its solution, this situation might occur frequently for certain formulas, and it is possible to *eagerly subsume recently learned clauses* efficiently, by reusing the markings of the literals in the learned clause at the end of conflict analysis (see Chapter 4 on CDCL again). Even though this technique is efficient and simple to implement, subsumption algorithms are more useful in combination with variable elimination (see Section 9.3), because variable elimination focuses on irredundant original clauses and is allowed to ignore redundant learned clauses [JHB12].

If an implementation maintains for each literal an occurrence list instead of using a one-watched [Zha05] or two-watched [ZS00, MMZ⁺01] literal scheme, then the search for a candidate clause C , checked for being backward subsumed by the given clause D , can be restricted to iterate over the occurrences of a single literal in the given clause D , chosen as one with the smallest number of occurrences (shortest occurrence list). This observation, originally made in the context of QBF solving [Bie04], is crucial for scaling backward subsumption to large formulas, and was first used for SAT preprocessing in SATELITE [EB05].

Another technique to improve the performance of backward subsumption in practice is based on so-called *signatures* [Bie04], which are an instance of Bloom filters [Blo70]. The basic idea is to avoid costly traversals of occurrence lists in the (frequent) case where no subsumed clauses can be found. This is achieved by checking a signature condition that must hold if there is a clause that can be subsumed by the given clause. If the condition does not hold, the traversal can be avoided. For details, we refer to the original paper.

A related backward-subsumption algorithm is due to Brafman [Bra04]. Given a clause D and a formula F , the algorithm iteratively computes the set

$$S = \bigcap_{l \in D} \text{clauses}_F(l),$$

where $\text{clauses}_F(l)$ denotes the set of all clauses of F in which the literal l occurs. The final set S contains all clauses of F that are subsumed by D . As soon as the algorithm detects that S is empty, it can conclude that D does not subsume any clauses. The original algorithm does not need to save signatures for clauses and literals, but it needs to save the occurrence lists for all the literals in F . In principle, though, it could also make use of signatures.

Backward subsumption can easily be turned into an algorithm that removes all subsumed clauses from a formula: start with the empty formula and one-by-one add original clauses with largest clauses first. Then check for each newly added clause whether it subsumes any of the previous clauses. This observation is particularly useful for applying subsumption during preprocessing. In practice,

it is still advisable to limit the effort spent on subsumption checks. This can, for instance, be done by limiting the maximum length of traversed occurrence lists.

9.2.4.3. Self-Subsuming Resolution

As observed in [EB05], subsumption is closely related to *strengthening* clauses, more precisely to *self-subsuming resolution* as implemented in SATELITE [EB05]. Consider two clauses $C \vee l$ and $D \vee \bar{l}$, which can be resolved upon l . If D subsumes C , then the resulting resolvent is simply C , which in turn subsumes the first antecedent $C \vee l$. Thus, instead of adding the resolvent C , we can replace $C \vee l$ by C , in effect strengthening the clause $C \vee l$ by removing the literal l . This technique is called self-subsuming resolution.

Subsumption algorithms can easily be extended to perform self-subsuming resolution. The only necessary change is to modify the subsumption check between two clauses: when checking if D subsumes C , we simply allow that at most one literal \bar{l} of D occurs negated in C . If this is the case, and all other literals of D occur in C , we can apply self-subsuming resolution to C and D by removing l from C . Checking that the literals of D occur in C (with one possible exception) can be achieved by marking literals (possibly with time stamps) or by a merge-sort-style check, assuming the literals in clauses are sorted [BP11].

Self-subsuming resolution was independently discovered as *global subsumption* for instantiation-based first-order theorem proving [Kor08] and actually was introduced in the SAT context via the notion of a *subsuming resolvent* in [OGMS02] (though without detailed experiments). In [EB05], it was partially motivated by the fact that clause learning (Chapter 4), and particularly clause minimization [SB09], implicitly rely on it. *On-the-fly subsumption* [HJS10, HS09] is another related technique that uses self-subsuming resolution to strengthen antecedent clauses used for deriving learned clauses in CDCL.

9.2.4.4. Implementations

Finding subsumed clauses in CNF formulas is closely related to finding *extremal sets* in data mining. In this context, Bayardo and Panda [BP11] showed that backward-subsumption algorithms developed in the SAT community [EB05] were competitive for this problem too, but their paper also presents a substantially faster algorithm, which in our setting translates to forward-subsumption checking and yields a substantial performance improvement also for SAT.

The basic idea is to use a one-watched-literal scheme and only watch literals with the fewest occurrences. Clauses are added again one-by-one, but now starting with the smallest clauses first. All one-watched-literal lists of the literals in a processed clause are traversed to find clauses which subsume the processed clause. If this is not the case (i.e., the forward-subsumption check fails), then the clause is added, and the literal with the shortest watch list (at this point) is watched. As already discussed above, the actual subsumption check between a previously added clause and the processed clause can be made faster too (for instance, by sorting literals in clauses [BP11]) and extends to self-subsuming resolution.

In the context of QUANTOR [Bie04], SATELITE [EB05], and MINISAT [ES06] backward subsumption was considered superior. However, forward-subsumption

Figure 1. Hypergraph Representation of a CNF Formula.

algorithms inspired by ideas of [BP11], as implemented in SPLATZ [Bie16] and CADICAL [Bie17], become more important, particularly during the process of removing from a given CNF all subsumed clauses and performing self-subsuming resolution until completion. These forward-subsumption algorithms are much more efficient than previously used backward-subsumption algorithms and can even regularly be applied to learned clauses during inprocessing too. Interleaved with variable elimination (see Section 9.3), which needs full occurrence lists in any case, there is still a benefit in using backward subsumption, since it allows to focus on trying to subsume or strengthen other clauses by newly derived clauses to trigger new variable-elimination attempts (as for instance in [BFFH20]).

9.2.5. Connected Components

The solving process for a formula can be significantly simplified by taking its underlying graph structure into account. One way to represent a formula as a graph is to define a hypergraph where variables correspond to vertices and clauses correspond to hyperedges connecting their variables. For example, the formula

$$(x \vee y \vee \bar{z}) \wedge (\bar{y} \vee z) \wedge (u \vee \bar{v}) \wedge (v \vee \bar{w})$$

can be represented by the hypergraph shown in Figure 1. As we can see in this example, the graph contains two different connected components.

It has been observed that formulas in practical SAT solving often contain multiple connected components [BS06]. Each of these components can be seen as an independent SAT problem, with the whole formula being satisfiable only if all of its components are satisfiable. Splitting a formula into its connected components during preprocessing and then solving these components independently has several advantages: the independent components can be solved in parallel, and as soon as one component is identified as unsatisfiable, it can be concluded that the whole formula is unsatisfiable. Even if all components are satisfiable, the parallelism can speed up the solving process. Similar ideas are used in component caching for model counting [BDP03, SBB⁺04], where the formula is preprocessed at every search node and decomposed into disconnected components for which the model count can be computed independently. The problem of model counting is also called #SAT and extensively covered in Chapter 25 and 26.

In the context of CDCL SAT solving (Chapter 4), formulas consisting of independent components can be simpler to solve even without relying on parallelism. Suppose a typical CDCL solver tries to find a satisfying assignment for a formula that consists of several independent components. During search, the solver might find an assignment that already satisfies some of the components, but then realize that the assignment falsifies another component. What the solver usually does in

that situation is to backjump and thereby undo some of its variable assignments. However, this could undo some of the assignments that are independent of the falsified component and thereby unassign components that were already satisfied.

By splitting up a formula, such a situation can be avoided. However, the same effect can be achieved by saving the last assigned truth value (also called *phase*) of a variable and then always assigning that saved value when making decisions. This *phase saving* technique was introduced in the RSAT solver [PD07] and has been standard in SAT solvers since then, making explicit component decomposition obsolete, at least for sequential plain CDCL solving.

Since 2018 several state-of-the-art SAT solvers quite frequently reset saved phases [Bie18, Bie19, BFFH20, ZC20, SCD⁺20, SSK⁺20], which counteracts the effect of phase saving to remember satisfying assignments for components. As an alternative to explicit component decomposition as in [BS06], it was proposed in [BFFH20] to simply remove all clauses satisfied by the largest autarky within saved phases following ideas in [KHB19], an application of autarky reasoning of Chapter 14 within SAT solving.

9.3. Resolution-Based Preprocessing

We continue by discussing preprocessing techniques that rely heavily on resolution, starting with bounded variable elimination, which as high-lighted already in the introduction is still considered the most important preprocessing technique in practical SAT solving.

9.3.1. Bounded Variable Elimination

Bounded variable elimination [Bie03, Bie04, SP04, EB05] is based on the technique of *clause distribution*, which lies at the core of the original Davis-Putnam procedure [DP60]. To perform clause distribution, we choose a variable, add all resolvents upon this variable to the formula, and remove the original clauses containing the variable.

Example 5. Consider the formula

$$F = (x \vee e) \wedge (y \vee e) \wedge (\bar{x} \vee z \vee \bar{e}) \wedge (y \vee \bar{e}) \wedge (y \vee z). \quad (9.1)$$

To perform clause distribution with the variable e , we first add all resolvents upon e . The clauses $(x \vee e)$ and $(y \vee e)$ can both be resolved with $(\bar{x} \vee z \vee \bar{e})$ and $(y \vee \bar{e})$. We thus add the corresponding four resolvents to obtain the formula

$$F \wedge (x \vee \bar{x} \vee z) \wedge (x \vee y) \wedge (y \vee \bar{x} \vee z) \wedge (y).$$

Now we remove all clauses that contain e to obtain

$$(y \vee z) \wedge (x \vee \bar{x} \vee z) \wedge (x \vee y) \wedge (y \vee \bar{x} \vee z) \wedge (y). \quad (9.2)$$

Repeated clause distribution can increase the number of clauses exponentially, rendering its unbounded use as a preprocessing technique unaffordable. Actually, already eliminating a single variable might increase the size quadratically. To

deal with this problem, the original technique of bounded variable elimination applies clause distribution only on variables whose elimination does not increase the number of clauses, which explains the name *bounded* variable elimination.

However, as proposed in the variable-elimination procedure of the QBF solver QUANTOR [Bie04], it has become common in SAT to relax the bound on additional clauses: in *incrementally relaxed bounded variable elimination*, introduced in the SAT solver GLUEMINISAT [NII15], the bound is increased³ incrementally every time a round of variable elimination has completed without increasing the size of the formula too much. This technique was ported to the highly influential SAT solver COMINISATPS [Oh16] that has formed the basis of the MAPLESAT series of SAT solvers [LGPC16, LLX⁺17, NR18], which ranked at the top in the SAT competitions from 2016 to 2018.

Since bounded variable elimination produces many redundant clauses, it is often combined with tautology elimination (as in NIVER [SP04]) as well as with subsumption and strengthening (in SATELITE [EB05]). Subsumption might lead to further variables being eliminated, triggered by removing clauses or literals.

Example 6. Consider again the formula (9.2), which resulted from the formula (9.1) by eliminating the variable e . We can observe that the resolvent $(x \vee \bar{x} \vee z)$ is a tautology and that it can therefore be removed from the formula. Moreover, the clauses $(y \vee z)$, $(x \vee y)$, and $(y \vee \bar{x} \vee z)$ are all subsumed by the clause (y) , and so they can be eliminated as well. Thus, after eliminating only a single variable, we end up with the trivially satisfiable formula (y) .

On the implementation side, clause distribution is best interleaved with subsumption using the generated resolvents immediately to subsume and strengthen existing clauses through backward subsumption. Furthermore, bounded variable elimination can be improved by on-the-fly subsumption during variable elimination [HS09] as follows: Whenever a (non-tautological) resolvent R of two clauses C and D is computed, check if $|R| = |C| - 1$ or $|R| = |D| - 1$ (after removing repeated literals, i.e., interpreting clauses as literal sets). In the former case, C is subsumed by R and so it can be replaced by R ; in the latter case, D is subsumed by R and so it can also be replaced by R . Moreover, the replacement can be performed regardless of whether e is actually eliminated or not (in case elimination of e would produce too many new clauses). Variables of removed clauses or literals have to be (re)scheduled as candidates for further elimination attempts.

Another important implementation detail is how to organize the schedule of elimination candidates. Common practice is to use a priority queue implemented as a binary heap in which the variables are ordered by their number of occurrences within the formula. Variables with the smallest number of occurrences are tried first, and the priority queue is updated dynamically as clauses are strengthened, removed, and added. In order to scale variable elimination to large formulas, variables that—when resolved—produce large resolvents or occur in large or in too many clauses, should not be eliminated. Limits vary by implementation, but typically the clause size or the resolvent size is limited to 20 to 100 literals. Variables that occur more than 100 to 1000 times, either negatively or positively, are typically skipped too.

³For instance, the bounds form a geometric series 0, 8, 16, 32, . . . , 8192.

The effectiveness of bounded variable elimination is highlighted by the observation that it automatically performs the earlier discussed elimination of pure literals, because there are no resolvents upon pure literals. Moreover, if a formula contains a unit clause (e) and either on-the-fly subsumption is performed or the formula contains no clauses that are subsumed by (e), then the result of eliminating the variable e is the same as applying the unit-clause rule with (e).

As observed in [EB05], the elimination of variables for which the CNF contains a functional definition produces redundant clauses; these clauses are actually resolvents of clauses that are not part of the functional definition. Thus, searching for such definitions (see Section 9.6.2) during elimination attempts reduces the number of required resolvents and often allows more variables to be eliminated.

Alternatively, as implemented in LINGELING [Bie10], it is possible to simplify the CNF of resolvents on the fly, for instance by applying “semantically” the dual of Minato’s algorithm for producing an irredundant sum-of-products [Min92] to CNF [EMS07]. The idea is to compile the CNF of the clauses containing the variable to be eliminated into a “semantic” representation, such as a binary decision diagram (BDD) [Bry86], eliminate the variable from the BDD by existential quantification, and then as in [EMS07] encode the resulting BDD back into an irredundant CNF (using Minato’s algorithm). Instead of using BDDs *function tables* represented as bit-maps as in LINGELING will also do. In any case, this approach avoids searching for functional definitions explicitly and captures all types of functional dependencies. Otherwise it reduces the number of produced clauses at least as much as the explicit method [EB05] discussed above.

For the sake of completeness, it should also be mentioned that there exist symbolic variants of bounded variable elimination that use decision diagrams [CS00, vDEB18], more precisely *zero-suppressed decision diagrams* (ZDD) [Min93]; but in practice they currently work only on very restricted sets of formulas (e.g., pigeon-hole formulas).

Finally, bounded variable elimination can also be applied “in reverse”, resulting in what is called *bounded variable addition* (BVA), as proposed in [MHB12]. Since the elimination of variables can increase the number of clauses, performing variable elimination in reverse (adding variables instead of eliminating them) can potentially shrink the size of a formula. Requiring to distinguish between two types of variables (i.e., original and added) makes the implementation of bounded variable addition much more problematic than implementing bounded variable elimination, particularly in the context of incremental SAT solving, where also the need of “recycling” variables might become an issue. In contrast to bounded variable elimination, bounded variable addition has therefore not yet established itself as a central preprocessing technique.

9.3.2. Techniques Based on Implication Graphs

Analyzing the structure of binary clauses (i.e., clauses that contain exactly two literals) in a CNF formula gives rise to preprocessing techniques through the notion of a (*binary*) *implication graph* [APT79] (BIG). Given a CNF formula, its binary implication graph is a directed graph that is obtained as follows: Introduce a vertex for every literal, and add the edges (\bar{l}, k) and (\bar{k}, l) for every binary clause $(l \vee k)$, where l and k are (possibly negative) literals.

Figure 2. The original (binary) implication graph (BIG) for the formula of Example 7 is shown on the left and on the right the result after one round of equivalent-literal substitution.

Example 7. The implication graph of the formula

$$(\bar{x} \vee y) \wedge (\bar{y} \vee z) \wedge (\bar{z} \vee u) \wedge (\bar{u} \vee y) \wedge (\bar{x} \vee \bar{z}) \wedge (x \vee z \vee u)$$

is shown on the left in Figure 2. Notice that the ternary clause $(x \vee z \vee u)$ does not affect the implication graph.

An edge in the implication graph directly represents an implication that is equivalent to a binary clause in the formula. In the example, x implies y , y implies z , z implies u , and so on. Notice also that for every edge of the form (e_1, e_2) , the implication graph contains a corresponding edge (\bar{e}_2, \bar{e}_1) , representing the contraposition of the implication.

By construction, every *strongly connected component*⁴ of a binary implication graph represents a set of *equivalent literals* [VGT93, Li00], i.e., literals who must have the same truth value in every satisfying assignment of the formula. The set of literals prescribed by a strongly connected component can therefore be replaced by a single representative literal in the underlying CNF formula; this replacement is known as *equivalence reduction* and *equivalent-literal substitution* (ELS).

Example 8. In the implication graph on the left in Figure 2, the literals y , z , and u form a strongly connected component. Their negations \bar{y} , \bar{z} , and \bar{u} also form a strongly connected component. Since a clause $(x \vee y)$ is represented by the two edges (\bar{y}, x) and (\bar{x}, y) in the binary implication graph, every strongly connected component has a corresponding strongly connected component that consists of its complementary literals. In the example, we can replace the strongly connected component $\{y, z, u\}$ by the vertex y , and the strongly connected component $\{\bar{y}, \bar{z}, \bar{u}\}$ by the vertex \bar{y} , to obtain the simplified formula

$$(\bar{x} \vee y) \wedge (\bar{x} \vee \bar{y}) \wedge (x \vee y).$$

Note that the clause $(x \vee y)$ stems from the original ternary clause $(x \vee z \vee u)$. The simplified formula corresponds to the implication graph depicted on the right of Figure 2 (with two new strongly connected components).

There are several different implementations for finding and replacing strongly connected components [APT79, dV01, BW03, VG05, GS05] in the context of SAT. For details, we refer to the respective literature, but usually the implementations are based on a depth-first search of the implication graph.

⁴A strongly connected component is a maximal set of vertices such that every vertex in the set is reachable from all other vertices in the set.

In certain cases, strongly connected components can even be used for detecting unsatisfiability: if both a literal l and its complement \bar{l} are contained in the same strongly connected component, then the formula is unsatisfiable. Additionally, the implication graph can be used for the detection of failed literals. In particular, if there is a path from a literal l to its complement \bar{l} , then l is a failed literal [VG05].

Example 9. In the binary implication graph shown in Figure 2, x is a failed literal because there is a path from x to \bar{x} . Note, however, that the implication graph does not always contain a path from a failed literal l to its complement \bar{l} . To see this, consider the formula $F = (\bar{x} \vee y \vee z) \wedge (\bar{x} \vee \bar{y}) \wedge (\bar{x} \vee \bar{z})$ and the literal x . Although it can be checked that x is a failed literal with respect to F , there is no path from x to \bar{x} in the implication graph, because the ternary clause $(\bar{x} \vee y \vee z)$, without which x would not be a failed literal, is not considered when constructing the implication graph.

9.3.3. Hyper Binary Resolution

We have already seen in the context of unit propagation how a formula can be simplified by continuously performing inference steps (namely, the *unit-clause rule*) until either a conflict is derived or no more inference steps are applicable. Hyper binary resolution is based on the same idea, but uses stronger inferences.

Towards hyper binary resolution, consider first *binary resolution*. The binary-resolution rule is obtained from the ordinary resolution rule by restricting it to binary clauses. A binary-resolution step can either produce another binary clause—for instance, if we resolve $(x \vee y)$ with $(\bar{x} \vee z)$ to obtain $(y \vee z)$ —or it can yield a unit clause—for instance, if we resolve $(x \vee y)$ with $(\bar{x} \vee y)$ to obtain (y) . Applying the binary-resolution rule and the unit-clause rule until none of them is applicable anymore can simplify a formula more aggressively than performing only unit propagation.

Example 10. Let $F = (x \vee y) \wedge (\bar{x} \vee y) \wedge (x \vee \bar{y}) \wedge (\bar{x} \vee \bar{y})$. As there are no unit clauses in F , unit propagation has no effect on the formula. However, by performing binary resolution of $(x \vee y)$ with $(\bar{x} \vee y)$, we derive (y) . After this, unit propagation can derive a conflict with the clauses (y) , $(x \vee \bar{y})$, and $(\bar{x} \vee \bar{y})$.

As observed by Bacchus [Bac02], every unit clause that can be derived by performing binary resolution in combination with unit propagation (as described above) can also be derived by failed-literal detection, but not vice versa.

Example 11. With respect to the formula $F = (\bar{x} \vee y \vee z) \wedge (\bar{x} \vee \bar{y}) \wedge (\bar{x} \vee \bar{z})$ from Example 9 above, the literal x is a failed literal since unit propagation derives a conflict on $F \wedge (x)$. Therefore (\bar{x}) can be derived by failed-literal detection. However, both unit propagation and binary resolution do not affect F . The reason for this is that they cannot use the first clause, which contains three literals.

Simply performing all resolutions, also with longer clauses, would produce too many clauses. This leads to the definition of hyper binary resolution [Bac02], an instance of *hyper resolution* [Rob74], which contracts several resolution steps into a single inference step.

Figure 3. Hyper binary resolution. Only the last resolvent ($l_n \vee l$) is actually added after a hyper binary resolution step. The intermediate resolvents are implicit.

Definition 12. Given an n -ary clause $(l_1 \vee \dots \vee l_n)$ and $n - 1$ binary clauses $(\bar{l}_1 \vee l), \dots, (\bar{l}_{n-1} \vee l)$, *hyper binary resolution* allows the derivation of the clause $(l_n \vee l)$, which is called a *hyper binary resolvent*.

Observe that the hyper binary resolvent ($l_n \vee l$) can be derived from the previous clauses by applying a number of resolution steps. We start with $(l_1 \vee \dots \vee l_n)$ and first resolve it with $(\bar{l}_1 \vee l)$ to obtain $(l_2 \vee \dots \vee l_n \vee l)$, which we then resolve with $(\bar{l}_2 \vee l)$ to obtain $(l_3 \vee \dots \vee l_n \vee l)$ and so on until we finally derive $(l_n \vee l)$. The intermediate resolvents, however, are not derived explicitly. Figure 3 illustrates the (implicit) resolutions involved in a single hyper binary resolution step.

By repeatedly performing hyper binary resolution in combination with unit propagation until no more inference steps are possible (or a conflict is derived), a formula can be simplified significantly. In fact, this combination derives the same literals that would be derived by performing failed-literal detection on all literals in combination with unit propagation [Bac02]. It can, for instance, derive the literal (\bar{x}) from the formula F in Example 11 by a single application of the hyper binary resolution rule.

Hyper binary resolution and unit propagation have been used in combination with the detection of binary equivalences (replacing them by single literals, similar to the technique based on strongly connected components discussed in Section 9.3.2). The resulting preprocessing technique can be implemented based on probing failed literals in a depth-first search of the binary implication graph [BW03]. As soon as a large (non-binary) clause is used to derive a unit clause during probing, a hyper binary resolvent is learned. A less general but faster version of this technique, which only probes roots of the binary implication graph, has been implemented by Gershman and Strichman [GS05].

More sophisticated algorithms for hyper binary resolution [HJB13] reuse decisions and propagation effort by scheduling decisions along the structure of the binary implication graph, but using multiple decisions at the same time, similar in spirit to efficient “distillation” on tries [HS07], with more details provided at the end of the next section.

These approaches avoid “transitive” hyper binary resolvents by prioritizing unit propagation over binary clauses. For instance, the set $\{(\bar{a}_i \vee a_{i+1}) \mid 1 \leq i < n\}$ of binary clauses has quadratically many hyper binary resolvents $(\bar{a}_i \vee a_j)$, with $1 \leq i < j \leq n$. Note that these additional transitive clauses are redundant with respect to detecting strongly connected components of equivalent literals as well as unit propagation (see also the discussion of “empowering” in [PD11]) and thus should not be derived (and stored). It is further useful to apply transitive reduc-

tion of the binary implication graph pro-actively [HJB10a]. As first implemented in PRECOSAT [Bie09] and further refined in [HJS11], there is also an on-the-fly variant of hyper binary resolution that learns binary clauses during propagation using dominator analysis on the binary implication graph (see also [HJB13]).

However, removing transitive resolvents does not prevent the worst case of quadratically many non-transitive hyper binary resolvents [HJB13], and running hyper binary resolution until completion is only feasible for certain formulas (mostly small and hard combinatorial problems). For large application formulas, hyper binary resolution has to be preempted, and it is advisable to “forget” hyper binary resolved clauses aggressively [BFFH20] during the “reduce” phase of the SAT solver which deletes useless learned clauses.

9.3.4. Advanced Probing Techniques

We start with asymmetric⁵ tautologies, which are a generalization of tautologies based on the concept of an *asymmetric literal*:

Definition 13. A literal l is an *asymmetric literal* in a clause $C \vee l$ with respect to a formula F if unit propagation deduces the unit clause \bar{l} from $F \wedge \bar{C}$, where \bar{C} is the conjunction of the negations of the literals in C .

Accordingly, if l is an asymmetric literal in $C \vee l$ w.r.t. F , then all models that falsify C but satisfy F , falsify l . In this case, l is redundant in $C \vee l$ and $F \wedge (C \vee l)$ can be simplified to $F \wedge C$ by “strengthening” $C \vee l$ and removing l . This simplification is also called *asymmetric literal elimination* (short ALE).

Example 14. Consider the formula $F = (a \vee \bar{x}) \wedge (x \vee \bar{l})$ and the clause $C = (a \vee b)$. Unit propagation on $F \wedge \bar{C} = F \wedge (\bar{a}) \wedge (\bar{b})$ produces the unit clause (\bar{l}) . Therefore, l is an asymmetric literal in $C \vee l$ with respect to F , and $(a \vee \bar{x}) \wedge (x \vee \bar{l}) \wedge (a \vee b \vee l) = F \wedge (C \vee l)$ can be simplified to $(a \vee \bar{x}) \wedge (x \vee \bar{l}) \wedge (a \vee b) = F \wedge C$ through asymmetric literal elimination.

In order to deduce that clauses are “redundant” based on this notion, we add literals instead of removing them, and during this process obtain a tautological clause [HJB10a].

Definition 15. A clause C is an *asymmetric tautology* (AT) with respect to F if there is a sequence l_1, \dots, l_n of literals such that $C \vee l_1 \vee \dots \vee l_n$ is a tautology and each l_i is an asymmetric literal in $C \vee l_1 \vee \dots \vee l_i$ with respect to F .

Example 16. Consider the formula $F = (\bar{x} \vee z) \wedge (\bar{y} \vee \bar{z})$ and the clause $C = (\bar{x} \vee \bar{y})$. The literal \bar{z} is an asymmetric literal in $(\bar{x} \vee \bar{y} \vee \bar{z})$ w.r.t. F since unit propagation on $F \wedge (x) \wedge (y)$ deduces the unit clause (z) (propagation of $F \wedge (x)$ is enough). Then z is an asymmetric literal in $(\bar{x} \vee \bar{y} \vee \bar{z} \vee z)$ w.r.t. F as unit propagation deduces also \bar{z} from $F \wedge (x) \wedge (y) \wedge (z)$ (again already unit propagation of $F \wedge (y)$ suffices). At this point we can stop, since we have already shown that C in combination with F is equivalent to a tautology, thus an asymmetric tautology.

⁵The term “asymmetric” has its origin in the notion of “asymmetric (tableau) rules” [DM94], which apparently inspired the MINISAT authors [ES03] to name a command line option “-**asymm**” used to enable a “strengthening” procedure now called “asymmetric literal elimination”.

Note that in this example we used the fact that unit propagation is confluent in the sense that the order in which the unit-clause rule is applied is irrelevant to the outcome; it is also monotonic in the sense that every unit clause that can be derived from a formula F can also be derived from every larger formula that contains all the clauses of F .

It can further be shown that if a clause C is an asymmetric tautology w.r.t. a formula F , then F implies C . This in turn means that C can be safely eliminated from the formula $F \wedge C$. Moreover, if only asymmetric literals from binary clauses need to be added to turn a clause into a tautology, then that clause is also called a *hidden tautology*, and the corresponding clause-elimination technique is called *hidden tautology elimination* (HTE) [HJB10a].

The related technique of *unhiding* [HJB11] avoids quadratic computation during repeated unit propagation. It is based on randomized depth-first traversal of the binary implication graph and relies on the *parenthesis theorem* to detect in almost constant time if a clause is a hidden tautology or if clauses can be strengthened by removing hidden literals. This form of literal removal is also known as *hidden literal elimination* (HLE), which can be seen a restricted variant of asymmetric literal elimination which only propagates over binary clauses.

It is well-known that a clause C is an asymmetric tautology with respect to a formula F if and only if it is a *reverse unit propagation* (RUP) clause [VG12].

Definition 17. A clause C is a RUP clause with respect to a formula F if unit propagation derives a conflict on $F \wedge \bar{C}$.

To test if a clause is an asymmetric tautology with respect to a formula F , it thus suffices to check if propagating its negation leads to a conflict. Note that RUP clauses are a generalization of the earlier-mentioned failed literals: a unit clause (l) is a RUP clause with respect to a formula F if and only if \bar{l} is a failed literal with respect to F . From the RUP definition it also becomes clear why asymmetric tautologies are implied, since unit propagation can only derive a conflict if the conjunction of the formula with the negated clause is unsatisfiable, which is the case if and only if the clause is implied by the formula.

Failed-literal probing alone is often already quite expensive. Thus checking all clauses for being asymmetric tautologies is even more costly. Still, removing them can benefit other preprocessing algorithms such as variable elimination.

The basic approach of asymmetric tautology checking takes a clause C , then assigns all its literals to false, followed by unit propagation. Advanced probing techniques like *distillation* [HS07] and *vivification* [PHS08] interleave assignments and propagations instead. This works as follows.

The literals of C are still assigned to be false in an arbitrary fixed order, but a complete round of propagation is started immediately after every single assumed assignment. If during such a propagation round a conflict is found or another not yet assigned literal of C is forced to true, then the clause is an asymmetric tautology and can in principle be removed. Alternatively, particularly if applied to learned clauses in CDCL [LLX⁺17, LXL⁺20], such asymmetric tautologies can be replaced by clauses learned through the standard CDCL conflict analysis, if, for instance, the learned clause turns out to be shorter. If, however, during propagation another not yet assigned literal of C is forced to false, then this

literal is actually an asymmetric literal and the clause C can be strengthened, by removing the literal from C . This presents the real benefit of interleaving assignments and propagation in vivification and distillation.

A disadvantage of clause-based probing, in contrast to literal based probing discussed before, is that potentially many redundant propagations are performed, for instance when many clauses share the same literals. These literals are then repeatedly assigned to false and propagated. An attempt to reduce this redundant propagation effort was made in distillation by reorganizing the clauses in a trie (i.e., as a shared prefix tree) and reusing propagations along the same prefix [HS07]. The implementation of vivification in CADICAL [Bie17] and KISSAT [BFFH20] achieves the same effect by sorting clauses and literals, thus simulating a trie structure on a plain CNF formula.

Another important question is which clauses should be checked, particularly if these techniques are applied to learned clauses during inprocessing [JHB12]. One proposal was to check learned clauses in parallel [WH13] in a separate thread. Another, which was actually the basis for the revival of these techniques [LLX⁺17], was to focus on learned clauses, check all clauses at most once, and check only those which have a high chance of being used (e.g., clauses of small LBD [AS09]). For more details see [LXL⁺20].

9.4. CNF Preprocessing Beyond Resolution

So far, we have only considered the elimination of clauses that are implied. However, as we discussed in the section on subsumption, in SAT solving often a more general notion of redundancy is used, requiring only that the elimination of a clause has no effect on the satisfiability status of a formula (see [JHB12]).

One of the most important types of clauses that are redundant but not necessarily implied, are *blocked clauses*. Intuitively, a clause is blocked if it contains a literal such that all resolvents upon this literal are tautologies [Kul99].

Definition 18. Given a formula F and a literal l , we denote by F_l the set of clauses of F that contain l . Then a clause C is a *blocked clause* in a formula F if it contains a literal l such that for every clause $D \in F_{\bar{l}}$, the resolvent of C and D upon l is a tautology. We say that l blocks C in F .

Example 19. Consider the formula $F = (\bar{x} \vee z) \wedge (\bar{y} \vee \bar{x})$ and the clause $(x \vee y)$. The literal x does not block $(x \vee y)$ in F since the resolvent $(y \vee z)$ of $(x \vee y)$ and $(\bar{x} \vee z)$ is not a tautology. However, the literal y blocks $(x \vee y)$ in F since the only clause in $F_{\bar{y}}$ is the clause $(\bar{y} \vee \bar{x})$, and the resolvent $(x \vee \bar{x})$ of $(x \vee y)$ and $(\bar{y} \vee \bar{x})$ is a tautology. Therefore, $(x \vee y)$ is blocked in F .

Blocked clauses were initially introduced by Kullmann [Kul99] as a generalization of the definition clauses in extended resolution [Tse68], and were later proposed as a basis for the preprocessing technique of blocked clause elimination [JBH10] (BCE). As further shown in [JBH12], blocked clause elimination can simulate several structural simplification techniques (see also Section 9.6) on the CNF-level, in particular *non-shared-input elimination*, *monotone-input reduction*, and *cone-of-influence reduction*. Moreover, the effectiveness of bounded variable elimination can be increased by interleaving it with blocked clause elimination.

Blocked clauses have been generalized in several ways. One well-known generalization are *resolution asymmetric tautologies*, better known as RATs. The RAT definition is obtained from the blocked-clause definition by replacing *tautologies* with *asymmetric tautologies* [JHB12].

Definition 20. A clause C is a *resolution asymmetric tautology* (RAT) in a formula F if it contains a literal l such that for every clause $D \in F_l$, the resolvent of C and D upon l is an asymmetric tautology with respect to F .

From this definition it immediately follows that every blocked clause in formula F is also a RAT with respect to F . Although the explicit elimination of RATs has not yet been shown to boost solver performance in SAT, generalizations of RAT elimination for quantified Boolean formulas (QBFs) have led to significant performance improvements in QBF solving [LE18].

Moreover, RAT lies at the core of the well-known DRAT proof system, which is the de-facto standard in modern SAT solving. Other generalizations of blocked clauses and RATs (e.g., *set-blocked clauses* [KSTB16, KSTB18] and *propagation-redundant clauses* (PR) [HKB17, HKB20]) have also not yet been used for clause elimination but instead for clause addition during solving and for proof generation, which we are not going to discuss here.

One type of clauses that generalizes blocked clauses, and whose elimination has shown some performance improvements in the SAT solver LINGELING [Bie17], are *covered clauses*. Intuitively, a clause is a covered if it can be turned into a blocked clause by adding so-called *covered literals* [HJB10b].

Definition 21. A literal k is a *covered literal* in a clause C with respect to a formula F if C contains a literal l such that all non-tautological resolvents of C upon l with clauses D in F_l contain k .

The addition of covered literals preserves satisfiability in the sense that $F \wedge C$ and $F \wedge (C \vee k)$ are equisatisfiable if k is covered by C in F ; before an example, we give the definition of covered clauses [HJB10b] based on covered literals.

Definition 22. A clause C is a *covered clause* with respect to a formula F if there exists a sequence k_1, \dots, k_n of literals such that each k_i is covered by $C \vee k_1 \vee \dots \vee k_{i-1}$ with respect to F and $C \vee k_1 \vee \dots \vee k_n$ is blocked in F .

Example 23. Consider the formula $F = (\bar{x} \vee y) \wedge (\bar{y} \vee z)$ and the clause $C = (x \vee \bar{z})$. Although C is not blocked in F , we can add the literal y since it is contained in the only resolvent upon x , namely $(y \vee \bar{z})$, obtained by resolving with $(\bar{x} \vee y)$. The resulting clause $(x \vee \bar{z} \vee y)$ is then blocked as there is only the tautological resolvent $(x \vee \bar{z} \vee z)$ upon y , obtained by resolving with $(\bar{y} \vee z)$. Thus, C is a covered clause with respect to F .

There exist even more general types of redundant clauses, such as *resolution-subsumed clauses* [JHB12] (“the clause contains a literal such that all resolvents upon the literal are tautological or subsumed”), and asymmetric variants of blocked as well as covered clauses (“the addition of asymmetric or covered literals turns the clause into a blocked clause”) [HJL⁺15, JHB12], thus extending *blocked clause elimination* (BCE) and *covered clause elimination* (CCE) to the more general concept of *asymmetric covered clause elimination* (ACCE).

It is, however, not clear if the elimination of such clauses can lead to noticeable performance improvements in practical SAT solving. The same applies to the elimination of *globally blocked clauses* [KHB19] motivated by circuit preprocessing techniques. There is also some renewed interest in covered clauses, which were recently shown to have orthogonal strength to propagation-redundant clauses [BCB20].

9.5. Solution Reconstruction

For many practical applications it is not sufficient to regard SAT as a mere decision problem. Consider, for instance, bounded model checking (Chapter 18): If a SAT solver determines that a propositional encoding of a safety property is satisfiable, we know that a bad state is reachable and thus that the safety property is violated. Without a concrete satisfying assignment, however, we cannot obtain an execution trace to analyze and diagnose the reason for the property violation. A similar situation occurs in SAT-based planning (Chapter 19), where a simple yes/no answer without the ability to generate actual plans is (mostly) useless.

Other applications require proofs after the SAT solver determined a formula to be unsatisfiable (e.g., to extract *clausal cores* or to generate *interpolants*). Preprocessors thus also need to make sure that valid proofs of a simplified formula can be turned into valid proofs of the original formula. For clausal proofs, which have been the dominant proof variant in the SAT competition since 2013, this is often easy to achieve [JHB12], and only requires that added clauses can be derived via a sequence of simple proof steps (for many techniques, a simple proof step via a RAT addition often suffices). Producing deletion information, used to speed up proof checking for DRAT proofs [HHJW13, WHHJ14], is slightly more involved, as additional care needs to be taken to avoid that clauses are deleted too early. See Chapter 15 on proofs of unsatisfiability for more details.

In the rest of this section, we focus on satisfiable formulas, and, following the literature [JB10], we use the terms *satisfying assignment*, *model*, and *solution* interchangeably. Moreover, we interpret *solution reconstruction* as the process of turning a satisfying assignment of the simplified formula (i.e., the formula produced by preprocessing) into a satisfying assignment of the original formula.

In order to obtain solution reconstruction for unit propagation (Section 9.2.1), it is common practice to simply keep unit literals permanently assigned. That is also the reason why they are sometimes called *root-level assigned*, *root-level forced* or simply *fixed* literals, where the *root level* is the top-most decision level (where no decisions have been made) in a CDCL solver (Chapter 4). This covers also the effect of failed-literal probing. Solvers might actually contain a global Boolean flag to record that the formula is *root-level inconsistent*, meaning that either the input CNF contains the empty clause or the empty clause has been derived (through preprocessing or in conflict analysis during CDCL search).

In industrial applications, it is not uncommon that preprocessing removes around 80% of the variables [EB05]. Focusing on the remaining “working set” of *active variables* can therefore improve cache efficiency and reduce memory consumption. Variables become inactive during search or preprocessing if they are for instance fixed (or eliminated). Accordingly, several SAT solvers distinguish

internal variables and *external variables* in order to keep the working set compact. External variables are those seen by the user of the (incremental) SAT solver and are mapped (and occasionally remapped during inprocessing) to the remaining internal variables on which the SAT solver works internally. Fixed external variables can either be recorded to be fixed (to a certain Boolean value) in this mapping directly, or can be mapped to a unique internal fixed variable (positively or negated), which represents all the fixed (external) variables.

All forms of strengthening and subsumption considered in this chapter, including vivification and distillation, preserve logical equivalence and thus can be ignored from the perspective of solution reconstruction (for satisfiable formulas). For pure literals solution reconstruction can be achieved by simply adding the corresponding unit clauses (which are RAT). However, as discussed in Section 9.2.3, this method does not preserve logical equivalence, since the formula might also allow models where pure literals are false. This is considered problematic for incremental SAT, since the user could be interested in such models in consecutive SAT queries. An alternative is to use a reconstruction stack as discussed further down, in essence treating pure literals in the same way as eliminated variables.

Equivalent-literal substitution (ELS) (see Section 9.3.2) also only preserves satisfiability, since substituted literals do not occur in the simplified formula anymore and can assume any value. One way of dealing with this situation, as implemented in LINGELING [Bie11], is to maintain a global union-find data structure [Tar79] of substituted literals which maps literals to the representative literal of their equivalent-literal class. The user can then obtain the solution value of a literal from its representative literal. This has the additional benefit that users can rather cheaply query the SAT solver, whether two literals have already been determined to be equivalent. This union-find data structure can also be shared among several solver threads efficiently as in PLINGELING [Bie11]. Fixed literals (units) can be handled within the same scheme by adding a pseudo-representative constant literal (for, say, the Boolean constant *false*).

9.5.1. Reconstruction Stack

Bounded variable elimination, is on the one hand the most important preprocessing technique, but on the other hand does not preserve logical equivalence, by the same argument as for equivalent-literal substitution: after elimination, the eliminated variable is not restricted anymore and can assume any value. Therefore, we really need a method for solution reconstruction.

One way to perform solution reconstruction for variable elimination works as follows. Take the given solution of the simplified formula (restricted to the remaining variables) and add satisfied literals as unit clauses to the original formula. Alternatively, add back the eliminated clauses to the simplified formula plus the satisfied literals of the solution as units to obtain the augmented formula. Then call a second time a (plain) SAT solver on this augmented formula, which is guaranteed to be satisfiable, and that way compute a satisfying assignment of the original formula. The hope is that the additional unit clauses make it easy to solve the augmented formula, which is not guaranteed though. A similar scheme was employed in the SAT preprocessor SATELITE [EB05], using temporary (bi-

nary) files for communicating the simplified CNF and the eliminated clauses to the second SAT solver.

A more sophisticated approach, guaranteed to have even linear complexity in the number of eliminated clauses, which was first described in the literature in [JB10], goes back to Niklas Sörensson. He observed that the given solution of the simplified formula can be “extended” to a solution of the original formula by propagating along the eliminated clauses in a specific way. The corresponding reconstruction algorithm can be described as follows.

Assume that whenever a variable is eliminated, the clauses in which the variable occurs are pushed on a stack, called the *reconstruction stack*. Further, make sure that the first literal in each pushed clause is either the eliminated variable or its negation, in order to map eliminated clauses to eliminated variables.

After obtaining a solution of the simplified formula, it is first extended by assigning an arbitrary value (e.g., false) to all eliminated variables. Then, solution reconstruction goes over the clauses on the reconstruction stack in reverse order, starting from the last pushed clause. Each clause is checked to be satisfied, and if not (i.e., all its literals are assigned to false), then the value of its first literal, which corresponds to the eliminated variable, is flipped (assigned opposite value).

Example 24. Consider the formula $(\bar{a} \vee b) \wedge (a \vee \bar{b}) \wedge (b \vee c) \wedge (\bar{b} \vee \bar{c})$ which is satisfiable and encodes that a and b need to have the same truth value but b and c need to have opposite values. Now assume that variable elimination first eliminates a , then b , and during this process pushes these four clauses in the given order onto the reconstruction stack. The simplified formula consists of the empty CNF and has as extended solution the assignment where all variables are set to false. Now going backward over the reconstruction stack the algorithm first checks whether the last clause $(\bar{b} \vee \bar{c})$ is satisfied, which is the case. The next clause in reverse order $(b \vee c)$ is falsified however. Thus we flip the value of its first literal b and set b to true. The next clause to be checked $(a \vee \bar{b})$ is also falsified (since a is still false and b just became true). Accordingly, we flip the value of its first literal a and set a to true. The last clause to be checked, $(\bar{a} \vee b)$, is satisfied. Thus the reconstructed solution has both a and b set to true (assigned to the same value), while c remains false (assigned differently).

In fact, this simple algorithm also works for more advanced clause elimination procedures: Blocked clauses are just pushed on the reconstruction stack with the blocking literal as first *witness literal*. The same principle extends without modification to more powerful clause redundancy properties [HJB10a, HJB10b, HJL⁺15], including RAT, CCE and ACCE [JHB12], the latter two with the caveat of requiring to potentially push multiple clauses on the reconstruction stack when eliminating a clause [BCB20]. This scheme also allows to handle autarky elimination [BFFH20] as well as equivalent-literal substitution elegantly [FBS19], instead of using a union-find data structure. Finally, solution reconstruction for propagation-redundant clauses [HKB17, HKB20] can be achieved in a similar way, using a reconstruction stack, even for incremental SAT solving [FBS19]. The only change needed, as implemented in CADICAL to support globally blocked clauses [KHB19], is to replace the single witness literal by a set of witness literals, which are all set to true if the corresponding clause is falsified.

9.6. Structure-Based Preprocessing

So far we have focused on preprocessing techniques developed specifically for formulas in conjunctive normal form. We now extend the discussion to preprocessing techniques that were proposed for more expressive constraints and structural representations. In particular, we discuss parity-reasoning techniques and preprocessing techniques applicable on Boolean circuits, which offer a compact representation of arbitrary propositional formulas.

9.6.1. Parity Reasoning

Although the CNF representation of propositional formulas has many advantages, it can be suboptimal in some cases. One such case, which occurs frequently, is when formulas encode so-called *XOR constraints* or *equivalence clauses*. An XOR constraint is of the form

$$l_1 \oplus l_2 \oplus \dots \oplus l_k = b,$$

where l_1, \dots, l_k are propositional literals and b is either 0 or 1. Following the standard semantics of the \oplus operator ($x \oplus y$ is true if and only if x and y are assigned different truth values), an assignment satisfies an XOR constraint with $b = 1$ if and only if it satisfies an odd number of the literals l_1, \dots, l_k . Respectively, it satisfies an XOR constraint with $b = 0$ if it satisfies an even number of the literals. Equivalence clauses are closely related to XOR constraints. An equivalence clause is of the form

$$l_1 \leftrightarrow l_2 \leftrightarrow \dots \leftrightarrow l_k.$$

An assignment satisfies an equivalence clause if and only if it falsifies an even number of the literals l_1, \dots, l_k . Observe that an equivalence clause of the form $l_1 \leftrightarrow \dots \leftrightarrow l_{2i+1}$, having an odd number of literals, is equivalent to the XOR constraint $l_1 \oplus \dots \oplus l_{2i+1} = 1$. Likewise, an equivalence clause $l_1 \leftrightarrow \dots \leftrightarrow l_{2i}$ with an even number of literals is equivalent to the XOR constraint $l_1 \oplus \dots \oplus l_{2i} = 0$. Thus equivalence clauses and XOR constraints are essentially the same concept.

An effective strategy for dealing with XOR constraints is to first scan the CNF encoding of a formula for sets of clauses that represent XOR constraints, and to then handle these constraints differently than ordinary clauses [Li00, HvM04, SNC09, Che09, Soo10, LJN10, LJN12a, LJN12b, Bie12, HJ12, SM19, SGM20].

The naive CNF encoding of an XOR constraint with k literals consists of 2^{k-1} clauses, where each clause rules out exactly one assignment that would falsify the constraint. More specifically, the CNF encoding of an XOR constraint $l_1 \oplus \dots \oplus l_k = b$ consists of all k -sized clauses over l_1, \dots, l_k , where an even number of literals occurs negated if $b = 1$ and an odd number occurs negated if $b = 0$.

Example 25. The XOR constraint

$$l_1 \oplus l_2 \oplus l_3 = 1$$

is falsified by every assignment that satisfies an even number of the literals l_1, l_2, l_3 . Its CNF encoding thus rules out all such assignments, leading to the clauses $(l_1 \vee l_2 \vee l_3), (\bar{l}_1 \vee \bar{l}_2 \vee l_3), (l_1 \vee \bar{l}_2 \vee \bar{l}_3), (\bar{l}_1 \vee l_2 \vee \bar{l}_3)$.

A popular method for dealing with XOR constraints, which is used by several solvers, including CRYPTOMINISAT [SNC09, Soo10], LINGELING [Bie12], and MARCH [HvM04], is *Gaussian elimination*. Gaussian elimination is based on the observation that XOR constraints can be viewed as equations over the finite field $\text{GF}(2)$ (also denoted \mathbb{F}_2 or \mathbb{Z}_2), where the \oplus operation corresponds to addition modulo 2 (and the \wedge operation corresponds to multiplication modulo 2).

A set of XOR constraints can then be seen as a system of linear equations, and we can derive new equations by adding together existing ones, just as known from high school algebra. If Gaussian elimination is performed in a preprocessing phase, it can possibly derive new unit clauses.

Example 26. Consider the clauses

$$(\bar{x} \vee y \vee z), (x \vee \bar{y} \vee z), (x \vee y \vee \bar{z}), (\bar{x} \vee \bar{y} \vee \bar{z}), \\ (y \vee z), (\bar{y} \vee \bar{z}).$$

These clauses correspond to the two XOR constraints

$$x \oplus y \oplus z = 0, \tag{9.3}$$

$$y \oplus z = 1. \tag{9.4}$$

As there are no unit clauses, unit propagation would not have an effect on the clauses. However, by adding the XOR constraint 9.3 to 9.4, and by using the fact that $l \oplus l = 0$ and $l \oplus 0 = l$ for every literal l , we can derive the XOR constraint

$$x = 1, \tag{9.5}$$

which is equivalent to the unit clause (x) .

Gaussian elimination can even show the unsatisfiability of particular formulas, as illustrated next.

Example 27. Consider the XOR constraints

$$x \oplus y = 1, \tag{9.6}$$

$$y \oplus z = 1, \tag{9.7}$$

$$x \oplus z = 1. \tag{9.8}$$

By adding 9.6 to 9.7, we derive

$$x \oplus z = 0. \tag{9.9}$$

If we add 9.8 to 9.9, we end up with the trivially unsatisfiable constraint $0 = 1$.

The use of Gaussian elimination can lead to exponential speedups in SAT solving. It has been shown that Tseitin formulas [Tse68] over expander graphs have only exponential-size resolution proofs [Urq87], meaning that CDCL solvers require exponential time to solve them. In contrast, Gaussian elimination can show the unsatisfiability of these formulas in polynomial time.

Moreover, Gaussian elimination can be expressed polynomially with extended resolution [SB06] and thus in the DRAT proof system [PR16]. It is still unclear though how many new variables are needed. For simple problems which require parity reasoning new variables can be avoided by reusing eliminated variables [CH20]. Note that Gaussian elimination can be seen as an instance of the more general approach of *algebraic* SAT solving in Chapter 7 on proof complexity.

There exist several approaches that extract and utilize equivalence clauses, especially in preprocessing. Already in 1998, Warners and van Maaren [WvM98] presented a preprocessor that utilizes linear programming to extract equivalence clauses from CNF formulas. By reasoning over these equivalence clauses in an initial solving phase and then running a basic DPLL procedure, their approach was the first to solve the notorious *parity formula* [CKS94] within reasonable time. Heule and van Maaren [HvM04] later improved this approach and integrated equivalence reasoning into the look-ahead solver MARCH (see Chapter 5 for details on look-ahead based solvers), which could achieve a considerable speedup by avoiding look-ups on variables for which look-ups on equivalent literals (as indicated via binary equivalences) had already been performed.

Another approach that relies on inference rules over equivalence clauses was presented by Li [Li00]. In an inprocessing fashion, he incorporated these inference rules—which apply to equivalence clauses with at most three literals—into the solver SATZ. The resulting solver, EQSATZ, was able to outperform the approach of Warners and van Maaren on some, but not all, of the parity formulas.

The current state of the art in parity reasoning, applied to approximate model counting, focuses on parity reasoning during search [SM19, SGM20], where much more efficient algorithms are required, extending ideas from [HJ12].

9.6.2. Circuit-Level Reasoning

Propositional encodings tend to be more natural to develop using the full language of propositional logic rather than aiming directly at a CNF-level encoding. Boolean circuits offer a succinct structural representation for propositional formulas. Succinctness comes from refining syntax trees of propositional formulas to directed acyclic graph structures by allowing *structural hashing*, i.e., by representing each subcircuit (subformula) only once. This is a common implementation technique for representing immutable data structures, also called *hash consing* in the context of functional languages; it is used in most BDD libraries (in form of a “unique table”) and related to *common subexpression elimination* in optimizing compilers. In practical implementations of circuit-level reasoning, restricted classes of circuits are used, with *and-inverter graphs* (AIGs) [KGP01] as one prominent example.

While SAT solvers working directly on the level of circuits have been developed (see, for instance, [Lar92] and in general Chapter 27), SAT solvers today tend to be implemented specifically for CNF formulas. In fact, standard Boolean constraint propagation achieved on the level of circuits is equivalently achieved by unit propagation on the CNF obtained via the Tseitin encoding [Tse68].

However, circuits offer a view to developing further structure-based CNF encodings and simplification techniques, by exploiting functional dependencies

explicit in circuits. A classical argument for the necessity of such structural information and against CNF is that this information is lost in the CNF encoding phase. While structural information is not evident in CNF, it has turned out that such arguments are partly wrong. In particular, CNF-level reasoning can achieve the same effects for various forms of circuit-level reasoning techniques.

One example is the Plaisted-Greenbaum CNF encoding of propositional formulas [PG86] which, based on the notion of polarities of subformulas, refines the Tseitin encoding [Tse68]. It allows to drop clauses representing one direction of the bi-implications used in the Tseitin encoding, thus locally encoding a unipolar subformula. While subformula polarities are computed following the circuit structure of a formula, it has been shown [JBH12] that blocked clause elimination, working “blindly” on the CNF, can remove all clauses left out by the Plaisted-Greenbaum encoding. This implies that blocked clause elimination from Section 9.4 achieves monotone-input reduction, i.e., it detects if the underlying circuit of the formula is monotone in terms of a particular input variable (input gate or primary input). As blocked clause elimination can be implemented efficiently, this renders the Plaisted-Greenbaum encoding on its own unnecessary.

Evidently, there are limits to what can be achieved (both in theory and in practice) in terms of structure-based simplifications solely on the CNF-level, but these limits are to an extent unclear. Structural hashing, for example, can be simulated by hyper binary resolution of Section 9.3.3 on the Tseitin encoding of AIGs, as shown in [HJB13]. However, for other gate types such as XORs and *if-then-else*, also called *multiplexer* (MUX), hyper binary resolution does not achieve structural hashing [HJB13].

More general hashing for minimizing circuit representations through detection of logically equivalent substructures can be achieved on the circuit level through BDD sweeping [KK97] and SAT sweeping [Kue04, MCJB05, ZKKS06, WKK12]. Stålmarck’s procedure [SS00] and Recursive Learning [KP92] are earlier circuit-level preprocessing techniques with similar effects.

There are CNF-level versions of Stålmarck’s procedure [GW00], Recursive Learning [MSG99] or more general SAT sweeping [HJB13, JLaMS15, CFM13]. These procedures allow to deduce literal equivalences implied by the CNF as well as literals forced to a specific truth value, because they have that same truth value in all models (so-called “backbones” [JLaMS15]). In contrast to hyper binary resolution, which also produces equivalences, sweeping is able to find more of these equivalences or even all, if required by some applications. These equivalences are typically used to reduce the CNF as described in Section 9.3.2.

The current state of the art in encoding circuits into CNF [EMS07] is based on techniques from circuit synthesis: *circuit-level rewriting* [BB04, BB06] with *cut enumeration* [MCB06a] and *technology mapping* [MCB06b]. Related work uses similar criteria [MV07, CMV09]. We are not aware of any CNF-level preprocessing technique able to simulate these optimizations.

When having to start with CNF, one approach to exploit circuit-level techniques is to first attempt to algorithmically recover a circuit-level representation potentially underlying the CNF formula, on which circuit-level techniques can then be applied. This process is also called *gate extraction* or *mining functional definitions*. Even though there is already a substantial amount of work

in this direction starting with [OGMS02, RMB04, FM07, IKS17] and most recently [LLM20, Sli20] with more references, the task of the recovery step is in general non-trivial and rarely used in practical SAT solving.

There is a related technique, called blocked clause decomposition [HB13, BFHB14, Che15], with a similar purpose: it partitions a given CNF into a set of blocked clauses (which is maximized) and some remaining clauses. The set of blocked clauses has similar properties as a circuit, i.e., clauses are ordered and models can be constructed polynomially, which has applications usually attributed to circuit-level reasoning, including SAT sweeping [HB13].

Beside circuits and XOR constraints already discussed in Section 9.6.1, there are other high-level representations or constraints for which dedicated preprocessing algorithms exist, but currently no (efficient) CNF-level technique is known. As explained for parity reasoning, a common approach is to extract such constraints, apply high-level preprocessing, and then encode the resulting constraints back to CNF. Closely related to XOR constraints are polynomials modulo 2 as considered in [CK07, CSCM19], and using Gröbner bases theory for preprocessing and inprocessing. Regarding pseudo-Boolean and cardinality constraints (see also Chapter 28) a similar argument applies [BLBLM14].

9.7. Conclusion

The development of novel types of preprocessing techniques and the optimized implementation of these techniques has made preprocessing a central part of the SAT solving workflow. In this chapter, we have discussed major developments in preprocessing in SAT, focusing mostly on CNF-level preprocessing techniques, but also considering some techniques on other representations.

In practice, the role of preprocessing is intertwined on one hand with the encoding phase, providing an automated way to re-encode CNF instances, and on the other hand with CDCL SAT solving. Developments in the latter direction have brought on the influential inprocessing SAT solving paradigm, which interleaves core CDCL search with complex combinations of preprocessing techniques.

Arguably, bounded variable elimination [EB05] is still the most important practical preprocessing technique today. However, the many other types of preprocessing techniques, developed in particular during the 21st century, play an evident role as well. In terms of supporting variable elimination, various other techniques are important for triggering further elimination steps of bounded variable elimination, by performing crucial redundancy-elimination steps that are not enabled by bounded variable elimination alone. Other individual techniques and their combinations can be central in different types of problem-specific applications of SAT solvers.

Going further, the various developments in CNF-level preprocessing have had a wide impact, well beyond mere preprocessing. By making use of polynomial-time checkable clause-redundancy properties, inprocessing SAT solving breaks the long-standing “resolution barrier” of standard CDCL SAT solvers, making the solvers more powerful than the resolution proof system. Clause redundancy properties have also resulted in generally applicable practical proof checking mechanisms, enabling the automated verification of proofs constructed by SAT solvers,

thus lifting the trustworthiness of “no” answers provided by SAT solvers to new levels (see Chapter 15).

There is much ongoing work on combining high-level and CNF-level preprocessing, particularly for non-linear algebraic reasoning [CSCM19, KBK19], while producing proofs for even parity reasoning is still a challenge [CH20]. In this context, revisiting techniques using binary decision diagrams might also be interesting [MM02, FKS⁺04, SB06, WFS06, BD09, vDEB18]. We also consider parallelization of preprocessing to still be in its infancy [WH13, GM13, HW13, BS18, OW19].

Finally, we want to point out that many of the preprocessing techniques discussed in this chapter have been lifted to more general logics and problems, such as QBF, MaxSAT, #SAT, and first-order logic, but instead of listing these extensions here, we refer to the chapters on these extensions in this handbook or the corresponding literature instead.

Acknowledgments

We would like to thank Lee Barnett, Katalin Fazekas, and Mathias Fleury for providing valuable feedback on late drafts of the chapter.

Chapter 10

Random Satisfiability

Dimitris Achlioptas

10.1. Introduction

Satisfiability has received a great deal of study as the canonical NP-complete problem. In the last twenty years a significant amount of this effort has been devoted to the study of randomly generated satisfiability instances and the performance of different algorithms on them. Historically, the motivation for studying random instances has been the desire to understand the hardness of “typical” instances. In fact, some early results suggested that deciding satisfiability is “easy on average”. Unfortunately, while “easy” is easy to interpret, “on average” is not.

One of the earliest and most often quoted results for satisfiability being easy on average is due to Goldberg [Gol79]. In [FP83], though, Franco and Paull pointed out that the distribution of instances used in the analysis of [Gol79] is so greatly dominated by “very satisfiable” formulas that if one tries truth assignments completely at random, the expected number of trials until finding a satisfying one is $O(1)$. Alternatively, Franco and Paull pioneered the analysis of random instances of k -SAT, i.e., asking the satisfiability question for random k -CNF formulas (defined precisely below). Among other things, they showed [FP83] that for all $k \geq 3$ the DPLL algorithm needs an *exponential* number of steps to report all cylinders of solutions of such a formula, or that no solutions exist.

Random k -CNF formulas. Let $F_k(n, m)$ denote a Boolean formula in Conjunctive Normal Form with m clauses over n variables, where the clauses are chosen uniformly, independently and without replacement among all $2^k \binom{n}{k}$ non-trivial clauses of length k , i.e., clauses with k distinct, non-complementary literals.

Typically, k is a (small) fixed integer, while n is allowed to grow. In particular, we will say that a sequence of random events \mathcal{E}_n occurs with high probability (w.h.p.) if $\lim_{n \rightarrow \infty} \Pr[\mathcal{E}_n] = 1$ and with uniformly positive probability (w.u.p.p.) if $\liminf_{n \rightarrow \infty} \Pr[\mathcal{E}_n] > 0$. One of the first facts to be established [FP83] for random k -CNF formulas is that $F_k(n, rn)$ is w.h.p. unsatisfiable for $r \geq 2^k \ln 2$. A few years later, Chao and Franco [CF86, CF90] showed that, in contrast, if $r < 2^k/k$, a very simple algorithm will find a satisfying truth assignment w.u.p.p.

Combined, these two facts established $m = \Theta(n)$ as the most interesting regime for considering the satisfiability of random k -CNF formulas.

The study of random k -CNF formulas took off in the late 1980s. In a celebrated result, Chvátal and Szemerédi [CS88] proved that random k -CNF formulas w.h.p. have exponential resolution complexity, implying that if F is a random k -CNF formula with $r \geq 2^k \ln 2$, then w.h.p. every DPLL-type algorithm needs exponential time to prove its unsatisfiability. A few years later, Chvátal and Reed [CR92] proved that random k -CNF formulas are satisfiable w.h.p. for $r = O(2^k/k)$, strengthening the w.u.p.p. result of [CF90]. Arguably, the biggest boost came from the experimental work of Mitchell, Selman and Levesque [MSL92] and the analysis of these experiments by Kirkpatrick and Selman in [KS94].

In particular, [SML96] gave extensive experimental evidence suggesting that for $k \geq 3$, there is a range of the clauses-to-variables ratio, r , within which it seems hard even to *decide* if a randomly chosen k -SAT instance is satisfiable or not (as opposed to reporting all cylinders of solutions or that no solutions exist). The analysis of these experiments using finite-size scaling methods of statistical physics in [KS94] showed that this peak in experimental decision complexity coincided with a precipitous drop in the probability that a random formula is satisfiable. For example, for $k = 3$ the analysis drew the following remarkable picture: for $r < 4$, a satisfying truth assignment can be easily found for almost all formulas; for $r > 4.5$, almost all formulas are unsatisfiable; for $r \approx 4.2$, a satisfying truth assignment can be found for roughly half the formulas and around this point the computational effort for finding a satisfying truth assignment, whenever one exists, is maximized.

This potential connection between phase transitions and computational complexity generated a lot of excitement. A particularly crisp question is whether the probability of satisfiability indeed exhibits a sharp threshold around some critical density (ratio of clauses to variables).

Satisfiability Threshold Conjecture. *For every $k \geq 3$, there exists a constant $r_k > 0$ such that,*

$$\lim_{n \rightarrow \infty} \Pr[F_k(n, rn) \text{ is satisfiable}] = \begin{cases} 1, & \text{if } r < r_k \\ 0, & \text{if } r > r_k. \end{cases}$$

By now, the Satisfiability Threshold Conjecture has attracted attention in computer science, mathematics, and statistical physics. It has stimulated numerous interesting results and is at the center of an area of intense research activity, some of which we will survey in the following sections. As we will see, recent results have both strengthened the connection between computational complexity and phase transitions and shown that it is far more nuanced than originally thought. In particular, to the extent that finding satisfying assignments in random formulas is hard, this hardness comes from phase transitions in the solution-space geometry of the formulas, not in their probability of satisfiability. But this is getting ahead of our story.

To conclude this introduction we note that while a number of other generative models have been proposed for random SAT instances over the years (see [Fra01]

for an excellent survey) random k -SAT is by far the dominant model. One reason is that random k -CNF formulas enjoy a number of intriguing mathematical properties. Another is that random k -SAT instances remain computationally hard for a certain range of densities, making them a popular benchmark for testing and tuning satisfiability algorithms. In fact, some of the better practical ideas in use today come from insights gained by studying the performance of algorithms on random k -SAT instances [GSCK00].

The rest of this chapter is divided into two major pieces. The first piece is an overview of the current state of the art regarding mathematical properties of random k -CNF formulas where the number of clauses $m = \Theta(n)$. The second piece concerns the performance of different algorithms on sparse random k -CNF formulas. Both pieces are concerned with (and limited to) *rigorous mathematical results*. For experimental algorithmic results we refer the reader to the survey by Cook and Mitchell [CM97]. For results using the methods of statistical physics we refer the reader to Part 2, Chapter 22.

10.2. The State of the Art

10.2.1. The Satisfiability Threshold Conjecture

The satisfiability threshold conjecture remains open. A big step was made by Friedgut [Fri99] who showed the existence of a sharp threshold for satisfiability around a critical *sequence* of densities (rather than a single density r_k).

Theorem 1 ([Fri99]). *For every $k \geq 3$, there exists a sequence $r_k(n)$ such that for any $\epsilon > 0$,*

$$\lim_{n \rightarrow \infty} \Pr[F_k(n, m) \text{ is satisfiable}] = \begin{cases} 1, & \text{if } m = (r_k(n) - \epsilon)n \\ 0, & \text{if } m = (r_k(n) + \epsilon)n. \end{cases}$$

While it is widely believed that $r_k(n) \rightarrow r_k$, a proof remains elusive. A useful corollary of Friedgut's theorem is the following, as it allows one to give lower bounds for r_k by only establishing satisfiability w.u.p.p. rather than w.h.p.

Corollary 2. *If $F_k(n, r^*n)$ is satisfiable w.u.p.p., then for all $r < r^*$, $F_k(n, rn)$ is satisfiable w.h.p.*

Although the existence of r_k has not been established, we will allow ourselves the notational convenience of writing $r_k \leq r^*$ to denote that for $r > r^*$, $F_k(n, rn)$ is w.h.p. unsatisfiable (and analogously for $r_k \geq r^*$). In this notation, the current best bounds for the location of the satisfiability threshold are, roughly,

$$2^k \ln 2 - \Theta(k) \leq r_k \leq 2^k \ln 2 - \Theta(1) .$$

The precise form of these bounds is given by Theorem 3, which we illustrate for some small values of k in Table 10.1.

Theorem 3. *There exists sequences $\delta_k, \epsilon_k \rightarrow 0$ such that for all $k \geq 3$,*

$$2^k \ln 2 - (k+1) \frac{\ln 2}{2} - 1 - \delta_k \leq r_k \leq 2^k \ln 2 - \frac{1 + \ln 2}{2} + \epsilon_k .$$

It is very easy to show that $r_k \leq 2^k \ln 2$. This is because the probability that $F_k(n, m)$ is satisfied by at least one assignment is trivially bounded by 2^n times the probability that it is satisfied by any particular assignment, which, in turn, is bounded by $(1 - 2^{-k})^m$ (indeed, this last expression is exact if we assume that clauses are chosen with replacement). Since $2(1 - 2^{-k})^r < 1$ for $r \geq 2^k \ln 2$, this implies that for all such r the probability of satisfiability is exponentially small. The sharpening of this upper bound for general k is due, independently, to Dubois and Boufkhad [DB97] and Kirousis et al. [KKKS98]. It corresponds to bounding the probability of satisfiability by 2^n times the probability that a particular assignment is a *locally maximum* satisfying assignment, i.e., one in which no 0 can be turned into 1 without violating satisfiability (it is clear that every satisfiable formula has at least one such satisfying assignment, e.g., the lexicographically greatest one).

The lower bound in Theorem 3 is due to Achlioptas and Peres [AP04] and was proven via the, so-called, second moment method. It corresponds to the largest density for which $F_k(n, m)$ w.h.p. has *balanced* satisfying assignments, i.e., satisfying assignments in which the number of satisfied literals is $km/2 + O(n)$. In other words, balanced satisfying assignments have the property that in spite of being satisfying their number of satisfied literals is like that of a uniformly random $\sigma \in \{0, 1\}^n$. Focusing on balanced assignments is done of technical necessity for the second moment method to work (we discuss this point in detail in Section 10.6.3) and there does not appear to be an inherent reason for doing so. Indeed, as k grows, the upper bound of Theorem 3 coincides with the results¹ for the location of the threshold (up to a $o(1)$ term in k), giving even more evidence that the $O(k)$ term in the lower bound is an artifact of the analysis.

The second moment method, used to prove the lower bound, ignores individual solutions and captures, instead, statistical properties of the entire solution-space. As such, it offers no guidance whatsoever on how to efficiently *find* satisfying assignments for those densities for which it establishes their existence. Indeed, as we will see shortly, no efficient algorithm is known that can find solutions beyond density $O(2^k/k)$, even w.u.p.p. In the third row of Table 10.1 we indicate this phenomenon by giving the largest densities for which any efficient algorithm is known to succeed [KKL06, FS96]).

Finally, we note that while both general bounds above extend to $k = 3$, better bounds exist for that case. In particular, the lower bound for r_3 in Table 10.1 is actually algorithmic and due, independently, to Hajiaghayi and Sorkin [HS03] and Kaporis, Kirousis and Lalas [KKL06]. We discuss its derivation in Section 10.7.2. The upper bound is due to Dubois, Boufkhad and Mandler [DBM03] and uses the idea of locally maximum assignments mentioned above in combination with conditioning on the literal degree sequence, thus curtailing certain large deviations contributions that inflate the unconditional expectation.

¹We use the term *results* as a way of referring to “p[hysics] results” in this area, the subject of Part 2, Chapter 22. In general, results rest on combining mathematically rigorous arguments with highly non-trivial unproven assumptions, the latter often informed by general considerations of statistical physics. The term is also motivated by the fact that many results eventually became rigorous mathematical results via proofs that were deeply informed by the physical arguments.

Table 10.1. Best known rigorous bounds for the location of the satisfiability threshold for some small values of k . The last row gives the largest density for which a polynomial-time algorithm has been proven to find satisfying assignments.

k	3	4	5	7	10	20
Best upper bound9	,
Best lower bound	.	.9	.9	.	.9	, 9
Algorithmic lower bound	.	.	9.	.	.	9 ,

10.3. Random MAX k -SAT

The methods used to derive bounds for the location of the satisfiability threshold, also give bounds for the fraction of clauses that can be satisfied above it. Specifically, let us say that a k -CNF formula with m clauses is p -satisfiable, for some $p \in [0, 1]$, if there exists an assignment satisfying at least $(1 - \frac{1-p}{2^k})m$ clauses. Observe that every k -CNF formula is 0-satisfiable, since the average number of satisfied clauses over all assignments is $(1 - 2^{-k})m$, while satisfiability is simply 1-satisfiability. Thus, given $p \in (0, 1]$, the relevant quantity is the largest density, $r_k(p)$, for which a random k -CNF formula is w.h.p. p -satisfiable. Analogously to the case $p = 1$, the naive union bound over $\{0, 1\}^n$ for the existence of a p -satisfying truth assignment implies $r_k(p) \leq T_k(p)$, where

$$T_k(p) = \frac{2^k \ln 2}{p + (1-p) \ln(1-p)} .$$

Note that since $\lim_{p \rightarrow 1} T_k(p) = 2^k \ln 2$, this recovers the naive satisfiability upper bound. Using the second moment method, in [ANP07] it was shown that asymptotically, this upper bound is tight up to second order terms.

Theorem 4. *There exists a sequence $\delta_k = O(k2^{-k/2})$, such that for all $k \geq 2$ and $p \in (0, 1]$,*

$$(1 - \delta_k) T_k(p) \leq r_k(p) \leq T_k(p) .$$

Algorithms fall far short from this bound. Analogously to satisfiability, the best known algorithm [CGHS04] finds p -satisfying assignments only for $r = O(T_k(p)/k)$.

10.3.1. The case $k \in \{2, 3\}$

For $k = 2$, satisfiability can be decided in polynomial time using a very simple method: tentatively set any unset variable v to 0; repeatedly satisfy any 1-clauses that result; if a 0-clause is generated set v permanently to 1, otherwise set it permanently to 0. A 2-CNF formula is satisfiable iff when this process terminates no 0-clauses are present. For random 2-CNF formulas, the trees of implications generated by this process mimic the connected component structure of random digraphs. Using this connection, Chvátal and Reed [CR92], Goerdts [Goe96] and Fernandez de la Vega [FdIV92] independently proved $r_2 = 1$. Later, in [BBC⁺01], Bollobás et al. [BBC⁺01], also using this connection, determined the scaling window for random 2-SAT, showing that the transition from satisfiability to unsatisfiability occurs for $m = n + \lambda n^{2/3}$ as λ goes from $-\infty$ to $+\infty$.

In [MZK⁺, MZK⁺99a, MZ98, MZK⁺99b], Monasson et al., using mathematically sophisticated but non-rigorous techniques of statistical physics, initiated the analytical study of random CNF formulas that are mixtures of 2- and 3-clauses, which they dubbed $(2+p)$ -CNF. Such formulas arise for a number of reasons. For example, a frequent observation when converting problems from other domains into satisfiability problems is that they result into mixed CNF formulas with a substantial number of clauses of length 2, along with the clauses of length 3. Another reason is that DPLL algorithms run by recursively solving satisfiability on *residual formulas*, restricted versions of their input CNF formula, which are mixtures of clauses of length at least 2. When given random 3-CNF formulas as input, many DPLL algorithms produce residual formulas that are mixtures of random 2- and 3-clauses, making properties of random $(2+p)$ -CNF crucial for analyzing their running time.

A random $(2+p)$ -CNF on n variables with m clauses is formed by choosing pm clauses of length 3 and $(1-p)m$ clauses of length 2, amongst all clauses of each length, uniformly and independently. Thus, $p = 0$ corresponds to random 2-SAT, while $p = 1$ corresponds to random 3-SAT. Below we will find it convenient to sidestep this original formulation and state results directly in terms of the number of 2- and 3-clauses, not of the total number of clauses m and p .

The fact $r_2 = 1$ implies that for any $\epsilon > 0$ a random 2-CNF formula on n variables with $(1 - \epsilon/2)n$ clauses is w.h.p. satisfiable, but adding ϵn 2-clauses to it w.h.p. results in an unsatisfiable formula. The results in [MZK⁺99b] suggested, rather remarkably, that if instead of adding ϵn random 2-clauses one adds up to $0.703\dots n$ random 3-clauses, the formula remains satisfiable. In other words, that there is no finite “exchange rate” between 2- and 3-clauses.

Inspired by these claims, Achlioptas et al. [AKKK01] proved that

Theorem 5. *A random CNF formula with n variables, $(1 - \epsilon)n$ 2-clauses and Δn 3-clauses is w.h.p. satisfiable for all $\epsilon > 0$ and all $\Delta \leq 2/3$, but w.h.p. unsatisfiable for $\epsilon = 0.001$ and $\Delta = 2.28$.*

In other words, the physical prediction of an infinite exchange ratio is valid as one can add at least $0.66n$ 3-clauses (and no more than $2.28n$). In [Ach99] it was conjectured that the inequality $\Delta \leq 2/3$ in Theorem 5 is tight. That is,

Conjecture 6. *For all $\Delta > 2/3$, there exists $\epsilon = \epsilon(\Delta) > 0$, such that a random CNF formula with n variables, $(1 - \epsilon)n$ 2-clauses and Δn 3-clauses is w.h.p. unsatisfiable.*

Conjecture 6 is supported by a presult of Biroli, Monasson and Weigt [BMW00], subsequent to [MZK⁺, MZK⁺99a], asserting that $2/3$ is indeed tight. As we will see, if true, it implies that the running time of a large class of DPLL algorithms exhibits a sharp threshold behavior: for each algorithm \mathcal{A} , there exists a critical density $r_{\mathcal{A}} \leq r_k$ such that \mathcal{A} takes linear time for $r < r_{\mathcal{A}}$, but exponential time for $r > r_{\mathcal{A}}$.

10.3.2. Proof Complexity and its Implications for Algorithms

We saw that sparse random k -CNF formulas are hard to prove unsatisfiable using resolution [CS88]. Ben-Sasson and Impagliazzo [BSI99] and Alekhovich and

Razborov [AR01] proved that the same is true for the polynomial calculus, while Alekhovich [Ale05] proved its hardness for k -DNF resolution. Random k -CNF formulas are believed to be hard for other proof systems also, such as cutting planes, and this potential hardness has been linked to hardness of approximation [Fei02]. Moreover, the hardness of proving their unsatisfiability has been explored for dense formulas, where for sufficiently high densities it provably disappears [BKPS02, FGK05, GL03, COGLS04, COGL07]. We will focus on the resolution complexity of random k -CNF formulas as it has immediate and strong implications for the most commonly used satisfiability algorithm, namely the DPLL procedure.

10.3.2.1. Resolution Complexity of k -CNF formulas

The resolution rule allows one to derive a clause $(A \vee B)$ from two clauses $(A \vee x)$ and $(B \vee \bar{x})$. A resolution derivation of a clause C from a CNF formula F is a sequence of clauses $C_1, \dots, C_\ell = C$ such that each C_i is either a clause of F or follows from two clauses C_j, C_k for $j, k < i$ using the resolution rule. A resolution refutation of an unsatisfiable formula F is a resolution derivation of the empty clause. The size of a resolution refutation is its number of clauses.

In contrast, the Davis-Putnam/DLL (DPLL) algorithm on a CNF formula F performs a backtracking search for a satisfying assignment of F by extending partial assignments until they either reach a satisfying assignment or violate a clause of F . It is well known that for an unsatisfiable formula F , the tree of nodes explored by any DPLL algorithm can be converted to a resolution refutation of F where the pattern of inferences forms the same tree.

For random k -CNF formulas in the unsatisfiable regime, the behavior of DPLL algorithms, and the more general class of resolution-based algorithms, is well-understood. Specifically, since every unsatisfiable 2-CNF formula has a linear-size resolution refutation, if $r > 1$ then even the simplest DPLL algorithms w.h.p. run in polynomial time on a random 2-CNF formula. On the other hand, for $k \geq 3$ the aforementioned result of Chvátal and Szemerédi [CS88] asserts that w.h.p. a random k -CNF formula in the unsatisfiable regime requires an exponentially long resolution proof of unsatisfiability. More precisely, let $\text{res}(F)$ be the size of the minimal resolution refutation a formula F (assume $\text{res}(F) = \infty$ if F is satisfiable). In [CS88] it was proved that

Theorem 7. *For all $k \geq 3$ and any constant $r > 0$, w.h.p. $\text{res}(F_k(n, rn)) = 2^{\Omega(n)}$.*

Corollary 8. *Every DPLL algorithm w.h.p. takes exponential time on $F_k(n, rn)$, for any constant $r \geq 2^k \ln 2$.*

10.3.2.2. $(2 + p)$ -CNF formulas and their Algorithmic Implications

Since all unsatisfiable 2-CNF formulas have linear-size resolution refutations and $r_2 = 1$, it follows that adding $(1 + \epsilon)n$ random 2-clauses to a random 3-CNF formula w.h.p. causes its resolution complexity to collapse from exponential to linear. In [ABM04b], Achlioptas, Beame and Molloy proved that, in contrast, adding $(1 - \epsilon)n$ random 2-clauses w.h.p. has essentially no effect on its proof complexity.

Theorem 9. For any constants $r, \epsilon > 0$, let F be a random formula with n variables, $(1 - \epsilon)n$ 2-clauses and rn 3-clauses. *W.h.p.* $\text{res}(F) = 2^{\Omega(n)}$.

Theorem 9 allows one to readily prove exponential lower bounds for the running times of DPLL algorithms for *satisfiable* random k -CNF formulas. This is because many natural DPLL algorithms when applied to random k -CNF formulas generate at least one unsatisfiable subproblem consisting of a random mixture of 2- and higher-length clauses, where the 2-clauses alone are satisfiable. (We will discuss how, when and for which algorithms this happens in greater detail in Section 10.9.) By Theorem 9, such a mixture has exponential resolution complexity (converting k -clauses with $k > 3$ to 3-clauses arbitrarily can only reduce resolution complexity) and, as a result, to resolve any such subproblem (and backtrack) any DPLL algorithm needs exponential time.

10.4. Physical Predictions for Solution-space Geometry

Random k -SAT, along with other random Constraint Satisfaction Problems, such as random graph coloring and random XOR-SAT have also been studied systematically in physics in the past two decades. For a general introduction and exposition to the physical methods see Part 2, Chapter 22. In particular, motivated by ideas developed for the study of materials known as spin glasses, physicists have put forward a wonderfully complex picture about how the geometry of the set of satisfying assignments of a random k -CNF formula evolves as clauses are added. Perhaps the most detailed and sophisticated version of this picture comes from [KMRT⁺07].

Roughly speaking, statistical physicists have predicted (using non-rigorous but mathematically sophisticated methods) that while for low densities the set of satisfying assignments forms a single giant cluster, at some critical density this cluster shatters into exponentially many clusters, each of which is relatively tiny and far apart from all other clusters. These clusters are further predicted to be separated from one another by huge “energy barriers”, i.e., every path connecting satisfying assignments in different clusters must pass through assignments that violate $\Omega(n)$ constraints. Moreover, inside each cluster the majority of variables are predicted to be frozen, i.e., take the same value in all solutions in the cluster; thus getting even a single frozen variable wrong requires traveling $\Omega(n)$ away and over a huge energy barrier to correct it.

The regime of exponentially many tiny clusters, each one having constant probability of vanishing every time a clause is added (due to its frozen variables), is predicted in [KMRT⁺07] to persist until very close to the threshold, namely for densities up to

$$2^k \ln 2 - \frac{3 \ln 2}{2} + o(1) , \quad (10.1)$$

where the $o(1)$ term is asymptotic in k . In comparison, the satisfiability threshold is predicted [MMZ06] to occur at

$$2^k \ln 2 - \frac{1 + \ln 2}{2} + o(1) , \quad (10.2)$$

i.e., fewer than $0.2n$ k -clauses later. For densities between (10.1) and (10.2), it is predicted that nearly all satisfying assignments lie in a small (finite) number of (atypically large) clusters, while exponentially many clusters still exist.

10.4.1. The Algorithmic Barrier

Perhaps the most remarkable aspect of the picture put forward by physicists is that the predicted density for the shattering of the set of solutions into exponentially many clusters scales, asymptotically in k , as

$$\ln k \cdot \frac{2^k}{k}, \quad (10.3)$$

fitting perfectly with the fact that all known algorithms fail at some density

$$c_{\mathcal{A}} \cdot \frac{2^k}{k}, \quad (10.4)$$

where the constant $c_{\mathcal{A}}$ depends on the algorithm. We will refer to this phenomenon as the “algorithmic barrier”. We note that so far there does not appear to be some natural general upper bound for $c_{\mathcal{A}}$ for the types of algorithms that have been analyzed, i.e., more sophisticated algorithms do have a greater constant, but with rapidly diminishing returns in terms of their complexity.

10.4.2. Rigorous Results for Solution-space Geometry

By now a substantial part of the picture put forward by physicists has been made rigorous, at least for $k \geq 8$. Success for smaller k stumbles upon the fact that the rigorous results rely on the second moment method which does not seem to perform as well for small k .

For the definitions in the rest of this section we assume we are dealing with an arbitrary CNF formula F defined over variables $X = x_1, \dots, x_n$, and we let $\mathcal{S}(F) \subseteq \{0, 1\}^n$ denote its set of satisfying assignments. We say that two assignments are adjacent if their Hamming distance is 1 and we let $H_F : \{0, 1\}^n \rightarrow \mathbb{N}$ be the function counting the number of clauses of F violated by each $\sigma \in \{0, 1\}^n$.

Definition 10. The **clusters** of a formula F are the connected components of $\mathcal{S}(F)$. A **region** is a non-empty union of clusters. The **height** of any path $\sigma_0, \sigma_1, \dots, \sigma_t \in \{0, 1\}^n$ is $\max_i H(\sigma_i)$.

One can get an easy result regarding the solution-space geometry of *very* sparse random formulas by observing that if a formula F is satisfiable by the *pure literal* rule alone, then the set $\mathcal{S}(F)$ is connected (recall that the pure literal rule amounts to permanently satisfying any literal ℓ whose complement does not appear in the formula and permanently removing all clauses containing ℓ ; the proof of connectivity is left as an exercise). The pure literal rule alone w.h.p. finds satisfying assignments in random k -CNF formulas with up to $\rho_k \cdot n$ clauses, for some $\rho_k \rightarrow 0$, so this is very far away from the densities up to which the best known algorithms succeed, namely $O(2^k/k)$.

The following theorem of Achlioptas and Coja-Oghlan [ACO08], on the other hand, asserts that for all $k \geq 8$, precisely at the asymptotic density predicted by physics in (10.3), the set of satisfying assignments shatters into an exponential number of well-separated regions. Given two functions $f(n), g(n)$, let us write $f \sim g$ if $\lim_{n \rightarrow \infty} f(n)/g(n) = 1$. Recall that the lower bound for the location of the satisfiability threshold provided by the second moment method is $s_k \equiv 2^k \ln 2 - (k+1) \frac{\ln 2}{2} - 1 - o(1) \sim 2^k \ln 2$.

Theorem 11. *For all $k \geq 8$, there exists $c_k < s_k$ such that for all $r \in (c_k, s_k)$, the set $\mathcal{S}(F_k(n, rn))$ w.h.p. consists of exponentially many regions where:*

1. *Each region only contains an exponentially small fraction of \mathcal{S} .*
2. *The Hamming distance between any two regions is $\Omega(n)$.*
3. *Every path between assignments in distinct regions has height $\Omega(n)$.*

In particular, $c_k \sim \ln k \cdot 2^k/k$.

The picture of Theorem 11 comes in even sharper focus for large k . In particular, for sufficiently large k , sufficiently close to the threshold, the regions become arbitrarily small and maximally far apart, while still exponentially many.

Theorem 12. *For any $0 < \delta < 1/3$, fix $r = (1 - \delta)2^k \ln 2$, and let*

$$\alpha_k = \frac{1}{k}, \quad \beta_k = \frac{1}{2} - \frac{5}{6}\sqrt{\delta}, \quad \epsilon_k = \frac{\delta}{2} - 3k^{-2}.$$

For all $k \geq k_0(\delta)$, w.h.p. the set $\mathcal{S} = \mathcal{S}(F_k(n, rn))$ consists of $2^{\epsilon_k n}$ regions where:

1. *The diameter of each region is at most $\alpha_k n$.*
2. *The distance between every pair of regions is at least $\beta_k n$.*

Thus, the solution-space geometry becomes like that of an correcting code with a little bit of “fuzz” around each codeword. This “shattering” phase transition is known as a *dynamical* transition, while the transition in which nearly all assignments concentrate on a finite number of clusters is known as a *condensation* transition. This dynamical phase transition has strong negative repercussions for the performance of random-walk type algorithms on random k -CNF formulas and exploring them precisely is an active area of research.

Remark 13. *The presults of [KMRT⁺07] state that the picture of Theorem 11 should hold for all $k \geq 4$, but **not** for $k = 3$. In particular for $k = 3$, the solution-space geometry is predicted to pass from a single cluster to a condensed phase directly.*

It turns out that after the set of satisfying assignments has shattered into exponentially many clusters, we can “look inside” these clusters and make some statements about their shape. For that, we need the following definition.

Definition 14. *The **projection** of a variable x_i over a set of assignments C , denoted as $\pi_i(C)$, is the union of the values taken by x_i over the assignments in C . If $\pi_i(C) \neq \{0, 1\}$ we say that x_i is **frozen** in C .*

Theorem 15 below [ACO08] asserts that the dynamical transition is followed, essentially immediately, by the massive appearance of frozen variables.

Theorem 15. *For all $k \geq 8$, there exists $d_k < s_k$ such that for all $r \in (d_k, s_k)$, a random $\sigma \in \mathcal{S}(F_k(n, rn))$ w.h.p. has at least $\gamma_k \cdot n$ frozen variables, where $\gamma_k \rightarrow 1$ for all $r \in (d_k, s_k)$. In particular, $d_k \sim \ln k \cdot 2^k/k$.*

The first rigorous analysis of frozen variables by Achlioptas and Ricci-Tersenghi [ART06] also establishes that

Corollary 16. *For every $k \geq 9$, there exists $r < s_k$ such that w.h.p. every cluster of $F_k(n, rn)$ has frozen variables.*

It remains open whether frozen variables exist for $k < 8$.

10.5. The Role of the Second Moment Method

Recall that the best upper bound for the satisfiability threshold scales as $\Theta(2^k)$, whereas all efficient algorithms known work only for densities up to $O(2^k/k)$. To resolve whether this gap was due to a genuine lack of solutions, as opposed to the difficulty of finding them, Achlioptas and Moore [AM06] introduced an approach which allows one to avoid the pitfall of computational complexity: namely, using the second-moment method one can prove that solutions exist in random instances, without the need to identify any particular solution for each instance (as algorithms do). Indeed, if random formulas are genuinely hard at some densities below the satisfiability threshold, then focusing on the *existence* of solutions rather than their efficient discovery is essential: one cannot expect algorithms to provide accurate results on the threshold's location; they simply cannot get there!

Before we delve into the ideas underlying some of the results mentioned above it is helpful to establish the probabilistic equivalence between a few different models for generating random k -CNF formulas.

10.6. Generative models

Given a set V of n Boolean variables, let $C_k = C_k(V)$ denote the set of all proper k -clauses on V , i.e., the set of all $2^k \binom{n}{k}$ disjunctions of k literals involving distinct variables. As we saw, a random k -CNF formula $F_k(n, m)$ is formed by selecting a uniformly random m -subset of C_k . While $F_k(n, m)$ is perhaps the most natural model for generating random k -CNF formulas, there are a number of slight variations of the model, largely motivated by their amenability to calculations.

For example, it is fairly common to consider the clauses as ordered k -tuples (rather than as k -sets) and/or to allow replacement in sampling the set C_k . Clearly, for properties such as satisfiability the issue of ordering is irrelevant. Moreover, as long as $m = O(n)$, essentially the same is true for the issue of replacement. To see that, observe that w.h.p. the number, q of repeated clauses is $o(n)$, while the set of $m - q$ distinct clauses is a uniformly random $(m - q)$ -subset of C_k . Thus, if a monotone decreasing property (such as satisfiability) holds with

probability p for a given $m = r^*n$ when replacement is allowed, it holds with probability $p - o(1)$ for all $r < r^*$ when replacement is not allowed.

The issue of selecting the literals of each clause with replacement (which might result in some “improper” clauses) is completely analogous. That is, the probability that a variable appears more than once in a given clause is at most $k^2/n = O(1/n)$ and hence w.h.p. there are $o(n)$ improper clauses. Finally, we note that by standard techniques, e.g., see [FS96], results also transfer between $F_k(n, m)$ and the model where every clause in C_k is included in the formula independently of all others with probability p , when $pC_k \sim m$.

10.6.1. The Vanilla Second Moment Method

The second moment method approach [ANP05] rests on the following basic fact: every non-negative random variable X satisfies $\Pr[X > 0] \geq \mathbf{E}[X]^2 / \mathbf{E}[X^2]$. Given any k -SAT instance F on n variables, let $X = X(F)$ be its number of satisfying assignments. By computing $\mathbf{E}[X^2]$ and $\mathbf{E}[X]^2$ for random formulas with a given density r one can hope to get a lower bound on the probability that $X > 0$, i.e., that $F_k(n, rn)$ is satisfiable. Unfortunately, this direct application fails dramatically as $\mathbf{E}[X^2]$ is exponentially (in n) greater than $\mathbf{E}[X]^2$ for every density $r > 0$. Nevertheless, it is worth going through this computation below as it points to the source of the problem and also helps in establishing the existence of clusters. We perform all computations below in the model where clauses are chosen with replacement from C_k .

For a k -CNF formula with m clauses chosen independently with replacement it is straightforward to show that the number of satisfying assignments X satisfies

$$\mathbf{E}[X^2] = \sum_{z=0}^n 2^n \binom{n}{z} f_S(z/n)^m, \quad (10.5)$$

where $f_S(\alpha) = 1 - 2^{1-k} + 2^{-k} \alpha^k$ is the probability that two fixed truth assignments that agree on $z = \alpha n$ variables, *both* satisfy a randomly drawn clause. Thus, (10.5) decomposes the second moment of X into the expected number of pairs of satisfying assignments at each possible distance.

Observe that f is an increasing function of α and that $f_S(1/2) = (1 - 2^{-k})^2$, i.e., truth assignments at distance $n/2$ are uncorrelated. Using the approximation $\binom{n}{\alpha n} = (\alpha^\alpha (1-\alpha)^{1-\alpha})^{-n} \times \text{poly}(n)$ and letting

$$\Lambda_S(\alpha) = \frac{2 f_S(\alpha)^r}{\alpha^\alpha (1-\alpha)^{1-\alpha}}$$

we see that

$$\begin{aligned} \mathbf{E}[X^2] &= \left(\max_{0 \leq \alpha \leq 1} \Lambda_S(\alpha) \right)^n \times \text{poly}(n), \\ \mathbf{E}[X]^2 &= \Lambda_S(1/2)^n. \end{aligned}$$

Therefore, if there exists some $\alpha \neq 1/2$ such that $\Lambda_S(\alpha) > \Lambda_S(1/2)$, then the second moment is exponentially greater than the square of the expectation and we

only get an exponentially small lower bound for $\Pr[X > 0]$. Put differently, unless the dominant contribution to $\mathbf{E}[X^2]$ comes from uncorrelated pairs of satisfying assignments, i.e., pairs with overlap $n/2$, the second moment method fails.

Unfortunately, this is precisely what happens for all $r > 0$ since the entropic factor $\mathcal{E}(\alpha) = 1/(\alpha^\alpha(1-\alpha)^{1-\alpha})$ in Λ_S is symmetric around $\alpha = 1/2$, while f_S is increasing in $(0, 1)$, implying $\Lambda'_S(1/2) > 0$. That is, Λ_S is maximized at some $\alpha > 1/2$ where the correlation benefit balances the penalty of decreased entropy.

While the above calculation does not give us what we want, it is still useful. For example, for any real number $\alpha \in [0, 1]$, it would be nice to know the number of pairs of satisfying truth assignments that agree on $z = \alpha n$ variables in a random formula. Each term in the sum in (10.5) gives us the *expected* number of such pairs. While this expectation may overemphasize formulas with more satisfying assignments (as they contribute more heavily to the expectation), it still gives valuable information on the distribution of distances among truth assignments in a random formula. For example, if for some values of z (and k, r) this expectation tends to 0 with n , we can readily infer that w.h.p. there are no pairs of truth assignments that agree on z variables in $F_k(n, rn)$. This is because for any integer-valued random variable Y , $\Pr[Y > 0] \leq \mathbf{E}[Y]$. Indeed, this simple argument is enough to provide the existence of clustering for all $k \geq 8$, at densities in the $\Theta(2^k)$ range (getting down to $(2^k/k) \cdot \ln k$ requires a lot more work).

10.6.2. Proving the Existence of Exponentially Many Clusters

To prove the existence of exponentially many regions one divides a lower bound for the total number of satisfying assignments with an upper bound for the number of truth assignments in each region. The lower bound comes from the expected number of *balanced* satisfying assignments since the success of the second moment method for such assignments, which we will see immediately next, implies that w.h.p. the actual number of balanced assignments is not much lower than its expectation. For the upper bound, one bounds the total number of *pairs* of truth assignments in each region as $\text{poly}(n) \times g(k, r)^n$, where

$$g(k, r) = \max_{\alpha \in [0, \Delta]} \Lambda_S(\alpha, k, r) ,$$

where Δ is the smallest number such that $\Lambda_S(\Delta, k, r) < 1$, i.e., Δn is a bound on the diameter of any region. Dividing the lower bound for the total number of satisfying assignments with the square root of this quantity yields the existence of exponentially many clusters.

10.6.3. Weighted second moment: the importance of being balanced

An attractive feature of the second moment method is that we are free to apply it to any random variable $X = X(F)$ such that $X > 0$ implies that F is satisfiable. With this in mind, let us consider random variables of the form

$$X = \sum_{\sigma} \prod_c w(\sigma, c)$$

where w is some arbitrary function. (Eventually, we will require that $w(\sigma, c) = 0$ if σ falsifies c .) Similarly to (10.5), it is rather straightforward to prove that

$$\mathbf{E}[X^2] = 2^n \sum_{z=0}^n \binom{n}{z} f_w(z/n)^m ,$$

where $f_w(z/n) = \mathbf{E}[w(\sigma, c)w(\tau, c)]$ is the correlation, with respect to a single random clause c , between two truth assignments σ and τ that agree on z variables. It is also not hard to see that $f_w(1/2) = \mathbf{E}[w(\sigma, c)]^2$, i.e., truth assignments at distance $n/2$ are uncorrelated for *any* function w . Thus, arguing as in the previous section, we see that $\mathbf{E}[X^2]$ is exponentially greater than $\mathbf{E}[X]^2$ unless $f'_w(1/2) = 0$.

At this point we observe that since we are interested in random formulas where literals are drawn uniformly, it suffices to consider functions w such that: for every truth assignment σ and every clause $c = \ell_1 \vee \dots \vee \ell_k$, $w(\sigma, c) = w(\mathbf{v})$, where $v_i = +1$ if ℓ_i is satisfied under σ and -1 if ℓ_i is falsified under σ . (So, we will require that $w(-1, \dots, -1) = 0$.) Letting $A = \{-1, +1\}^k$ and differentiating f_w , yields the geometric condition

$$f'_w(1/2) = 0 \iff \sum_{\mathbf{v} \in A} w(\mathbf{v})\mathbf{v} = 0 . \quad (10.6)$$

The condition in the r.h.s. of (10.6) asserts that the vectors in A , when scaled by $w(\mathbf{v})$, must cancel out. This gives us another perspective on the failure of the vanilla second moment method: when $w = w_S$ is the indicator variable for satisfiability, the condition in the right hand side of (10.6) does not hold since the vector $(-1, -1, \dots, -1)$ has weight 0, while all other $\mathbf{v} \in A$ have weight 1.

Note that the r.h.s. of (10.6) implies that in a successful w each coordinate must have mean 0, i.e., that each literal must be equally likely to be $+1$ or -1 when we pick truth assignments with probability proportional to their weight under w . We will call truth assignments with $km/2 \pm O(\sqrt{m})$ satisfied literal occurrences *balanced*. As was shown in [AP04], if X is the number of balanced satisfying assignments then $\mathbf{E}[X^2] < C \cdot \mathbf{E}[X]^2$, for all $r \leq s_k$, where $C = C(k) > 0$ is independent of n . Thus, $\Pr[X > 0] \geq 1/C$ and by Corollary 2 we get $r_k \geq s_k$.

To gain some additional intuition on the success of balanced assignments it helps to think of $F_k(n, m)$ as generated in two steps: first choose the km literal occurrences randomly, and then partition them randomly into k -clauses. At the end of the first step, truth assignments that satisfy many literal occurrences clearly have significantly greater conditional probability of eventually being satisfying assignments. But such assignments are highly correlated with each other since in order to satisfy many literal occurrences they tend to agree with the majority truth assignment on more than half the variables. Focusing on balanced assignments only, curbs the tendency of satisfying assignments to lean towards the majority vote assignment.

Finally, we note that it is not hard to prove that for $r \geq s_k + O(1)$, w.h.p. $F_k(n, rn)$ has no satisfying truth assignments that only satisfy $km/2 + o(n)$ literal occurrences. Thus, any asymptotic improvement over the lower bound for r_k provided by balanced assignments would mean that tendencies toward the majority assignment become essential as we approach the threshold. By the same token,

we note that as k increases the influence exerted by the majority vote assignment becomes less and less significant as most literals occur very close to their expected $kr/2$ times. As a result, as k increases, typical satisfying assignments get closer and closer to being balanced, meaning that the structure of the space of solutions for small values of k (e.g., $k = 3, 4$) might be significantly different from the structure for large values of k , something also predicted by the physical methods.

10.7. Algorithms

For the purposes of this chapter we will categorize satisfiability algorithms into two broad classes: DPLL algorithms and random walk algorithms. Within the former, we will distinguish between backtracking and non-backtracking algorithms. More concretely, the DPLL procedure for satisfiability is as follows:

DPLL(F)

1. Repeatedly satisfy any pure literals and 1-clauses.
 If the resulting formula F' is empty, exit reporting “satisfiable”.
 If a contradiction (0-clause) is generated, exit.
2. Select a variable $x \in F'$ and a value v for x
3. DPLL($F'_{v=x}$)
4. DPLL($F'_{v=1-x}$)

Clearly, different rules for performing Step 2 give rise to different algorithms and, in practice, the complexity of these rules can vary from minimal to huge. Perhaps the simplest possible rule is to consider the variables in a fixed order, e.g., x_1, x_2, \dots, x_n , always selecting the first variable in the order that is present in the formula, and always setting x to the same value, e.g., $x = 0$. If one forgoes the pure literal rule, something which simplifies the mathematical analysis on random formulas, the resulting algorithms are known as ORDERED DLL. If one also forgoes backtracking, the resulting algorithm is known as UC, for Unit Clause propagation, and was one of the first algorithms to be analyzed on random formulas.

10.7.1. Random walk algorithms

In contrast to DPLL algorithms, random walk algorithms always maintain an entire assignment which they evolve until either it becomes satisfying or the algorithm is exhausted. While, in principle, such an algorithm could switch the value of arbitrarily many variables at a time, typically only a constant number of variables are switched and, in fact, the most common case is to switch only one variable (hence “walk”). An idea that appears to make a significant difference in this context is that of *focusing* [SAO05], i.e., restricting the choice of variable(s) to switch among those contained in clauses violated by the present assignment.

Unfortunately, while there are numerous experimental results regarding performance of random walk algorithms on random formulas, the only mathematically rigorous result known is due to Alekhovich and Ben-Sasson [ABS07] asserting that the algorithm “select a violated clause at random and among its violated

literals select one at random and flip it”, due to Papadimitriou [Pap91], succeeds in linear time on random 3-CNF for densities as high as 1.63, i.e., up to the largest density for which the pure literal rule succeeds (recall that the success of the pure literal implies that the set of satisfying assignments is connected).

It is worth pointing out that, at this point, there exist both very interesting results regarding the performance of random walk algorithms on random formulas [CMMS03, SM03] and also very interesting mathematical results [FMV06, COMV07] regarding their performance on the planted model, i.e., on formulas generated by selecting uniformly at random among all $2^{k-1} \binom{n}{k}$ k -clauses satisfied by a fixed (planted) assignment. Perhaps, our recent understanding of the evolution of the solution-space geometry of random k -CNF formulas will help in transferring some of these results.

10.7.2. Non-backtracking Algorithms

On random CNF formulas UC is equivalent to simply repeating the following until either no clauses remain (success), or a 0-clause is generated (failure): if there is a clause of length 1 satisfy it; otherwise, select a random unassigned variable and assign it a random value. What makes the analysis of UC possible is the fact that if the input is a random k -CNF formula, then throughout the execution of UC the following is true. Let $V(t)$ be the set of variables that have not yet been assigned a value after t steps of the algorithm, and let $\mathcal{C}_i(t)$ be the set of clauses of length i at that time. Then the set $\mathcal{C}_i(t)$ is distributed exactly as a random i -CNF formula on the variables $V(t)$, with exactly $|\mathcal{C}_i(t)|$ clauses.

To see the above claim, imagine representing a CNF formula by a column of k cards for each k -clause, each card bearing the name of one literal. Assume, further, that originally all the cards are “face-down”, i.e., the literal on each card is concealed (and we never had an opportunity to see which literal is on each card). At the same time, assume that an intermediary with photographic memory knows precisely which literal is on each card. To interact with the intermediary we are allowed to either

- Point to a particular card, or,
- Name a variable that has not yet been assigned a value.

In response, if the card we point to carries literal ℓ , the intermediary reveals (flips) all the cards carrying $\ell, \bar{\ell}$. Similarly, if we name variable v , the intermediary reveals all the cards carrying v, \bar{v} . In either case, faced with all the occurrences of the chosen variable we proceed to decide which value to assign to it. Having done so, we remove all the cards corresponding to literals dissatisfied by our setting and all the cards (some of them still concealed) corresponding to satisfied clauses. As a result, at the end of each step only “face-down” cards remain, containing only literals corresponding to unset variables. This card-game representation immediately suggests our claimed “uniform randomness” property for UC and this can be made easily rigorous by appealing to the method of “deferred decisions”. In fact, *all* algorithms that can be carried out via this game enjoy this property.

Lemma 17 (Uniform randomness). *If $V(t) = X$ and $|\mathcal{C}_i(t)| = q_i$, the set of i -clauses remaining at time t form $F_i(|X|, q_i)$ on the variables in X .*

Armed with such a simple representation of Markovian state, it is not hard to show that as long as an algorithm takes care of unit clauses whenever they exist, its success or failure rests on whether the set of 2-clauses ever acquires density greater than 1. The main tool used to determine whether that occurs it is to pass to a so-called “liquid” model and approximate the evolution of the number of clauses of each length via a system of differential equations. Indeed, both of these ideas (uniform randomness plus differential equations) were present in the work of Chao and Franco in the mid-80s [CF86], albeit not fully mathematically justified.

The card-game described above does not allow one to carry out the pure literal heuristic, as it offers no information regarding the number of occurrences of each literal in the formula. To allow for this, we switch to a slightly different model for generating random k -CNF formulas. First, we generate km literals independently, each literal drawn uniformly at random among all $2n$ literals and, then, we generate a formula by partitioning these km literals into k -clauses uniformly at random. (This might result in a few “improper” clauses; we addressed this essentially trivial point in Section 10.6.)

One can visualize the second part of this process as a uniformly random matching between km literals on the left and their km occurrences in k -clauses on the right. As the matching is uniformly random, similarly to the card game, it can be “exposed” on the fly. (Indeed, the card game above is just the result of concealing the left hand of the matching.) With this representation we can now execute algorithms such as: if there is a pure literal or a clause of length 1 satisfy it; otherwise, select a random literal of maximum degree and satisfy it; or, alternatively, select a “most polarized” variable and assign it its majority value. To analyze either one of these algorithms, note that it is enough to maintain as Markovian state the number of clauses of each length and the number of variables having i positive and j negative literal occurrences for each $i, j \geq 0$.

With this long introduction in place we can now describe the state of the art:

- Historically, the first fully rigorous lower bound for r_3 was given by Broder, Frieze and Upfal [BFU93] who considered the pure literal heuristic. They showed that for $r \leq 1.63$, w.h.p. this eventually sets all the variables (and that for $r > 1.7$ w.h.p. it does not). The exact threshold for its success was given later in [LMS98, Mol05].
- Following that, only algorithms expressible in the card-game model were analyzed for a while. In [AS00] Achlioptas and Sorkin showed that the optimal algorithm expressible in this model works up to 3.26... For a survey of the state of the art up to that point, along with a unified framework for analyzing satisfiability algorithms via differential equations, see [Ach01].
- The configuration model for analyzing satisfiability algorithms has been taken up for $k = 3$. Specifically, the simple algorithm mentioned above, “in the absence of unit clauses satisfy a random literal of maximum degree”, was proposed and analyzed by Kaporis, Kirousis and Lalas [KKL02] who showed that it succeeds w.h.p. up to density 3.42... More complicated algorithms that select which literal to satisfy by considering the degree of each literal *and* that of its complement, achieve the best known lower bound, 3.52..., for the 3-SAT threshold, and were analyzed, independently,

by Kaporis, Kirousis and Lalas [KKL06] and Hajiaghayi and Sorkin [HS03]. It seems likely that this bound can be further improved, at least slightly, by making even more refined considerations in the choice of variable and value, but it also seems clear that this is well within the regime of diminishing returns.

- For $k > 3$, the best results come from consider the following very natural “shortest clause” algorithm SC: pick a random clause c of minimum length; among the literals in c pick one at random and satisfy it. A weakening of this algorithm which in the absence of 1-, 2-, and 3-clauses selects a random literal to satisfy was analyzed by Frieze and Suen in [FS96] and gives the best known algorithmic lower bound for the k -SAT threshold for $k > 3$, namely $r_k \geq \gamma_k 2^k/k$, where $\gamma_k \rightarrow 1.817$. In [FS96], the authors give numerical evidence that even the full SC algorithm only succeeds up to some $\zeta_k 2^k/k$, where $\zeta_k = O(1)$.

In a nutshell, the only algorithms that have been proven to find satisfying assignments efficiently in random k -CNF formulas are extremely limited and only succeed for densities up to $O(2^k/k)$. In particular, both their variable ordering and their value assignment heuristic can be implemented given very little, and completely local, information about the variable-clause interactions. Of course, this limitation is also what enables their analysis.

Question 18. *Is there a polynomial-time algorithm which w.u.p.p. finds satisfying assignments of random k -CNF formulas of density $2^k/k^{1-\epsilon}$ for some $\epsilon > 0$?*

As we saw, the geometry of the space of satisfying assignments undergoes a phase transition at $\ln k \cdot 2^k/k$. As a result, an affirmative answer to Question 18 might require a significant departure from the type of algorithms that have been analyzed so far.

10.8. Belief/Survey Propagation and the Algorithmic Barrier

In [MPR02], Mézard, Parisi, and Zecchina proposed a new satisfiability algorithm called Survey Propagation (SP) which performs extremely well experimentally on instances of random 3-SAT. This was a big breakthrough and allowed for optimism that, perhaps, random k -SAT instances might not be so hard, even close to the threshold. Unfortunately, conducting experiments with random k -CNF formulas becomes practically harder at a rapid pace as k increases: the interesting densities scale as $\Theta(2^k)$ so, for example, already $k = 10$ requires extremely large n in order for the formulas to be plausibly considered sparse.

As mentioned earlier, in [KMRT⁺07] it is predicted that just below the satisfiability threshold there is a small range of densities, scaling as $2^k \ln 2 - \Theta(1)$, for which although exponentially many clusters exist, almost all satisfying assignments lie in a *finite* number of (atypically large) clusters. This “condensation” of nearly all satisfying assignments to a small number of clusters induces long-range correlations among the variables, making it difficult to estimate their marginal distributions by examining only a bounded neighborhood around each variable. SP is an ingenious heuristic idea for addressing this problem by considering not

the uniform measure over satisfying assignments but, rather, (an approximation of) the uniform measure over clusters, where each cluster is represented by the fixed point of a certain iterative procedure applied to any assignment in the cluster.

That said, for all densities below the condensation transition, SP is not strictly necessary: if SP can compute variable marginals, then so can a much simpler algorithm called Belief Propagation, i.e., dynamic programming on trees. This is because when the measure is carried by exponentially many well-scattered clusters, marginals are expected to decorrelate. Indeed Gershenfeld and Montanari [GM07] gave very strong rigorous evidence that BP succeeds in computing marginals in the uncondensed regime for the coloring problem. So, although SP might be useful when working very close to the threshold, it is not readily helpful in designing an algorithm that can *provably* find solutions even at *much* lower densities, e.g., say at $r = 2^{k-2}$, roughly in the middle of the satisfiable regime.

One big obstacle is that, currently, to use either BP or SP to find satisfying assignments one sets variables iteratively. When a constant fraction of the variables are frozen in each cluster, as is the case after the dynamical transition, setting a single variable typically eliminates a constant fraction of all clusters. As a result, very quickly, one can be left with so few remaining clusters that decorrelation stops to hold. Concretely, in [MRTS07], Montanari, Ricci-Tersenghi and Semerjian showed that (even with the relatively generous assumptions of statistical physics computations) the following algorithm **fails** for densities greater than $\ln k \cdot 2^k/k$. That is, step 2 below fails to converge after only a small fraction of all variables have been assigned a value:

1. Select a variable v at random.
2. Compute the marginal distribution of v using Belief Propagation.
3. Set v to $\{0, 1\}$ according to the computed marginal distribution; simplify the formula; go to step 1.

10.9. Backtracking Algorithms

Backtracking satisfiability algorithms operate by building an assignment step by step. In particular, the choices they make when no unit clauses and pure literals are present are called *free* and when those choices lead to contradictions (empty clauses), backtracking occurs. In contrast, their non-backtracking variants encountered in Section 10.7.2 simply give up when that happens. Moreover, the only non-backtracking algorithms that have been analyzed maintain their residual formula uniformly random conditional on some small notion of “state”, reflecting the number of clauses of each length and perhaps, additionally, the number of occurrences of each literal. Let us call such algorithms “myopic”.

It is not hard to prove that the largest density, $r_{\mathcal{A}}$, for which a myopic non-backtracking algorithm \mathcal{A} will find satisfying assignments of a random k -CNF formula is precisely the largest density for which its residual 2-CNF subformula remains below density 1 throughout \mathcal{A} 's execution (see e.g. [Ach01]). For densities beyond $r_{\mathcal{A}}$ one can endow \mathcal{A} with a backtracking scheme and attempt to analyze its performance. Unfortunately, any non-trivial amount of backtracking makes it

hard to have a compact probabilistic model for the residual formula. As a result, a probabilistic analysis akin to that possible for $r < r_{\mathcal{A}}$ appears beyond the reach of current mathematical techniques (but see [CM04, CM05, Mon05] for an analysis using techniques of statistical physics). Nevertheless, for *all* backtracking extensions of myopic algorithms it is possible to prove that they take exponential time when the initial k -CNF formula is above a certain critical density. This is because of the following immediate implication of Theorem 9.

Corollary 19. *If a DPLL algorithm ever generates a residual formula that is an unsatisfiable mixture of uniformly random clauses in which the 2-clause density is below 1, then w.h.p. it will spend exponential time before backtracking from it.*

That is, by Corollary 19, once a node in the backtracking search is reached that corresponds to an unsatisfiable random mixture (but where the 2-clauses alone are satisfiable), the search cannot leave the sub-tree for an exponentially long time. Standard results (see e.g. [Ach01]) imply that w.u.p.p. this is precisely what happens for UC started with $3.81n$ 3-clauses and for SC started with $3.98n$ 3-clauses. This is because for such initial densities, at some point, the corresponding algorithm w.u.p.p. generates a residual $(2+p)$ -CNF formula which is unsatisfiable w.h.p. per the results of Theorem 5.

Theorem 20. *For any constant $r \geq 3.81$, any backtracking extension of UC w.u.p.p. takes time $2^{\Omega(n)}$ on $F_3(n, rn)$. Similarly for SC and $r \geq 3.98$.*

We note that the only reason for Theorem 20 is not a high probability result is that w.u.p.p. each algorithm might generate a contradiction and backtrack, thus destroying the uniform randomness of the residual formula, before creating a formula like the one mandated by Corollary 19. It is worth pointing out, though, that whenever this occurs w.h.p. it is for trivial local reasons. In particular, Frieze and Suen in [FS96], introduced the following form of backtracking: when a contradiction is reached, record the portion of the assignment between the last free choice and the contradiction; these literals become *hot*. After flipping the variable involved in the last free choice, instead of making the choice that the original heuristic would suggest, give priority to the complements of the hot literals in the order that they appeared; once the hot literals are exhausted continue as with the original heuristic. This backtracking rule is quite natural in that it is the last part of the partial assignment that got into trouble in the first place. Moreover, it appears to be a genuinely good idea. Experiments on random formulas comparing this backtracking extension of UC with just reversing the last free choice show that the histogram of run-times is *significantly better* for a large range of densities [ABM04b]. Another property of this backtracking rule is that as long as the value of each variable in a partial assignment has been flipped at most once, as happens when dealing with trivial, local contradictions, the residual formula is uniformly random. In particular, for this particular backtracking extension Theorem 20 holds w.h.p.

Theorem 20 sheds light on a widely-cited observation of Mitchell, Selman and Levesque [MSL92], based on experiments with ORDERED-DLL on small problems, stating that random 3-SAT is easy in the satisfiable region up to the 4.2 threshold, becomes sharply much harder at the threshold and quickly becomes easy again at

larger densities in the unsatisfiable region. The upper end of this “easy-hard-easy” characterization is somewhat misleading since, as we saw, the result of [CS88] in fact asserts that w.h.p. random 3-CNF formulas only have exponential-size proofs of unsatisfiability above the threshold. By now, the rate of decline in running time as the density is increased has been analyzed as well by Beame et al. [BKPS02]. Theorem 20 shows that the lower end of this characterization is also misleading in that the onset of exponential behavior occurs significantly below the (conjectured) satisfiability threshold at density 4.2. This concurs with experimental evidence that even the best of current DPLL implementations seem to have bad behavior below the threshold [CDA⁺03]. Moreover, as we will see shortly, the gap between the onset of exponential behavior and the satisfiability threshold increases rapidly with k .

Corollary 19 probably points to a much larger truth than what is specifically derived for the algorithms and backtracking schemes mentioned above. This is because the proof of Theorem 9 is quite robust with respect to the probability distribution of the clauses in the mixture. The essential ingredient seems to be that the variable-clause incidence graph is an expander, suggesting that, in fact, random k -CNF formulas are not the only formulas for which one could hope to prove a result similar to Theorem 20. Moreover, precisely the combinatorial richness of expanders suggests that restarting a DPLL algorithm on a random k -CNF formula is unlikely to yield dramatically different results from run to run, unless, of course, one is willing to restart an exponential number of times.

The bounds on the 3-clause density needed to cause exponential behavior in satisfiability algorithms will be readily improved with any improvement on the $2.28n$ upper bound for unsatisfiability in random $(2+p)$ -SAT. In particular, if Conjecture 6 is true, then Theorem 9 implies [ABM04b] that the running time of every myopic algorithm goes from linear to exponential around a critical, algorithm-specific density.

10.10. Exponential Running-Time for $k > 3$

The most obvious drawback of Theorem 20 is that it implies exponential behavior for densities that are only *conjectured* (but not proven) to be in the “satisfiable regime”. For all $k \geq 4$, the analogue to Theorem 20 holds for densities that are *provably* in the satisfiable regime [ABM04a]. Moreover, the ratio between the density at which the algorithms begins to require exponential time, and the greatest density for which formulas are known to be satisfiable is of order $1/k$. Concretely,

Theorem 21. *For $k = 4$ and $r \geq 7.5$ and for $k \geq 5$ and $r \geq (11/k)2^{k-2}$, ORDERED-DLL w.u.p.p. requires time $2^{\Omega(n)}$ on $F_k(n, rn)$.*

Analogues of Theorem 21 hold for many other backtracking extensions of “myopic” [Ach01] algorithms and, similarly to the results for $k = 3$, one can get high probability results by considering the Frieze-Suen style backtracking.

Chapter 11

Exploiting Runtime Variation in Complete Solvers

Carla P. Gomes and Ashish Sabharwal

Those working on the satisfiability problem, in particular the designers of highly competitive practical SAT solvers, are faced with an intriguing phenomenon that is both a stumbling block and an opportunity: the performance of backtrack-style complete SAT solvers can vary dramatically depending on “little” details of the heuristics used, such as the way one selects the next variable to branch on (the variable selection heuristic) and in what order the possible values are assigned to the variable (the value selection heuristic). The inherent exponential nature of the search process appears to magnify the unpredictability of such procedures. In fact, it is not uncommon to observe a DPLL-style solver “hang” on a given instance, whereas a different heuristic, or even just another randomized run of the same algorithm, solves the instance within seconds or minutes.

How can one understand this behavior? Even more importantly, how can we devise ways to exploit such extreme variation in the runtime distribution of combinatorial search methods? This chapter focuses on these two questions, in the context of DPLL-style complete search algorithms for SAT.

In the first part of this chapter, we explore runtime variation in a formal manner, characterizing it in terms of certain non-standard classes of statistical distributions. The approach here is to treat combinatorial search methods as complex physical phenomenon, and measure and analyze their performance through statistics obtained over repeated runs. Specifically, this approach reveals that the runtime distribution of many search algorithms often shows what is known as “fat tailed” and “heavy tailed” behavior. Intuitively, this means that the chance that a search procedure will take a certain amount of runtime decays very slowly with the runtime, thereby resulting in an unusually high chance of seeing runs that appear to take forever to terminate. These distributions can have an infinite variance and, in fact, even infinite mean. This is very different from standard distributions like the Gaussian, where the variance is bounded and data points have a significantly low chance of being too far away from the mean. While this provides an explanation for very long runs of SAT solvers that one often observes in practice, a complementary phenomenon—namely, the existence of very small “backdoors” in real-world problem instances—helps us understand how solvers

can sometimes get “lucky” and solve very large complex problems within seconds. The idea here is that if the problem instance under consideration has a small set of variables that capture its key combinatorics, then a well-designed search algorithm has a reasonable chance of discovering this small set and reducing the problem to a much simpler one by assigning truth values to these backdoor variables. Quite surprisingly, instances from many small interesting structured domains have been found to have extremely small backdoor sets (e.g., a few dozen variables in problem instances with thousands of variables).

Randomization-based combinatorial search techniques play a dual role in this setting: revealing and highlighting dramatic runtime variation even on a single instance with a single solver, and opening up ways to address and exploit this variation. Randomization in computational processes, i.e., the ability to decide the next step of an algorithm based on the result of a random experiment, is perhaps one of the most important discoveries in algorithm design. In many problems of interest, randomized algorithms are much simpler than deterministic algorithms of comparable performance, although often the complexity analysis or correctness proofs for randomized algorithms are more involved. The ability to ‘flip a coin’ during computation can make a significant difference in what one can achieve. For each choice of such coin flips, we essentially get a different deterministic algorithm. Thus, executing a randomized algorithm on an input can be viewed as executing a randomly chosen deterministic algorithm on that input. This immediately brings out the strength of randomized algorithms: while it is easy for an adversary to design many worst-case inputs where a given deterministic algorithm fails terribly (in terms of runtime), it is significantly harder to come up with an input where most of the deterministic algorithms represented by a single randomized algorithm fail simultaneously. For a wide selection of randomized algorithms for various combinatorial problems, we refer the reader to Motwani and Raghavan [MR95]. The inherent theoretical power of randomization is the subject of complexity theory, and is discussed in standard texts [e.g. Pap94].

One natural class of techniques for SAT (not covered in this chapter) relying heavily on randomization is that underlying local search solvers, such as *Walksat* [SKC96]. Such algorithms start with an initial candidate solution and make “local” changes to it until either a solution is found or a pre-specified time limit is reached. In order to have any chance of avoiding local “minima” and “traps”, such algorithms rely immensely on randomizing their often greedily biased choice of which variable to flip. Such methods and their history are described in detail in Chapter 6 of this Handbook. We refer the reader to that chapter for an extensive discussion of the use of randomization in local search SAT solvers. Another area involving randomization in SAT is the study of random instances of the k -SAT and other related problem, which has been the subject of extensive research amongst both theoreticians and practitioners, and has revealed intriguing “phase transition” phenomena and “easy-hard-easy” patterns. These aspects are discussed in detail in Chapter 10 of this Handbook.

The present chapter in its second half will largely focus on the use of randomization techniques in DPLL-style backtrack SAT solvers, as a way of addressing the heavy-tailed runtime distributions of such solvers. The presence of heavy-tailed behavior and unusually long runs also implies that there are many runs

that are much shorter than others. The presence of small backdoor sets further indicates that it can—and almost always does—pay off to give up on the current computation of a SAT solver every so often and *restart* the computation from a different state or with a different random seed. This assumes that restarts will send the search in fairly different directions. While there are many opportunities for randomizing a DPLL-style SAT solver which will be mentioned, it turns out the even very simple ones—such as only breaking ties at random—already have a significant desirable effect. In discussing these techniques, we will assume familiarity with standard concepts used in backtrack search for SAT, and refer the reader to Chapter 3 of this Handbook for details.

11.1. Runtime Variation in Backtrack Search

As mentioned earlier, the performance of a randomized backtrack search algorithm can vary dramatically from run to run, even on the same instance. The runtime distributions of backtrack search algorithms are often characterized by what is known as heavy-tailed behavior. This section discusses this behavior and provides formal probabilistic models that help us understand such non-standard distributions.

We note that a related phenomenon is observed in random problem distributions that exhibit an “easy-hard-easy” pattern in computational complexity, concerning so-called “exceptionally hard” instances: such instances seem to defy the “easy-hard-easy” pattern. They occur in the under-constrained area, but they seem to be considerably harder than other similar instances and even harder than instances from the critically constrained area. This phenomenon was first identified by Hogg and Williams [HW94] in the graph coloring problem and by Gent and Walsh [GW94] in the satisfiability problem. An parameterized instance is considered to be exceptionally hard for a particular search algorithm when it occurs in the parameterization region where almost all problem instances are satisfiable (i.e., the under-constrained area), but is considerably harder to solve than other similar instances, and even harder than most of the instances in the critically constrained area [GW94, HW94, SG95]. However, subsequent research showed that such instances are not inherently difficult; for example, by simply renaming the variables or by considering a different search heuristic such instances can be easily solved [SK96, SG97]. Therefore, the “hardness” of exceptionally hard instances does not reside in the instances *per se*, but rather in the combination of the instance with the details of the search method. This is the reason why researchers studying the hardness of computational problems use the median to characterize search difficulty, instead of the mean; the behavior of the mean tends to be quite erratic [GSC97].

11.1.1. Fat and Heavy Tailed Behavior

The study of the full runtime distributions of search methods—instead of just the moments and median—has been shown to provide a better characterization of search methods and much useful information in the design of algorithms. In particular, researchers have shown that the runtime distributions of complete

backtrack search methods reveal intriguing characteristics of such search methods: quite often complete backtrack search methods exhibit *fat* and *heavy-tailed* behavior [FRV97, GSC97, HW94]. Such runtime distributions can be observed when running a deterministic backtracking procedure on a distribution of random instances, and perhaps more importantly, by repeated runs of a randomized backtracking procedure on a *single* instance.

Heavy-tailed distributions were first introduced by the Italian-born Swiss economist Vilfredo Pareto in the context of income distribution. They were extensively studied mathematically by Paul Lévy in the period between the world wars. Lévy worked on a class of probability distributions with heavy tails, which he called *stable* distributions. At the time, however, these distributions were largely considered probabilistic curiosities or pathological cases, mainly used as counterexamples. This situation changed dramatically with Mandelbrot's work on fractals. In particular, two seminal papers by Mandelbrot were instrumental in establishing the use of stable distributions for modeling real-world phenomena [Man60, Man63].

Relatively recently, heavy-tailed distributions have been used to model phenomena in areas as diverse as economics, statistical physics, and geophysics. In particular, they have been applied to stock-market analysis, Brownian motion, weather forecasting, and earthquake prediction — and even for modeling of time delays on the World Wide Web [cf. AFT98, Man83, ST94].

Let us begin with the notion of *fat-tailedness*, which is based on the concept of *kurtosis*. The *kurtosis* is defined as μ_4/μ_2^2 (μ_4 is the fourth central moment about the mean and μ_2 is the second central moment about the mean, i.e., the variance). If a distribution has a high central peak and long tails, then the kurtosis is in general large. The *kurtosis* of the standard normal distribution is 3. A distribution with a *kurtosis* larger than 3 is *fat-tailed* or *leptokurtic*. Examples of distributions that are characterized by *fat-tails* are the exponential distribution, the log-normal distribution, and the Weibull distribution.

Heavy-tailed distributions have “heavier” tails than fat-tailed distributions; in fact they have some infinite moments. For instance, they can have infinite mean, infinite variance, etc. More rigorously, a random variable X with probability distribution function $F(\cdot)$ is heavy-tailed if it has the so-called Pareto like decay of the tails, i.e.:

$$1 - F(x) = \Pr[X > x] \sim Cx^{-\alpha}, \quad x > 0,$$

where $\alpha > 0$ and $C > 0$ are constants. The constant α is called the *index of stability* of the distribution, because which moments of X (if any) are finite is completely determined by the tail behavior. Note that $\alpha = \inf\{r > 0 : \mathbb{E}[X^r] = \infty\}$; hence all the moments of X which are of order strictly less than α are finite, while those of higher order ($\geq \alpha$) are infinite. For example, when $1 < \alpha < 2$, X has infinite variance, and infinite mean and variance when $0 < \alpha \leq 1$.

Like *heavy-tailed* distributions, *fat-tailed* distributions have long tails, with a considerable mass of probability concentrated in the tails. Nevertheless, the tails of *fat-tailed* distributions are lighter than *heavy-tailed* distributions. The log-log plot of $1 - F(x)$ (i.e., the survival function) of a heavy-tailed distribution shows approximately linear behavior with slope determined by α . This is in

contrast to a distribution that decays exponentially, where the tail of a log-log plot should show a faster-than-linear decrease. This property can be used as a visual check for the index of stability of a problem. An example of this is shown in Figure 11.1. The top panel of the figure shows the log-log plot of the survival function, $1 - F(x)$, of the runtime distribution of a quasigroup completion problem (QCP) instance.¹ The log-log plot remains essentially linear till over a hundred thousand backtracks, indicating heavy-tailed behavior. In contrast, the bottom panel of the figure shows a clear faster-than-linear decrease within a few hundred backtracks, indicating that the runtime distribution is not heavy-tailed.

Figure 11.1. Top: log-log plot with heavy-tailed behavior. Bottom: no heavy-tailed behavior.

DPLL style complete backtrack search methods have been shown to exhibit heavy-tailed behavior, both in random instances and real-world instances. Example domains are QCP [GSC97], scheduling [GSMT98], planning [GSK98], model checking, and graph coloring [JM04, Wal99]. If the runtime distribution of a backtrack search method is heavy-tailed, it will produce runs spanning over several

¹The specific details of the problem are not important. For completeness, we mention that this is an instance of order 11 with 30% pre-assigned entries.

orders of magnitude, some extremely long but also some extremely short. Methods like randomization and restarts try to exploit this phenomenon [GSK98]. Several formal models generating heavy-tailed behavior in search have been proposed [CGS01, GFSB04, JM04, WGS03a, WGS03b]. We discuss next one such model based on tree search.

11.1.1.1. Tree Search Model for Heavy Tails

Heavy-tailed behavior in backtrack-style search arises essentially from the fact that wrong branching decisions may lead the procedure to explore an exponentially large subtree of the search space that contains no solutions. Depending on the number of such “bad” branching choices, one can expect considerable variation in the time to find a solution from one run to another. Heavy-tailed behavior has been shown not to be inherent to backtrack search in general, but rather to depend on the structure of the underlying tree search and on the *pruning* power of the heuristics [CGS01].

In the following analysis, we contrast two different tree-search models: a balanced model that does not exhibit heavy-tailed behavior, and an *imbalanced* model that does. A key component of the imbalanced model is that it allows for highly irregular and imbalanced trees, which are radically different from run to run. For the imbalanced tree-search model, one can formally show that the runtime of a randomized backtrack search method is heavy tailed for a range of values of the model parameter p , which characterizes the effectiveness of the branching heuristics and pruning techniques. The heavy-tailedness leads to a runtime distribution with an infinite variance, and sometimes an infinite mean.

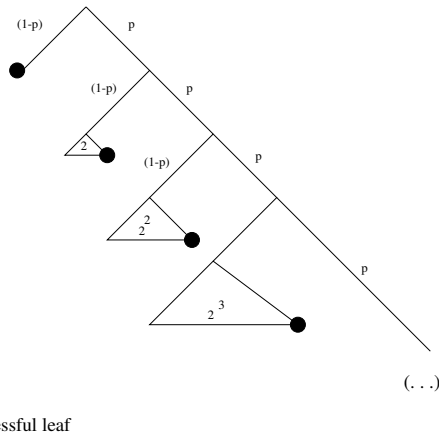

Figure 11.2. The imbalanced tree model with $b = 2$. This tree model has a finite mean and an infinite variance when $1/b^2 < p < 1/b$; both the mean and the variance are infinite when $p \geq 1/b$.

The imbalanced tree model is depicted in Figure 11.2. The model assumes that the probability that the branching heuristic will make a wrong decision is p , hence that, with probability $(1 - p)$ the search is guided directly to a solution.

With probability $p(1-p)$, a search space of size b , with $b \geq 2$, needs to be explored. In general, with probability $p^i(1-p)$, a search space of b^i nodes needs to be explored. Intuitively, p is the probability that the overall amount of backtracking increases geometrically by a factor of b . This increase in backtracking is modeled as a global phenomenon. The larger b and p are, the “heavier” the tail. Indeed, when b and p are sufficiently large, so that $bp \geq 1$, the expected value of T (where T is the number of leaf nodes visited, up to and including the successful leaf node) is infinite: $\mathbb{E}[T] = \infty$. If, however, $bp < 1$ (“better search control”), we obtain a finite mean of $\mathbb{E}[T] = (1-p)/(1-pb)$. Similarly, if $b^2p > 1$ the variance of T is infinite; otherwise, it is finite.

Bounded Heavy-Tailed Behavior for Finite Distributions. The imbalanced tree-search model does not put an *a priori* bound on the size of the search space. In practice, however, the runtime of a backtrack search procedure is bounded above by some exponential function of the size of the instance. We can adjust the model by considering heavy-tailed distributions with bounded support—“bounded heavy-tailed distributions”, for short [cf. HBCM98]. The analysis of the bounded case shows that the main properties of the runtime distribution observed for the unbounded, imbalanced search model have natural analogues when dealing with finite but exponential-sized search spaces. Heavy-tailed distributions have infinitely long tails with power-law decay, while bounded heavy-tailed distributions have exponentially long tails with power-law decay. Also, the concept of an infinite mean in the context of a heavy-tailed distribution translates into a mean that is exponential in the size of the input, when considering bounded heavy-tailed distributions.

Figure 11.3. Example distributions for the imbalanced and bounded imbalanced models, contrasted with the balanced model. Parameters: $b = 2$, $n = 20$, $p = 0.5$ and 0.75 (n is the number of variables).

Figure 11.3 illustrates and contrasts the distributions for various balanced and imbalanced models. We use the log-log plot of the tails of the various dis-

tributions to highlight the differences between them. The linear behavior over several orders of magnitude for the imbalanced models is characteristic of heavy-tailed behavior. The drop-off at the end of the tail of the distribution for the bounded case illustrates the effect of the boundedness of the search space. However, given the relatively small deviation from the unbounded model (except at the very end of the distribution), we see that the effect of bounding is relatively minor. In the plot we also contrast the behavior of the imbalanced model that of a balanced model (for details, see [CGS01]). The sharp drop-off for the balanced model indicates the absence of heavy-tailedness.

The heavy-tailedness of both of the imbalanced tree-search models occurs as a consequence of the competition between two critical factors: an exponentially increasing penalty in the size of the space to be searched as the number of “mistakes” caused by the branching heuristic increases, and an exponentially decreasing probability that a series of branching mistakes will be made.

11.1.2. Backdoors

Insight into heavy-tailed behavior comes from considering backdoor variables. These are variables which, when set, give us a polynomial subproblem. Intuitively, a small backdoor set explains how a backtrack search method can get “lucky” on certain runs, where backdoor variables are identified early on in the search and set the right way. Formally, the definition of a backdoor depends on a particular algorithm, referred to as *sub-solver*, that solves a tractable sub-case of the general constraint satisfaction problem [WGS03a].

Definition 11.1.1. A *sub-solver* A an algorithm that given as input a Boolean formula F^2 satisfies the following four conditions:

- i. Trichotomy: A either rejects the input F , or “determines” F correctly (as unsatisfiable or satisfiable, returning a solution if satisfiable),
- ii. Efficiency: A runs in polynomial time,
- iii. Trivial solvability: A can determine if F is trivially true (has no clauses) or trivially false (has an empty clause),
- iv. Self-reducibility: if A determines F , then for any variable x and value $v \in \{0, 1\}$, A determines $F[v/x]$.³

For instance, A could be a unit propagation mechanism, a pure literal elimination scheme, a solver for 2-CNF / Horn SAT, an algorithm that enforces arc consistency in CSPs, or, in general, any polynomial time algorithm satisfying the conditions above. Using the definition of sub-solver we can now formally define the concept of a backdoor set for SAT. Let A be a sub-solver and F be a Boolean formula.

²While the notions of sub-solvers and backdoors are applicable to any constraint satisfaction problem, we define them here in the context of SAT.

³We use $F[v/x]$ to denote the simplified formula obtained by fixing the value of variable x to v in F .

Definition 11.1.2. A nonempty subset S of the variables of F is a *weak backdoor* for F w.r.t. A if for some assignment $a_S : S \rightarrow \{0, 1\}$, A returns a satisfying assignment of $F[a_S]$. S is a *strong backdoor* for F w.r.t. A if for all $a_S : S \rightarrow \{0, 1\}$, A returns a satisfying assignment or concludes the unsatisfiability of $F[a_S]$.

Intuitively, the backdoor corresponds to a set of variables, such that when set correctly, the sub-solver can solve the remaining problem. While the notion of weak backdoors is useful for reasoning about satisfiable instances, the notion of strong backdoors considers both satisfiable and unsatisfiable formulas..

Szeider [Sze05] considered the parameterized complexity of the problem of determining whether a SAT instance has a weak or strong backdoor set of size k or less for DPLL style sub-solvers, i.e., subsolvers based on unit propagation and/or pure literal elimination. He showed that detection of weak and strong backdoor sets is unlikely to be fixed-parameter tractable. Nishimura et al. [NRS04] provided more positive results for detecting backdoor sets where the sub-solver solves Horn or 2-CNF formulas, both of which are linear time problems. They proved that the detection of such a strong backdoor set is fixed-parameter tractable, while the detection of a weak backdoor set is not. The explanation that they offered for such a discrepancy is quite interesting: for strong backdoor sets one only has to guarantee that the chosen set of variables gives a subproblem within the chosen syntactic class; for weak backdoor sets, one also has to guarantee satisfiability of the simplified formula, a property that cannot be described syntactically.

Dilkina et al. [DGS07] studied the tradeoff between the complexity of backdoor detection and the backdoor size. They proved that adding certain obvious inconsistency checks to the underlying class can make the complexity of backdoor detection jump from being within NP to being both NP-hard and coNP-hard. On the positive side, they showed that this change can dramatically reduce the size of the resulting backdoors. They also explored the differences between so-called deletion backdoors and strong backdoors, in particular with respect to the class of renamable Horn formulas.

Concerning the size of backdoors, random formulas do not appear to have small backdoor sets. For example, for random 3-SAT problems near the phase transition, the backdoor size appears to be a constant fraction (roughly 30%) of the total number of variables [Int03]. This may explain why the current DPLL based solvers have not made significant progress on hard randomly generated instances. Empirical results based on real-world instances suggest a more positive picture. Structured problem instances can have surprisingly small sets of backdoor variables, which may explain why current state-of-the-art solvers are able to solve very large real-world instances. For example the logistics-d planning problem instance (log.d) has a backdoor set of just 12 variables, compared to a total of nearly 7,000 variables in the formula, using the polynomial time propagation techniques of the SAT solver `Satz` [LA97]. Hoffmann et al. [HGS05] proved the existence of *strong* backdoor sets of size just $O(\log n)$ for certain families of logistics planning problems and blocks world problems.

Even though computing minimum backdoor sets is worst-case intractable [Sze05], if we bound the size of the backdoor, heuristics and techniques like randomization and restarts can often uncover a small backdoor in practice [KSTW05]. In fact, state-of-the-art SAT solvers are surprisingly effective in find-

Figure 11.4. Constraint graph of a real-world instance from the logistics planning domain. The instance in the plot has 843 vars and 7,301 clauses. One backdoor set for this instance w.r.t. unit propagation has size 16 (not necessarily the minimum backdoor set). Left: Constraint graph of the original instance. Center: Constraint graph after setting 5 variables and performing unit propagation. Right: Constraint graph after setting 14 variables and performing unit propagation.

ing small backdoors in many structured problem instances. Figure 11.4 shows a visualization of the constraint graph of a logistics planning problem and how this graph is drastically simplified after only a few variables occurring in a small backdoor (found by SAT solvers) are set. In related work, Slaney and Walsh [SW01] studied the structural notion of “backbones” and Dequen and Dubois introduced a heuristic for DPLL based solvers that exploits the notion of backbone and outperforms other heuristics on random 3-SAT problems [DD03, DD01].

11.2. Exploiting Runtime Variation: Randomization and Restarts

As it turns out, one of the most effective ways to address and exploit heavy-tailed behavior is to add “restarts” to a backtracking procedure. We describe this technique next, followed by a brief discussion of various ways to randomize a backtrack search algorithm.

11.2.1. Restarts: Randomized and Deterministic Strategies

A *restart*, as the name suggests, is the process of stopping the current computation of a SAT solver and restarting it from the beginning with a different random seed.⁴ For solvers employ caching techniques such as clause learning, the information learned in one run is kept and used even after a restart, thus not letting the computational effort spent so far go completely waste.

In the presence of heavy tailed behavior, a sequence of short runs instead of a single long run may be a more effective use of computational resources. Gomes et al. [GSK98] proposed randomized rapid restarts (RRR) to take advantage of

⁴As we will see later in Section 11.2.2, restarting can be effective even for a deterministic algorithm when other features such as learned clauses naturally guide the deterministic search process in a different direction after the restart.

heavy-tailed behavior and boost the efficiency of complete backtrack search procedures. In practice, one gradually increases the cutoff to maintain completeness [BMS00, GSK98]. It has been demonstrated that a restart strategy with a fixed cutoff eliminates heavy-tail behavior and has finite moments [GSCK00].

Figure 11.5. Restarts: Tail ($1 - F(x)$) as a function of the total number of backtracks for a QCP instance, log-log scale; the lower curve is for a cutoff value of 4 and the upper curve is without restarts.

As an example, Figure 11.5 shows the result of applying a strategy of fixed-length short runs—*rapid randomized restarts* of a complete randomized search procedure—to a QCP instance of order 20 with 5% pre-assignment. The figure displays a log-log plot of the tail of the distribution. From the figure, we see that without restarts and given a total of 50 backtracks, we have a failure rate of about 70%. Using restarts (once after every 4 backtracks), this failure rate drops to about 10%. With an overall limit of only 150 backtracks, the restart strategy nearly always solves the instance, whereas the original procedure still has a failure rate of about 70%. Such a dramatic improvement due to restarts is typical for heavy-tailed distributions; in particular, we get similar results on critically constrained instances. The fact that the curve for the experiment with restarts takes a definite downward turn is a clear indication that the heavy-tailed nature of the original cost distribution has disappeared.

Figure 11.6 shows the effect on the number of backtracks needed to solve a logistics planning problem as a function of the fixed cutoff value used. From the plot we see that the optimal cutoff value here is around 12. This is, in fact, quite typical of real-world problems, for which the optimal cutoff value is surprisingly small. Further, the logarithmic vertical scale indicates that one can shift the performance of the procedure by several orders of magnitude by tuning the cutoff parameter.

Prior to the discovery of heavy-tailed behavior and backdoor sets, randomized restart policies have been studied in the context of general randomized Las Vegas procedures. Luby et al. [LSZ93] showed that when the underlying runtime

Figure 11.6. Restarts: The effect of different cutoff values on solution cost for the `logistics.d` planning problem.

distribution of the randomized procedure is fully known, the optimal restart policy is a fixed cutoff. When there is no *a priori* knowledge about the distribution, they also provided a *universal strategy* which minimizes the expected cost. This consists of runs whose lengths are powers of two, and each time a pair of runs of a given length has been completed, a run of twice that length is immediately executed. The universal strategy is of the form: 1, 1, 2, 1, 1, 2, 4, 1, 1, 2, 4, 8, . . . Although the universal strategy of Luby et al. is provably within a log factor of the optimal fixed cutoff, the schedule often converges too slowly in practice. Walsh [Wal99] introduced a restart strategy, inspired by Luby et al.'s analysis, in which the cutoff value increases geometrically. The advantage of such a strategy is that it is less sensitive to the details of the underlying distribution. Following the findings of Gomes et al. [GSK98] and starting with `zChaff`, state-of-the-art SAT solvers now routinely use restarts. In practice, the solvers use a default cutoff value, which is increased, linearly, every given number of restarts, guaranteeing the completeness of the solver in the limit [MMZ⁺01]. Another important feature is that they retain learned clauses across restarts.

In reality, we will be somewhere between full and no knowledge of the runtime distribution. Horvitz et al. [HRG⁺01] introduced a Bayesian framework for learning predictive models of randomized backtrack solvers based on this situation. Extending that work, Kautz et al. [KHR⁺02] considered restart policies that can factor in information based on real-time observations about a solver's behavior. In particular, they introduced an *optimal* policy for dynamic restarts that considers observations about solver behavior. They also considered the dependency between runs. They gave a dynamic programming approach to generate the optimal restart strategy, and combined the resulting policy with real-time observations to boost performance of backtrack search methods.

Variants of restart strategies include randomized backtracking [LBMS01] and the random jump strategy [Zha02] which has been used to solve a dozen previously open problems in finite algebra. Finally, one can also take advantage of the high variance of combinatorial search methods by combining several algorithms

into a “portfolio,” and running them in parallel or interleaving them on a single processor [GS01, NDS⁺04].

As a closing note, we mention that the notion of backdoor sets discussed earlier came about in the context of the study of heavy-tailed behavior as observed in backtrack-style search. Heavy-tailed distributions provide a justification of why restarts are effective, namely to prevent the search procedure from getting stuck in unproductive portions of the search space that do not contain solutions. Such distributions also imply the existence of a wide range of solution times, often including short runs. This is where backdoors enter the picture: Intuitively, a small backdoor explains how a backtrack search can get “lucky” on certain runs, since the backdoor variables are identified early on in the search and set in the right way.

Williams et al. show that even though finding a small set of backdoor variables is computationally hard, the very existence of a small backdoor in a problem provides a concrete computational advantage to its solution [WGS03a, WGS03b]. They consider three scenarios. First, a deterministic scenario is considered with an exhaustive search of backdoor sets. In this scenario, one obtains provably better search complexity when the backdoor contains up to a certain fraction of all variables. They then show that a randomized search technique, which in effect repeatedly guesses backdoor sets, provably outperforms a deterministic search. Finally, in the third scenario the availability of a variable selection heuristic is considered, which provides guidance in looking for a backdoor set. This strategy can reduce the search space even further. By exploiting restart strategies, for example, one can obtain a polynomially solvable case when the backdoor contains at most $\log(n)$ variables, where n is the total number of variables in the problem instance. This final scenario is quite likely the closest to the behavior of the effective randomized backtrack SAT solvers that are currently available.

11.2.2. Other Randomization Opportunities in Backtrack Search

There are also several other opportunities to introduce randomization into a backtrack search method, at the different points where the next operation to be performed by the backtrack solver is to be selected. In particular, randomization can be incorporated into the variable selection heuristic, the value selection heuristic, look-ahead procedures such as propagation and failed literal tests, and look-back procedures such as the choice of conflict clause to learn. Even a simple modification to a deterministic SAT solver, such as adding randomized tie-breaking in variable and value selection heuristics, can dramatically change its behavior [GSC97, GSCK00].

In general, backtrack search procedures use *deterministic* heuristics to select the next operation. Highly tuned heuristics are used for variable and value selection. If several choices are heuristically determined to be equally good, then a deterministic algorithm applies some fixed rule to pick one of the operations, for example, using lexicographical order. Therefore, the most straightforward way to apply randomization is in this tie-breaking step: if several choices are ranked equally, choose among them at random [GSC97, GSCK00]. Even this simple modification can dramatically change the behavior of a search algorithm,

as we will see below. If the heuristic function is particularly powerful, however, it may rarely assign the highest score to more than one choice. To handle this, we can introduce a “heuristic-equivalence” parameter to the algorithm. Setting the parameter to a value H greater than zero means all choices that receive scores within H percent of the highest score are considered equally good. This expands the choice set for random tie-breaking [GSK98].

A more general procedure, which includes the tie-breaking and the H -percent equivalence-window procedures as special cases, imposes a probability distribution on the set of possible values for a given operation. For example, in the tie-breaking case, we are implicitly assigning a uniform probability to the values that are considered by the heuristic to be equally good, while in the case of using the H -percent window, we assign a uniform probability to all choices whose scores lie within H percent of the highest score. An alternative would be to impose a different distribution on the values within the H -percent window (for example, an exponential distribution), biasing the selection toward the highest score.

Random reordering is another way of “randomizing” an algorithm. This technique involves randomly reordering the input data, followed by the application of a deterministic algorithm [MR95]. Walsh [Wal99] applied this technique to study the runtime distributions of graph-coloring problems, using a deterministic, exact coloring algorithm based on DSATUR [Tri96].

A key issue when introducing randomization into a backtrack search algorithm is that of guaranteeing completeness. We note that the introduction of randomness into the branching-variable/value selection does not affect the completeness of the backtrack search. Some basic bookkeeping ensures that the procedures do not revisit any previously explored part of the search space, which means that, unlike the use of local search methods, we can still determine inconsistencies. The bookkeeping mechanism involves keeping track of some additional information for each variable in the stack, namely which assignments have been tried thus far. This can be done relatively inexpensively.

Randomization of the look-ahead and look-back procedures can also be done in a relatively straightforward manner, for example, by randomizing the decision of whether to apply such procedures after each variable/value assignment. This technique can be useful, especially when look-ahead techniques are expensive. On the other hand, randomization of the backtrack points requires the use of data structures that are more complicated in general, so there may be a substantial increase in the time/space requirements of the algorithm. Lynce *et al.* [LBMS01, LMS02] discuss learning strategies and randomization of the backtrack points (specifically, random backtracking and unrestricted backtracking), as well as how to maintain completeness).

We should note that when implementing a randomized algorithm, one uses a pseudo random-number generator, which is in fact a deterministic algorithm for generating “random” numbers. By choosing different initial random seeds, we obtain different runs of the algorithm. For experimental purposes, it is important to save the “seed” given to the random-number generator, so that the same experiment can be replayed. Also, when using restarts, it is important to pass on the seed from one run to another (rather than generating a new seed for each restart) in order to use the full strength of the pseudo random-number generator.

One can also speak of “deterministic randomization” [Wol02], which expresses the fact that the behavior of some very complex deterministic systems is so unpredictable that it actually appears to be random. This notion of deterministic randomization is implicitly used, for example, in calculating “random” backtrack points by applying a deterministic formula to the clauses learned during search [LBMS01, LMS02]. Another example is the restarting of (deterministic) backtrack search solvers that feature clause learning: each time the solver is restarted, it behaves quite differently from the previous run (because of the additional learned clauses), and thus appears to behave “randomly” [MMZ⁺01, LMS02].

11.3. Conclusion

The heavy-tailed nature of the runtime distribution of SAT solvers, and of constraint solvers in general, on many problem instances of interest has been an insightful discovery with a practical impact. The theory behind such distributions, as well as concepts such as backdoor sets, help us understand the brittle nature of combinatorial search algorithms, where even the most efficient implementations seem to “hang” forever with certain heuristic settings and solve the same instance quickly with other settings or with simple random renaming of the instance variables. This has led to an interest in randomizing SAT solvers and in introducing very frequent restart schedules, both of which have generally been quite successful. Aggressive restart strategies are now an integral part of nearly all DPLL-style SAT solvers and some of the latest solvers, such as `Rsat` [PD06], are beginning to explore interesting new ways of retaining information across restarts.

Chapter 12

Automated Configuration and Selection of SAT Solvers

Holger H. Hoos, Frank Hutter, and Kevin Leyton-Brown

12.1. Introduction

Although SAT is widely believed to be hard in the worst case, many interesting types of SAT instances can be solved efficiently in practice, using heuristic algorithms. A wide variety of different heuristic mechanisms have been identified by the research community over the decades, partly by unambiguously improving on past ideas, but largely by finding different heuristics that work well on different types of SAT instances. Because of this sensitivity to instance characteristics, there is no single best SAT solver, and state-of-the-art solvers typically expose some design choices as parameters that can be set at runtime, thereby enabling users to optimize performance to a given class of SAT instances. This chapter focuses on automated approaches for performing such optimization, which is termed *algorithm configuration*. We also discuss the related problem of *algorithm selection*: i.e., methods for choosing one algorithm from a finite, typically modestly sized *portfolio* on a per-instance basis, with the goal of achieving better performance across instances than can be obtained from any single solver in the portfolio.

Automated algorithm configuration and per-instance algorithm selection are both examples of *meta-algorithmic design techniques*, i.e., generic methods for building algorithms for a given problem from a set or space of candidate algorithms (which can be small, as in the case of algorithm selection, or large, as in the case of algorithm configuration). Automated algorithm configuration and per-instance algorithm selection are of particular interest in the context of SAT, because of their major impact on solving SAT and related problems, such as MaxSAT, ASP, CSP and QBF. Conversely, SAT has played a major role in the development of algorithm configuration and selection techniques.

While the major part of this chapter is focused on automated algorithm configuration and per-instance algorithm selection, we also survey some conceptually more complex approaches that go beyond “pure” configuration and selection: combining configuration and selection together; building algorithm schedules rather than simply picking a single algorithm; extending methods to leverage

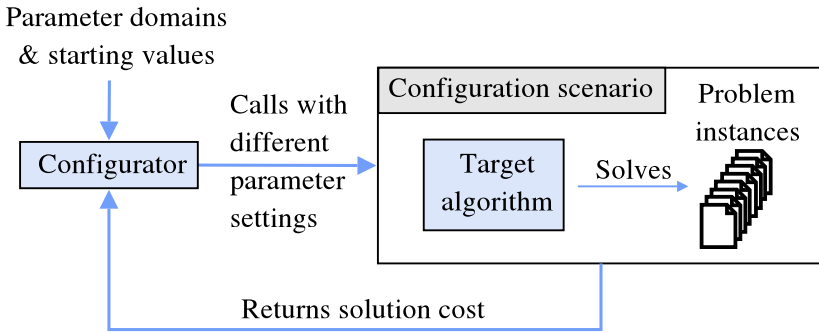

Figure 12.1. A configuration scenario includes an algorithm to be configured and a collection of problem instances. A configuration procedure executes the target algorithm with specified parameter settings on some or all of the instances, receives information about the performance of these runs, and uses this information to decide which subsequent parameter configurations to evaluate.

parallel computation; analyzing the importance of parameters; dynamically controlling parameters; and using configuration techniques for finding bugs in SAT solvers. Finally, we outline some open challenges related to the methods discussed in this chapter, the tools based on them, and their application.

12.2. Algorithm configuration

Algorithm configuration is the problem of automatically identifying parameter settings that optimize the performance of a given algorithm on a specific set or distribution of problem instances, as illustrated in Figure 12.1. Observe that an algorithm configuration procedure is a *meta-algorithm* in the sense that it takes another, arbitrary algorithm as part of its input.

More formally, the algorithm configuration problem can be stated as follows: given an algorithm A with possible parameter settings $\Theta = \Theta_1 \times \dots \times \Theta_n$, a distribution \mathcal{D} over possible inputs with domain Π that A can be run on, and a cost metric $c : \Theta \times \Pi \rightarrow \mathbb{R}$, find the configuration $\theta = \langle \theta_1, \dots, \theta_n \rangle \in \Theta$ that minimizes c in expectation over \mathcal{D} . A common special case arises where \mathcal{D} is a uniform distribution over $\Pi = \{\pi_1, \dots, \pi_k\}$, in which case we can write the problem as finding the minimizer of the blackbox function $f(\theta) := \frac{1}{k} \sum_{i=1}^k c(\theta, \pi_i)$. When applying algorithm configuration to SAT solvers, the π_i are SAT instances deemed representative for the kind of instances for which we aim to optimize performance. We call f a blackbox function, because it depends on the cost $c(\theta, \pi_i)$, which cannot be reasoned about analytically, but can only be evaluated by actually running A with configuration θ on π_i .

Although the problem of “tuning” algorithm parameters might seem narrow, we note that many aspects of algorithm design can be expressed parametrically, from high-level design decisions to low-level aspects of specific heuristic mecha-

nisms. For example, parameters can be real-valued, integer-valued, or categorical. Parameters can also be conditional on an instantiation of other parameters—consider, e.g., the parameters of a heuristic mechanism h , which are completely ignored unless h is enabled via another, categorical parameter. Finally, combinations of otherwise valid parameter instantiations can be forbidden.

Indeed, the flexibility offered by expressing heuristic ideas parametrically and the effectiveness of algorithm configuration procedures can empower algorithm developers to adopt a new design philosophy that is both easier and produces better results. Instead of seeking to minimize the number of exposed parameters, a developer can instead aim to encode all plausible design ideas parametrically, leaving their eventual evaluation to the algorithm configuration procedure (see, e.g., [HBHH07, KXHLB09, KXHLB16]). This philosophy has been formalized in a design paradigm called Programming by Optimization (PbO), which facilitates the exploration and automatic optimization of design choices as an integral part of the software development process [Hoo12].

Over the past decade, evidence has accumulated that algorithm configuration is an effective way to design high-performance algorithms across a wide range of applications. This is because human experts are not only ill-suited for solving these noisy high-dimensional optimization problems manually, but often also unmotivated to carry out this tedious task (not to mention that experts rarely have time and are also expensive in practice). Our focus in this chapter is on SAT; nevertheless, it is important to point out that automated algorithm configuration has been demonstrated to produce dramatic improvements in a wide range of other combinatorial optimization problems beyond SAT, such as MIP [HHLB10], AI planning [VFG⁺13], TSP [CFH08], and answer set programming [SLS12]; these improvements routinely exceed those achieved manually by human experts. Likewise, very similar automated approaches have yielded better performance than humans for optimizing hyperparameters of deep convolutional neural networks [BBBK11, SLA12] and their architectures [DSH15], as well as generic image recognition pipelines [BYC14]; they have even led to effective push-button approaches for machine learning, by jointly selecting feature selection methods, algorithms and hyperparameter settings in prominent machine learning packages [THHLB13, FKE⁺15].

Automated algorithm configuration approaches also have benefits beyond optimizing algorithm performance. They can additionally be used to speed up the process of developing effective software (freeing developers from the burden of tedious experimentation); to apply highly parameterized algorithms to a new problem domain; and to improve protocols for empirical research in computer science (enabling fair comparisons of software based on the same fully formalized parameter optimization approach).

In the remainder of this section, we briefly survey some widely used algorithm configuration procedures—particularly those that have been widely applied to SAT. Throughout, we emphasize key conceptual ideas and methods.

12.2.1. ParamILS

The ParamILS framework [HHS07, HHLBS09] was the first to give rise to practical, general-purpose algorithm configuration procedures; it still yields excel-

lent performance on many problems today. This approach uses iterated local search [LMS02] as its underlying search strategy. It begins with a default parameter configuration, evaluates performance against a list of random configurations, and then performs local search in configuration space, starting from the best configuration so far. The local search process changes the setting of one parameter at a time and keeps those changes resulting in empirical performance improvements. After finding a local minimum, ParamILS randomly changes some parameters in order to escape; with a small probability, it also performs a complete restart to a random point in the configuration space. Throughout, ParamILS keeps track of the best configuration seen so far, the so-called *incumbent*.

ParamILS has two variants that differ in the approach they take to deciding how many runs to use for estimating the performance of each configuration. The *BasicILS* variant is most straightforward: it evaluates each configuration according to a fixed number of runs on a fixed set of instances. However, this variant has the drawback that it can spend far too long evaluating configurations that exhibit poor overall performance. The more practical *FocusedILS* variant starts by performing only a single run per configuration; if a new configuration does not outperform the incumbent on the same instance, it is rejected. If it beats the incumbent, FocusedILS doubles the number of instances to consider and tries again, until eventually it evaluates the new configuration on the same set of instances as the incumbent has been evaluated on. The number of runs allocated to incumbents also grows slowly over time. Overall, FocusedILS thus devotes most of its time to promising configurations, while also maintaining statistically robust performance estimates for incumbent configurations.

Both ParamILS variants can be sped up via an *adaptive capping* strategy for choosing the time after which to terminate unsuccessful target algorithm runs. Intuitively, when comparing the performance of two configurations θ_1 and θ_2 on an instance, and we already know that θ_1 solves the instance in time t_1 , we do not need to run θ_2 for longer than t_1 : we do not need to know precisely how bad θ_2 is, as long as we know that θ_1 is better. While this strategy exactly preserves the search trajectory of ParamILS and leads to substantial speedups, it does not perform effectively after a perturbation step. A more aggressive adaptive capping variant terminates all evaluations prematurely if they require more time than the corresponding evaluations of the *incumbent* configuration times a small bound multiplier.

ParamILS has led to very substantial improvements of SAT solvers for various applications. For example, it reduced the penalized average running time (with penalty factor 10, i.e., PAR-10)¹ of the SAT solver Spear [BH07] on a set of formal software verification instances by a factor of 500 [HBHH07]; this allowed Spear to win the QF_BV category of the SMT competition 2007. More recently, ParamILS was used to configure sat13, a high-performance SAT solver by Donald Knuth, achieving a 1.4-fold improvement in geometric average speedup over a default defined by the algorithm designer, even when tested on a diverse set of benchmark instances up to over three orders of magnitude harder than those in the given training set [Knu15]. This demonstrates that general-purpose automatic algorithm configuration can achieve very significant performance improvements

¹PAR-10 counts timeouts at a maximal captime $\bar{\kappa}$ as having taken time $10 \cdot \bar{\kappa}$ [HHLBS09].

over manual optimization carried out by the very best algorithm designers.

12.2.2. GGA and GGA++

The Gender-based Genetic Algorithm (GGA) [AST09] is a genetic algorithm for algorithm configuration that evolves a population of parameter configurations (having pairs of configurations mate and produce offspring) and uses the concept of gender to balance the diversity and fitness of the population. GGA's intensification mechanism for increasing the number of runs N it performs for each configuration over time keeps N constant in each generation, starting with small N_{start} in the first generation and linearly increasing N up to a larger N_{target} in a user-defined target generation and thereafter. GGA implements an adaptive capping mechanism by evaluating several candidate configurations in parallel until the first ones succeed and then terminating the remaining evaluations.

In experiments by Ans'otegui et al. [AST09], GGA performed more robustly than ParamILS on three configuration scenarios with 4 to 7 parameters. In a later comparison by Hutter et al. [HHLB11], ParamILS and GGA performed comparably across 15 configuration scenarios with 4 to 26 parameters, and ParamILS performed substantially better for the 76-dimensional configuration problem of optimizing the mixed integer programming solver CPLEX. GGA was also successfully used to configure solvers for various variants of MaxSAT, allowing the automated construction of portfolios that won several categories in the 2013 and 2014 MaxSAT evaluations [AMS14].

Inspired by the model-based approach underlying SMAC (see Section 12.2.3 below), Ans'otegui et al. [AMST15] introduced GGA⁺⁺, a version of GGA that relies on random forest models for performance prediction. More precisely, GGA⁺⁺ enhances the evolutionary approach underlying GGA by using a novel random forest variant in combination with a targeted sampling procedure to optimize configurations obtained by recombination. Ans'otegui et al. [ansotegui-ijcai15] reported promising results compared to GGA and SMAC on two algorithm configuration scenarios based on prominent SAT solvers; unfortunately, however, this comparison was confounded by two significant bugs in the algorithm wrapper (see Footnote 9 of Eggenberger et al. [ELH19] for details).

12.2.3. SMAC

Sequential, Model-based Algorithm Configuration (SMAC) [HHLB11] is an algorithm configuration method that uses a *empirical performance model* [LBNS09, HXHLB14] (that maps parameter values to algorithm performance and is learned from data) to identify algorithm configurations worth evaluating. In essence, SMAC can be understood as using this model to replace the local search component of ParamILS. SMAC begins by carrying out some initial algorithm runs on both the algorithm default and, optionally, a small set of random configurations. It calls the best performing of these the *incumbent* and then iterates the following steps until a given time budget is exhausted:

1. fit a probabilistic regression model to the performance data gathered so far;

2. use the model to determine a list of promising configurations², interleaving configurations sampled uniformly at random;
3. compare configurations from the promising list to the current incumbent, saving the resulting performance data, and updating the incumbent if appropriate.³

As with ParamILS, the mechanism used for comparing configurations is critical; SMAC uses an approach very similar to that of FocusedILS, performing adaptive capping and dedicating more running time to better-performing configurations. Another key element of SMAC involves the means by which the model is used to identify promising configurations; it uses a so-called *acquisition function* to trade off exploration (choosing configurations in parts of the space where the model has low confidence) with exploitation (choosing configurations in parts of the space where the model predicts fast running times). This acquisition function is computed based on model predictions and then optimised across the configuration space to identify the most promising next configuration.

SMAC can be used with different types of empirical performance models and different acquisition functions. Work using it to configure solvers for SAT and similar combinatorial problems most commonly uses random forests [Bre01] as its underlying performance model and adopts the expected improvement acquisition function [JSW98], optimised via iterated local search. Random forests are particularly suitable for modelling the running time of solvers for hard combinatorial problems, as they can easily handle mixed continuous/categorical inputs, have a low computational complexity for constructing the model and making predictions, act as automated feature selectors to detect the few most important inputs, and can deal with large heteroscedastic noise. However, since they do not usually make probabilistic predictions, they had to be extended by using randomly-chosen split points and uncertainties computed based on the discrepancy of the predictions across the different trees [HXHLB14].

Hutter et al. [HHLB11] used 17 different configuration scenarios to compare the performance of SMAC to that of GGA and ParamILS. In this evaluation, SMAC performed statistically significantly better than ParamILS in 11 of 17 cases (achieving speedup factors ranging from $0.93\times$ to $2.25\times$) and statistically significantly better than GGA in 13 of 17 scenarios (achieving speedup factors ranging from $1.01\times$ to $2.76\times$).

SMAC has also been used in numerous practical applications. Notably, it was used by the US Federal Communication Commission to build a solver for determining the feasibility of radio spectrum repackings in its 2016–17 Incentive Auction; this solver made use of SAT encodings and various prominent SAT algorithms. The stakes of this auction were extremely high: 84 MHz of radio spectrum were purchased across the whole US and Canada at a cost of over \$10 billion. As reported by Newman et al. [NFLB17], configuration with SMAC yielded large performance gains in this domain. Gnovelty+PCL [DP13] was the best single

²It is not necessary to identify more than one configuration in this step, but doing so can amortize the cost of fitting the model in Step 1.

³In order to ensure that the time for the construction and use of models does not outweigh the time for actually running algorithms, SMAC iteratively evaluates configurations from the promising list until the time for step 3 is larger than that required for steps 1 and 2 combined.

solver, able to solve 79.96% of representative problem instances within a minute; the parallel portfolio (see Section 12.4.3) of the best 20 algorithms could only solve 81.58% within the same amount of wall-clock time. After configuration, an eight-algorithm parallel portfolio based on SATenstein [KXHLB16] and clasp [GKNS07] identified using Hydra [XHLB10, see Section 12.4.1] was able to solve 96.03% of these problems in a minute (and 87.73% in only a second). Subsequent analysis showed that this improvement in solver performance is likely to have led directly to better economic outcomes, on the order of over \$700 million in cost savings and over \$300 million in additional economic value created by a more efficient auction outcome [NLBMS17].

12.2.4. The Configurable SAT Solver Challenges

The SAT community has a long history of regularly assessing the state of the art via competitions [JBR12]. The first SAT competition dates back to the year 2002 [SBH05], and the event has been growing over time: in 2018, as many as 106 solver versions participated across four tracks [HJS18].

A drawback of traditional solver competitions is that they fail to reward solver developers for identifying versatile, powerful designs that incorporate a large number of interchangeable heuristics; instead, they reward developers primarily for configuring their solvers in a way that ultimately targets the distribution used for evaluation. The *Configurable SAT Solver Challenge (CSSC)*, held alongside the SAT competition in 2013 and in 2014 as part of the 2014 FLoC Olympic Games, addressed this issue [HLB⁺17]. It evaluated SAT solver performance *after* application-specific customization, taking into account the fact that effective algorithm configuration procedures can automatically customize solvers for a given distribution of benchmark instances. Specifically, for each distribution \mathcal{D} of instances and each SAT solver S with configuration space Θ_S , an automated fixed-time offline configuration phase determined parameter settings of $\theta_S \in \Theta_S$ optimized for high performance on \mathcal{D} . Then, the performance of S on new instances from \mathcal{D} (not seen during the configuration process) was evaluated with these settings θ_S , and the solver with the best performance was declared the winner. To avoid bias arising from the choice of algorithm configuration method, the CSSC independently used all three of the most widely used algorithm configuration methods: ParamILS, GGA, and SMAC.

Overall, the two CSSC events held to date have yielded four main insights. First, algorithm configuration often improved performance substantially, in some cases yielding orders-of-magnitude speedups (e.g., in the 2014 CSSC, the PAR-10 score of clasp [GKNS07] improved from 705 to 5 on N -Rooks instances [MS14], and the PAR-10 score of ProbSAT [BS12] on 5-SAT instances improved from 3000 to 2, i.e., from solving no instance at all in 300 seconds to solving all instances in an average of 2 seconds). Second, some solvers benefited more from configuration than others, meaning that algorithm rankings were substantially different after configuration than before. For example, in the Random SAT+UNSAT track of CSSC 2013, the solvers ranking first (clasp [GKNS07]), second (Lingeling [Bie13]) and third (Riss3g [Man13]) would have ranked 6th, 4th and 5th, respectively, based on performance with default parameter settings. Third, the configuration

budget used also affected the ranking; in particular, algorithms with larger configuration spaces needed longer configuration budgets (on the order of days) to achieve peak performance. Fourth, out of the three configurators used in the CSSC 2014, SMAC yielded the best performance in 51 configuration scenarios, ParamILS in 17, and GGA in 4. If only SMAC had been used for the configuration process, the largest slowdown of any solver on test instances would have been by a factor of 1.5; the same slowdown factor would have been 1.8 if ParamILS had been used exclusively, and 30.5 if GGA had been used exclusively.

12.2.5. Other Approaches

Finally, we survey some recent algorithm configuration approaches whose focus is not on the strategy for selecting the next configuration to evaluate but on the resources used for each evaluation.

12.2.5.1. iRace

The iterative racing procedure *irace* [LIDLSB11] uses an intensification mechanism based on racing a set of candidate configurations against each other, i.e., performing runs for each of them on one instance at a time and dropping candidates whose performance is statistically dominated. Based on the evaluations thus gathered, it constructs one-dimensional density estimates of which values perform well for each parameter; its search strategy is then an estimation of distribution approach that samples individual parameter values from these one-dimensional distributions. To increasingly focus the sampling process towards the most promising configurations, *irace* gradually decreases the standard deviations of these distributions (this process is dubbed *volume reduction*). Recently, Pérez Cáceres et al. [PCLHS17] have integrated a capping mechanism inspired by that used in ParamILS into *irace* and reported promising initial results on various configuration scenarios.

12.2.5.2. Structured Procrastination

The *Structured Procrastination (SP)* algorithm [KLBL17] is notable for offering the first nontrivial performance guarantees for general algorithm configuration with an average running time minimization objective. This work considered a worst-case setting in which an adversary causes every deterministic choice to play out as poorly as possible, but where observations of random variables are unbiased samples. In this setting, it is straightforward to argue that any fixed, deterministic heuristic for searching the space of configurations can be extremely unhelpful. The approach underlying SP therefore focuses on obtaining candidate configurations via random sampling.

Any method based on random sampling will eventually encounter the optimal configuration; the crucial question is the amount of time that this will take and whether the algorithm is guaranteed to eventually recognize the optimal configuration as such when it has been sampled often enough. Out of the methods surveyed so far, in discrete configuration spaces, ParamILS and SMAC provably converge to the optimal configuration, while GGA and GGA++ do not have this

property.⁴ The key result of Kleinberg et al. [KLBL17] is that SP is guaranteed to find a near-optimal configuration with high probability, with worst-case running time that nearly matches a lower bound on what is possible and that asymptotically dominates that of existing alternatives, such as SMAC.

Unfortunately, SP is not useful in practice; it takes an extremely long time to run, even on configuration scenarios that are easy for existing methods, and hence has not been implemented or evaluated empirically. The problem is that SP treats every instance like the worst case, in which it is necessary to achieve a fine-grained understanding of every configuration’s running time in order to distinguish between them. Extending SP to make it practical remains an active topic of research. Notably, a new variant called *Structured Procrastination with Confidence* [KLBLG19] maintains SP’s theoretical guarantees while improving performance outside the worst case. While it is more promising than SP, this very recent algorithm has only been evaluated empirically on a single dataset to compare it to the two algorithms discussed next. (In this comparison, it achieved better performance, but a much more extensive study would be required to draw reliable conclusions.)

12.2.5.3. LeapsAndBounds, CapsAndRuns

A configuration procedure called LeapsAndBounds [WGS18b] is based on SP but improves upon it in various ways. In theoretical terms, LeapsAndBounds offers an improvement by more closely matching the lower bound in SP’s analysis and refining that analysis to remove dependence on one of the parameters used. More importantly for our discussion here, LeapsAndBounds also improves performance outside the worst case. A second refinement of SP called CapsAndRuns [WGS18a] goes even further in this direction. Limited initial experiments (running Minisat [ES04] on SAT instances generated using CNFuzzDD (<http://fmv.jku.at/cnfuzzdd>) show considerable promise over the original version of SP. However, LeapsAndBounds has not been evaluated beyond this single setting, and has not been compared to ParamILS, SMAC, GGA/GGA++ or irace.

12.3. Per-instance algorithm selection

Per-instance algorithm selection entails automatically choosing from a “portfolio” of different algorithms for a given problem (such as SAT) every time a new problem instance is presented [Ric76]. This choice is made based on features of the given instance π , as illustrated in Figure 12.2. Like an algorithm configurator, a per-instance algorithm selector is a meta-algorithm that takes a set of algorithms as part of its input.

More formally, the *per-instance algorithm selection problem* is defined as follows. We start with a set \mathcal{P} of algorithms, which we call a *portfolio*, a distribution \mathcal{D} over possible inputs with domain Π , and a cost metric $c : \mathcal{P} \times \Pi \rightarrow \mathbb{R}$. We will

⁴GGA and GGA++ use a finite maximum number N_{end} to evaluate each configuration, but indefinite growth of this number is required for reliably selecting the optimal configuration in the presence of noise.

Figure 12.2. The computational core of algorithm selection at test time: for each new instance π , features $\mathcal{F}(\pi)$ are computed, and based on these, function f selects an algorithm a from the set of candidate algorithms \mathcal{P} to run on π .

summarize problem instances as vectors of ϕ real-valued *features*; we represent this reduction as $\mathcal{F} : \mathcal{D} \rightarrow \mathbb{R}^\phi$. Our goal is to construct a function $f : \mathbb{R}^\phi \rightarrow \mathcal{P}$ that maps any given input (here: a SAT instance) to an algorithm from the portfolio; this function is called a *per-instance algorithm selector*. Typically, the aim is to minimize c in expectation over \mathcal{D} , but more complex goals are possible, such as aiming for diversity across subcategories of problem instances; indeed, such evaluation functions have been used in past SAT competitions.

Per-instance algorithm selection has two distinct phases: an offline training phase, in which a selector is constructed, and an online use phase, where that selector is used to determine the algorithm to be run on new problem instances π . As we will see in the following, selector construction is often approached as a supervised machine learning task, using (cost-based) classification or regression techniques, although there also exist approaches based on feature-based clustering of instances.

In the following, we consider per-instance algorithm selection approaches along with two extensions, which turn out to be important for achieving state-of-the-art performance in SAT and other problems: pre-solving schedules and backup solvers. The former are sequences of algorithms run prior to the algorithm selection process, mostly in order to avoid potentially costly feature extraction on instances that are solved easily; the latter are used as a fall-back when feature computation fails. We describe in the greatest detail approaches that have had broad impact in the SAT community and that have been demonstrated to achieve both strong and robust performance.

12.3.1. SATzilla

The first version of SATzilla was built for the 2003 SAT Competition and was indeed the first algorithm selection system to be entered into such a competition [NLBA⁺03, NLBH⁺04]. It used independent ridge regression models to predict the performance of component SAT solvers based on a rich set of up to 84 instance features, and selected the solver with the best predicted running time. These models were trained in an offline phase on a broad and diverse set of training instances. In the 2004 submission, a local-search-based pre-solver was added to quickly solve easily satisfiable instances without incurring the cost of computing features. Overall, SATzilla won two silver and one bronze medal across the nine tracks of the 2003 SAT Competition and two bronze medals in the 2004

SAT Competition, providing an early indication for the potential of per-instance algorithm selection for SAT.

For the 2007 SAT Competition, this basic design was elaborated in various ways [XHHLB07]. Two key updates were made to the empirical performance models. First, SATzilla 2007 was based on so-called hierarchical hardness models, using a sparse multinomial logistic regression (SMLR) classifier to predict the probability of instance satisfiability and then using this result to weight the predictions of two quadratic regression models, trained only on satisfiable and unsatisfiable instances respectively [XHLB07]. Second, a method from survival analysis [SH79] was used to address bias stemming from the fact that true algorithm running times are not fully observed when long runs are capped. Several other innovations tuned performance by optimizing on a separate validation set of instances. A pre-solver selection mechanism allowed up to two solvers to be run sequentially before feature computation; an automatic solver subset selection mechanism was used to drop solvers whose inclusion worsened overall performance; and a backup solver was identified for use when feature computation failed. Finally, the set of features was somewhat reduced (to 48) to exclude those whose time complexity exceeded their marginal value. This version of SATzilla was very successful in the 2007 SAT Competition, winning three gold, one silver, and one bronze medal. Following the 2007 competition, SATzilla was improved further by making the selector construction more scalable and completely automated, by integrating candidate solvers based on local search, by predicting competition score instead of running time, and by using hierarchical hardness models that take into account different types of SAT instances [XHHLB08]. The resulting version won three gold and two silver medals in the 2009 competition [XHHLB09].

In 2011, a substantially improved version of SATzilla was introduced, which showed outstanding performance in the evaluation track of the 2011 SAT Competition and in the 2012 SAT Challenge [XHHLB12]. This version of SATzilla differed from the previous design by using cost-sensitive decision forests to predict for every pair of component solvers the one that would perform better on a given SAT instance, then employing majority voting over these predictions to select the solver to run. Specifically, the pairwise classification mechanism at the heart of this approach penalized misclassifications in direct proportion to their impact on overall selector performance, without predicting running time or competition score. As in earlier versions of SATzilla, pre- and backup-solvers were used in addition to the main per-instance algorithm selection mechanism. However, the decision about whether to initiate feature computation (rather than immediately running the statically determined backup solver) was made by a random forest classifier, using a subset of cheaply computable features. In the 2012 SAT Competition, this version of SATzilla used a total of 31 SAT solvers and 138 instance features; it ended up winning first prizes in two of the three main tracks and second prize in the remaining track, while also placing first in the sequential portfolio track. In the application track of this competition, it solved 6.4% more instances than the single best “interacting multi-engine” solver (which combined multiple SAT solving engines in a design that allows for richer interaction than found in a per-instance algorithm selector like SATzilla), 11.8% more instances than the

best conventional, “single-engine” solver, and only 6.5% fewer instances than the virtual best solver (a hypothetical, perfect selector).

12.3.2. ISAC, 3S and CSHC

ISAC (Instance-Specific Algorithm Configuration) uses a clustering approach to perform algorithm selection [KMST10]. Specifically, ISAC clusters the instances in the given training set based on their features, using the g -means algorithm in combination with a post-processing scheme that reassigns instances from clusters whose size falls below a user-defined threshold. For each cluster, the cluster centre and the best-performing solver (from the given set of component solvers) are stored; given a new problem instance, ISAC determines the nearest cluster centre (using a 1-nearest neighbour approach) and runs the solver associated with it. ISAC was originally designed to combine algorithm configuration and per-instance selection, by automatically configuring a single, parametric solver for each cluster (see Section 12.4.1). Initial results for SAT and two other problems (set covering and mixed integer programming) were promising, but limited in scope; in the case of SAT, ISAC was applied to a single local-search-based SAT solver, SAPS [HTH02], on which it showed substantial speedups over the default configuration on several benchmarks [KMST10]. Later, used as a pure per-instance algorithm selector in combination with a large number of high-performance SAT solvers, ISAC was demonstrated to achieve substantial performance improvements compared to the single best solver on a broad set of random SAT instances from several SAT competitions, and more modest improvements on hand-crafted and industrial SAT instances; however, in all cases, performance in terms of PAR-10 scores was more than a factor of 9.9 worse than that of the virtual best solver [CMMO13].

The clustering approach used by ISAC also underlies 3S (semi-static solver schedules), which combines per-instance algorithm selection with sequential algorithm scheduling [KMS⁺11]. Like ISAC, 3S uses the g -means algorithm for clustering problem instances. For a given instance i to be solved, it then uses a k -nearest neighbour approach to determine a set of similar training instances and selects the algorithm with the best performance on this instance set. This mechanism is enhanced by weighting algorithm performance on a reference instance i' by the distance of i' to i , and by adapting the neighbourhood size k based on the features of i . 3S incorporates the per-instance algorithm selector thus obtained into a static algorithm schedule, determined using mixed integer programming. While this approach is conceptually similar to the pre-solver schedules used in SATzilla from 2007 onwards, it offers considerably more flexibility in the design of sequential schedules. On random SAT instances, 3S was reported to reduce the gap between the 2009 version of SATzilla (which then constituted the state of the art for these types of instances) and the virtual best solver (VBS) (a hypothetical, perfect per-instance algorithm selector) by 57%. Unlike SATzilla, 3S participated in the 2011 SAT Competition, where it showed impressive performance, winning 2 gold, 2 silver and 3 bronze medals. In a comparison based on scenarios from the 2012 SAT Challenge, 3S was reported to obtain PAR-10 scores between 49% and 81% worse than those reached by the 2012 version of SATzilla [MSSS13].

Like ISAC and 3S, the CSHC (cost-sensitive hierarchical clustering) algorithm selection system is based on the idea of feature-based partitioning of problem instance space into clusters [MSS13]. However, instead of unsupervised clustering, as used in ISAC and 3S, CSHC creates these clusters using a supervised learning algorithm. Effectively, it thus constitutes a cost-sensitive approach for constructing decision trees (we note that all decision tree algorithms determine hierarchical rules for “clustering” the training examples stored in each leaf node). The reader may recall that more recent versions of SATzilla also relied on (random forests of) cost-sensitive decision trees; however, the approaches are different. SATzilla uses decision trees to predict which of two algorithms will be faster, followed by voting across quadratically many such classifiers to choose a single algorithm; CHSC’s decision trees directly predict the best algorithm to run. More specifically, starting with all instances in the given training set, CSHC recursively partitions a given “cluster” of instances into two “sub-clusters”, based on a single feature value, such that the performance of the best-performing algorithm in each “sub-cluster” is optimized. When asked to solve a new instance i , CSHC first runs the 3S static algorithm schedule for a fixed fraction (10%) of the overall time budget. If this does not solve the instance, it computes features and uses the learned decision tree to identify a leaf node and thereby the algorithm that performed best on that “cluster” of instances. CSHC was reported to achieve slightly better performance than the 2012 version of SATzilla on a number of scenarios based on the 2012 SAT Challenge, although the observed performance differences were reported not to be statistically significant [MSS13].

12.3.3. SNNAP

A combination of supervised and unsupervised learning forms the basis for SNNAP (solver-based nearest neighbour for algorithm portfolios) [CMMO13]. Specifically, SNNAP uses random forests to predict the running times of individual solvers; these predictions then provide the basis for identifying instances from the given training set that are similar to the instance to be solved. Instance similarity is assessed based on a (small) fixed number of best solvers known or predicted to perform best on a given instance, using Jaccard distance. The solver to be run is then selected as the one predicted to perform best on the k nearest instances in the given training set to the instance to be solved, for a user-defined value of k . In the experiments reported by Collautti et al., $k = 60$ and similarity calculations are based on the three best solvers for any given instance.

SNNAP has been demonstrated to show substantially stronger performance than ISAC on large collections of instances collected from SAT competitions between 2006 and 2012 [CMMO13]. A comparison against a 2015 internal development version of SATzilla, which is a minor variant of the 2011 version described previously, revealed that on 5 of 7 scenarios based on the 2011 SAT Competition and the 2012 SAT Challenge, SNNAP performed significantly worse than SATzilla, with statistically tied and slightly better performance, respectively, on the two remaining scenarios [LHHS15].

12.3.4. AutoFolio

As is evident from the previous sections, when designing an algorithm selection system, many design choices have to be made. These choices can have substantial impact on performance, and what works best generally depends on the given use case. Therefore, following the previously outlined programming by optimization approach, AutoFolio combines a highly parametric framework for algorithm selection with a general-purpose algorithm configurator, which is used to instantiate this framework in such a way that performance is optimized for a given use case (such as a specific set or distribution of SAT instances [LHHS15]). AutoFolio is not restricted to SAT, but can be applied to arbitrary algorithm selection problems.

The underlying algorithm selection framework, called *claspfolio 2*, was originally developed in the context of algorithm selection for answer set programming (ASP) and incorporates techniques and ideas from a broad range of high-performance per-instance algorithm selection approaches [HLS14]. This framework encompasses strategies from a broad range of algorithm selection systems, including 3S [KMS⁺11], ISAC [KMST10], SATzilla [XHHLB08, XHHLB12], and SNNAP [CMMO13]; for each selection approach, AutoFolio considers subsidiary design choices and parameter settings. Furthermore, several techniques for pre-processing the training data from a given algorithm selection scenario and for constructing pre-solver schedules can be configured independently from the selection approach. Automated configuration of this flexible framework is performed using SMAC [HHLB11], in combination with cross-validation on the given training set to robustly evaluate the performance of candidate configurations.

AutoFolio has been empirically evaluated against other algorithm selection techniques across a broad range of algorithm selection scenarios, including several benchmark sets derived from SAT competitions [LHHS15]. In those experiments, AutoFolio was found to be the only approach that achieved state-of-the-art performance for all benchmarks; notably, for each benchmark scenario, it was statistically tied with or exceeded the performance of the best of SNNAP, ISAC and SATzilla. However, there remained a considerable gap to the performance bounds obtained from the virtual best solvers for these algorithm selection scenarios (e.g., a factor of 8.8 in PAR-10 score between the AutoFolio selector and the VBS, compared to a factor of 1.8 between the single best solver and the AutoFolio selector on the SAT12-INDU benchmark), indicating room for further improvements in automated algorithm selection.

12.3.5. The Sparkle SAT Challenge

Solver competitions, such as the quasi-annual SAT solver competitions and races, serve several purposes. Aside from providing an objective, neutral performance assessment of the participating algorithms, they also provide a powerful incentive for improving the state of the art in solving the problem in question. Unfortunately, as discussed in Section 12.2.4, traditional competition designs assess – and incentivize improvement of – broad-spectrum performance of fairly monolithic solvers. This becomes an issue for problems such as SAT, where the overall

state of the art is represented by a set of algorithms, and more precisely for algorithm selectors, since they leverage the performance complementarity in such a solver set, rather than simply benefiting from the performance of the fastest single algorithm.

Therefore, just as the Configurable SAT Solver Challenges built the existence of powerful, general-purpose algorithm configurators into the design of a competition, the Sparkle SAT Challenge is predicated on the ready availability of per-instance algorithm selection systems for SAT. The key idea underlying this competition, which was held as part of the 2018 FLoC Olympic Games, was to let competitors submit SAT solvers that would be integrated into a per-instance algorithm selector constructed using AutoFolio [LHHS15]. Participating solvers would then be evaluated based on the degree to which they contribute to the overall performance of the selection system thus obtained [LH18]. To make it easier for participants to optimize the contributions of their solvers, and hence not only their standing in the competition, but also the overall performance of the final algorithm selector, daily evaluations (on a set of training instances) were conducted and published during a leader-board phase.

The Sparkle SAT Challenge was conducted using a newly designed software platform called Sparkle, which aims to make the construction and evaluation of algorithm selectors more easily accessible to solver developers and practitioners. It used the well-known feature extractor by Xu et al. [XHHLB12] in combination with the state-of-the-art AutoFolio selector construction system discussed in Section 12.3.4. Solver contributions to overall selector performance were assessed using relative marginal contribution (RMC), a normalised version of marginal contribution [XHHLB12]. More sophisticated approaches exist, but would have been computationally too expensive to use in the competition [see, e.g., FKM⁺16, FKM⁺18]. While official results were based on RMC to an actual selector obtained from AutoFolio, RMC to the virtual best solver over the same set of component algorithms was also reported. It is worth noting that the Sparkle system used to run the challenge not only fully automates the construction of the selector, but also the comprehensive evaluation of component solver and selector performance, which is compiled into a detailed technical report generated by Sparkle.

The results from the Sparkle SAT Challenge, as presented during the 2018 FLoC Olympic Games [LH18], gave rise to three main findings.

First, as observed consistently in the literature and in other competitions, using per-instance algorithm selection, performance complementarity between SAT solvers was leveraged, leading to substantial performance improvements over the single best solver (SBS). These improvements tended to be much larger than those between the SBS and the runners-up in terms of stand-alone solver performance. The difference in stand-alone performance between the SBS and the runner-up was less than 1% in terms of PAR2 score, while the automatically constructed selector was more than 7.5% better than the SBS, despite the fact that the test instances differed substantially from the training instances used as a basis for constructing the selector. This highlights the continued importance of per-instance algorithm selection for achieving state-of-the-art performance in solving SAT.

Second (as previously observed by Xu et al. [XHHLB12]) the stand-alone per-

formance of SAT solvers tended to be uncorrelated with their contributions to a state-of-the-art per-instance selector built from them, and likewise uncorrelated with their contributions to the VBS. This suggests that conventional competitions may not be the most effective way of improving the state of the art in SAT solving, since they motivate solver developers to optimize stand-alone performance. In the Sparkle SAT Challenge, the solver ranked third in terms of stand-alone performance had a relative marginal contribution to selector performance that was over five times lower than that of the solver ranked last.

Third, when given the opportunity to repeatedly evaluate the contributions of their solvers to overall selector performance, solver developers appear to have succeeded in maximizing those contributions and, as a result, also overall selector performance. We attribute this partly to the easy and frictionless access to cutting-edge selector construction methods offered by the Sparkle platform. In particular, selector performance on training data accessible to participants in the challenge improved by a factor of more than 2 in terms of PAR2 score.

12.4. Related approaches

Automated algorithm configuration and per-instance algorithm selection, although very widely studied in the literature, are not the only meta-algorithmic design techniques. In this section, we briefly outline additional techniques, many of which have been applied to SAT.

12.4.1. Combining algorithm configuration and algorithm selection

Algorithm configuration and algorithm selection have different strengths. Algorithm configuration is good at searching enormous parameter spaces to find settings that yield peak average performance, at a cost of hours or days of off-line compute time. Algorithm selection is good at exploiting variability in the running times of different solvers (or different configurations) *within* instance distributions of interest, and can select the best of a small, fixed set of solvers quickly enough to be used online. In many practical applications, the algorithm configuration setting is closer to the needs of a typical practitioner than the algorithm selection setting: notably, it can be much easier to maintain a single algorithm codebase with parameterized components than different codebases for multiple solvers. However, sometimes different codebases arise separately (as in the SAT competition setting), and sometimes practitioners face heterogeneous sets of problem instances, on which no single configuration yields sufficiently strong average performance. In order to get the best of both worlds, we can use algorithm configuration to obtain a set of complementary configurations that can be fruitfully combined using algorithm selection.

One simple approach to combining algorithm configuration and algorithm selection is to cluster a heterogeneous set of problem instances into a set of homogeneous subsets, to run configuration on each of these subsets to obtain specialized configurations, and then to treat these specialized configurations as the solvers to be combined with a per-instance algorithm selector. This is the approach followed by *instance-specific algorithm configuration* (ISAC [KMST10]).

A more sophisticated way to combine configuration and selection is to use configuration to iteratively identify configurations that are maximally complementary to an existing set. *Hydra* [XHLB10] follows this idea, building on an approach first proposed by Leyton-Brown et al. [LBNA⁺03]. *Hydra* starts from an empty portfolio and then iteratively adds a new configuration that maximally improves the oracle performance of the configurations in the portfolio. Because the oracle performance of an algorithm portfolio is a submodular function, this approach is guaranteed to yield portfolios whose oracle performance is within a factor of $1 - 1/e$ from optimal.

12.4.2. Algorithm schedules

While per-instance algorithm selection often works very well, it depends on the availability of cheaply computable instance features that jointly correlate well with algorithm running time. An alternative strategy that does not depend on the existence of such features is building an *algorithm schedule* that runs several algorithms in a fixed or adaptive sequence. Algorithm schedules work when many solvers have high variance in their running time distributions across instances (i.e., solve some instances very quickly and others very slowly) and when different instances are easy for different solvers.

Indeed, algorithm schedules can also be useful even when informative instance features do exist, because they offer a way to solve easy instances without computing features. This matters particularly when performance is measured by making a multiplicative rather than additive comparison to optimal, because feature computation can dominate running time on easy instances. It is for this reason that several per-instance algorithm selection systems use pre-solver schedules, as described in Section 12.3.

Algorithm schedules can be constructed using various techniques. They can be defined by hand, built by local search in the joint space of algorithms and running times (as done for determining the pre-solving schedules used by SATzilla [XHHLB08]), or by means of mixed integer programming [KMS⁺11] or answer set programming [HKLS15]. It is also possible to start with an empty schedule and use a *Hydra*-like approach to greedily append one configuration at a time to the current schedule, along with a time budget for which it should be allowed to run [SSH15]. (In contrast to *Hydra*, the objective function optimized by algorithm configuration in this case is performance gain of the schedule *per additional time spent*, but otherwise the approach is similar.)

12.4.3. Parallel portfolios

So far, this chapter has focused on approaches that require only a single processor core. Of course, modern computing is increasingly parallel, particularly as cloud resources become available. Parallel portfolios are based on the idea of running multiple sequential solvers in parallel on a given problem instance to be solved; if these component solvers have complementary strength, this can lead to an improvement in performance in terms of wall-clock time and, in some cases, even in terms of overall CPU time, when solving decision problems such as SAT.

Parallel portfolios can thus be used to construct solvers that effectively exploit parallel computing resources without the well-known difficulties associated with developing intrinsically parallel solvers.

Even simple parallel portfolios can be very powerful. To give one notable example, in the 2011 SAT Competition, the solver pfolio [Rou11] won 11 medals in the parallel track and 5 medals in the sequential track (where its parallelism was realised by task switching) by following an incredibly straightforward strategy: running the best solvers from several categories of the 2009 SAT Competition in parallel. This approach was effective, because the solvers forming the parallel portfolio performed well individually and complemented each other well. Roughly speaking, automated methods for constructing parallel portfolios also aim to identify an optimal compromise between complementarity and individual strength.

Algorithm configuration and per-instance selection can both be extended to the parallel case. Algorithm configuration can be used to create strong parallel solvers based only on the parametric code of a sequential solver [LHLBS17]. Once more, Hydra's greedy approach is effective: starting with an empty portfolio (on zero processor cores), greedily add the configuration to run on the next processor core that most improves performance when run alongside the existing portfolio. Algorithm selection can also be generalized to produce a parallel portfolio of solvers rather than a single solver [LHH15]. In particular, a rather broadly applicable approach for parallelizing an existing algorithm selection approach is to adapt its underlying machine learning model to rank the solvers, and then simply to select the top-ranked K solvers to concurrently run on K processor cores.

12.4.4. Parameter control

Just as different solvers and solver configurations exhibit strong performance on different problem instances, so it is the case that different strategies work best during different phases of solving a single instance. For example, local search algorithms need to effectively switch between exploration and exploitation phases, and tree search algorithms may benefit from using different heuristics at different depths of the search tree or as a function of the number of clauses already learned. This observation gives rise to the meta-problem of adapting the parameters of a given algorithm online as a function of the current search state. While algorithm configuration can be formulated as a black-box optimization problem and algorithm selection as a supervised learning problem, *parameter control* is a more complex problem akin to reinforcement learning [LL00, LL01, EFW⁺02, BC12, AN16, BBHL19].

12.4.5. Parameter importance analysis

It is important to complement the automated methods for constructing strong solvers discussed up to this point with analysis techniques that can yield insights about what components were responsible for observed performance improvements. For algorithm configuration, it is possible to use model-based approaches to detect which parameters have an important influence on performance. Techniques

can be based on forward selection [LBNS09, HHLB13]; based on a decomposition of the variance of predicted performance into components attributable to each single parameter and combination of (two or more) parameters [HHLB14]; or based on local effects around the best found configuration [BMLH18]. Alternatively, ablation analysis can be used to assess the relative contributions of individual parameters to observed performance differences between algorithm configurations [FH16]. It is also possible to perform a model-based variant of such an ablation analysis, which means that the analysis can be performed without executing additional runs of the algorithm under study [BLE⁺17].

12.4.6. Using algorithm configuration to find bugs in solvers

As mentioned at the beginning of this chapter, algorithm configuration has uses beyond performance optimization; one of these is the identification of parameter configurations that lead to errors, and especially those that do so quickly. Algorithm configuration optimizes a user-defined performance metric; in SAT solving, common choices are minimizing the number of timeouts for a given cutoff time and minimizing (penalized) average running time. A subtlety is how one should count runs that terminate quickly but either with no result (e.g., due to a segmentation fault) or with an incorrect result (e.g., UNSAT for a satisfiable instance). When seeking to produce good average performance, such runs are typically given a terrible score (e.g., the timeout multiplied by a large constant) in order to drive the configurator towards areas of the configuration space that do not cause erroneous behaviour. In contrast, blindly minimizing average measured running time actually causes the configurator to find configurations that terminate as quickly as possible; often this yields buggy configurations that *break* quickly [ELH19]. This can be viewed as a tool for automatically finding whitebox tests that expose problems quickly [HHLB10, ML16].

12.5. Conclusions and open challenges

The meta-algorithmic techniques described here have already improved the state of the art in SAT solving for various types of applications [see, e.g., HBHH07, NFLB17], but there still remain several open challenges in terms of methods, tools and applications.

Regarding methods, one of the biggest challenges is to develop an approach that works robustly, even for SAT instances that do not resemble the instances seen at training time. It would be highly desirable to have available an effective configuration method for highly heterogeneous instances, which could be used to identify better default configurations. However, in many cases, there simply does not exist a single configuration that performs well across instances. Instead, we believe that it might be more promising to develop a robust approach for selecting the best out of a small number of automatically-determined default configurations. An interesting research challenge consists of identifying such robust defaults based on a limited number of training instances. Ways to effectively integrate domain knowledge from solver developers would be extremely helpful towards this goal.

In terms of tools, it would be helpful to make it easier for developers and users of SAT solvers to take advantage of meta-algorithmic tools and the performance improvements they afford. Currently, considerable expertise is required to determine, e.g., which parameters should be configured for which kinds of instance sets, and to automatically build robust solvers for application to new instances, using approaches such as Hydra. This high barrier to entry could be lowered, at least in part, by designing a highly parametric CDCL solver, with a rich configuration space that covers most of the techniques used in modern CDCL-based SAT solvers, similar to the way that SATenstein [KXHLB09, KXHLB16] covers a substantial part of the space of stochastic local search solvers. Furthermore, there remains a need for making automatic algorithm configuration and per-instance selection methods easier to use for practitioners.

We see significant room for further innovation in solver competitions, which have historically been a significant driver of new work in the field. We see substantial value in competitions that deeply integrate both automated algorithm configuration (as done in the Configurable SAT Solver Challenges) and per-instance algorithm selection (as done in the Sparkle SAT Challenge). We are also excited about recent work that has shown how ideas from coalitional game theory can be used to derive new evaluation metrics for such competitions [FKM⁺16, KFM⁺18]. We hope that these metrics can be used in future competitions (perhaps alongside existing alternatives) to further improve the way in which innovative ideas in solver design are recognized.

Finally, as is evident both from the literature and from competitions, algorithm configuration and algorithm selection have the potential to produce performance gains in solving virtually any application problem. Specifically, we see significant opportunities in applying meta-algorithmic technologies to improve SMT solvers, which play a key role in some of the most important applications of SAT-related techniques in the areas of hardware and software verification.

Chapter 13

Symmetry and Satisfiability

Karem A. Sakallah

Symmetry is at once a familiar concept (we recognize it when we see it!) and a profoundly deep mathematical subject. At its most basic, a symmetry is some transformation of an object that leaves the object (or some aspect of the object) unchanged. For example, Fig. 13.1 shows that a square can be transformed in eight different ways that leave it looking exactly the same: the identity “do-nothing” transformation, 3 rotations, and 4 mirror images (or reflections). In the context of decision problems, the presence of symmetries in a problem’s search space can frustrate the hunt for a solution by forcing a search algorithm to fruitlessly explore symmetric subspaces that do not contain solutions. Recognizing that such symmetries exist, we can direct a search algorithm to look for solutions only in non-symmetric parts of the search space. In many cases, this can lead to significant pruning of the search space and yield solutions to problems which are otherwise intractable.

In this chapter we will be concerned with the symmetries of Boolean functions, particularly the symmetries of their conjunctive normal form (CNF) representations. Our goal is to understand what those symmetries are, how to model them using the mathematical language of group theory, how to derive them from a CNF formula, and how to utilize them to speed up CNF SAT solvers.

In a surprising twist, the quest for exploiting symmetries to improve the performance of SAT solvers led to the development of a new highly-scalable symmetry detection algorithm inspired by the backtrack search architecture of SAT solvers! The chapter provides an informal description of this algorithm and concludes with a brief review of symmetry applications in a number of fields.

13.1. Motivating Example

Consider the Boolean function $f(a, b, c)$ specified in Table 13.1. It can be expressed algebraically in sum-of-minterms form as

$$f(a, b, c) = a'bc + ab'c \tag{13.1}$$

It is not too difficult to observe that this function remains invariant under a swap of inputs a and b :

$$f(b, a, c) = b'ac + ba'c = ab'c + a'bc = a'bc + ab'c \tag{13.2}$$

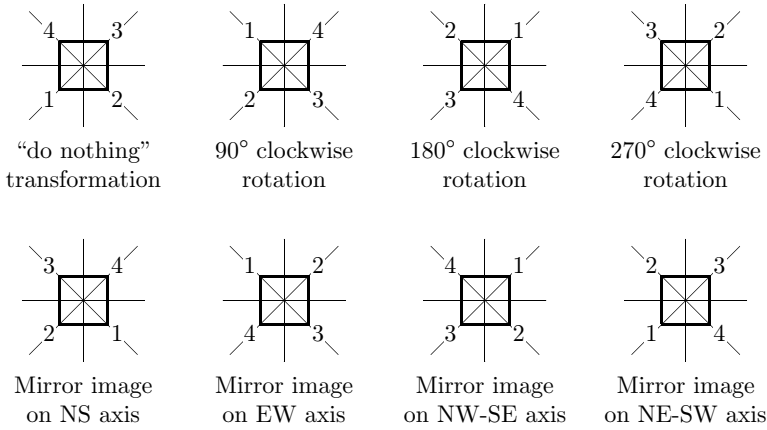

Figure 13.1. Symmetries of the square

It is also rather obvious that this invariance follows from the commutativity of the Boolean AND and OR operators. Viewing this function as an “object” with three “features” labeled a , b , and c , we may consider this swap as a transformation that leaves the essential nature of the object (its “function”) unchanged, hence a symmetry of the object. Allowing for possible inversion, in addition to swaps, of the inputs we can readily check that the following two transformations are also symmetries of this function:

$$f(b', a', c) = b''a'c + b'a''c = a'bc + ab'c \quad (13.3)$$

$$f(a', b', c) = a''b'c + a'b''c = ab'c + a'bc = a'bc + ab'c \quad (13.4)$$

Besides commutativity, invariance under these two transformations relies on the involution of double complementation, i.e., the fact that $x'' = x$. Note that the transformation in (13.3) can be described as a swap between a and b' (equivalently between b and a'). On the other hand, the transformation in (13.4) is a *simultaneous swap* between a and a' , and between b and b' .

To facilitate later discussion, let us label these swaps as follows:

Table 13.1. Truth table for example Boolean function (13.1)

a	b	c	f
0	0	0	0
0	0	1	0
0	1	0	0
0	1	1	1
1	0	0	0
1	0	1	1
1	1	0	0
1	1	1	0

Table 13.2. Symmetry composition table for example function (13.1). The entry in row r and column c represents the result of applying symmetry c followed by symmetry r .

$r * c$	ε	α	β	γ
ε	ε	α	β	γ
α	α	ε	γ	β
β	β	γ	ε	α
γ	γ	β	α	ε

Label	Swap
ε	No swap
α	Swap a with b
β	Swap a with b'
γ	Swap a with a' and b with b'

A natural question now arises: are these the only possible transformations that leave this function unchanged? At this point we cannot answer the question definitively. However, we can try to verify that combining the above transformations will not yield new transformations. Specifically, if we let $\sigma * \tau$ denote the application of τ followed by σ we obtain the *symmetry composition table* in Table 13.2¹. Thus the set of transformations $\{\varepsilon, \alpha, \beta, \gamma\}$ is *closed* under the composition operator $*$.

To visualize this function's symmetries, consider its Karnaugh map (K-map) in Table 13.3. The map clearly shows that the function's solution space (the 8 possible truth assignments to the function's three propositional variables) consists of two symmetric subspaces. Specifically, the distribution of the function's 1s and 0s in the subspace where $a = 0$ is identical to their distribution in the subspace where $a = 1$. Stated another way, the function's 8 possible truth assignments can be collapsed to just these 4 equivalence classes: $\{0, 6\}$, $\{1, 7\}$, $\{2, 4\}$, and $\{3, 5\}$. The assignments in each such class are equivalent in the sense that they yield the same function value (either 0 or 1). Thus, to determine the satisfiability of the function, it is sufficient to consider only one such assignment from each equivalence class. This can be accomplished by conjoining the function with a constraint that filters out all but the chosen representative assignment from each class. A convenient filter for this example is either the constraint (a), which restricts the search for a satisfying assignment to the bottom 4 cells of the map, or the constraint (a'), which restricts the search to the top 4 cells of the map². These filters are referred to as *symmetry-breaking predicates* (SBPs for short) because they serve to block a search algorithm from exploring symmetric assignments in the solution space.

The rest of this chapter is divided into ten sections. In Sec. 13.2 we cover some preliminaries related to Boolean algebra and set partitions. Sec. 13.3 introduces the basics of group theory necessary for representing and manipulating the symmetries of Boolean functions. This is further articulated in Sec. 13.4 for the

¹Some authors define composition using the opposite order: $\sigma * \tau$ means "apply σ followed by τ ." This does not matter as long as the operation order is defined consistently.

²Other, less convenient, filters include $(a'c' + ac)$ which selects assignments $\{0, 2, 5, 7\}$ and excludes assignments $\{1, 3, 4, 6\}$.

Table 13.3. K-map for example function (13.1). The small numbers in the map cells indicate the decimal index of the corresponding minterm (variable assignment) assuming that a is the most significant bit and c is the least significant bit.

CNF representation of such functions. In Sec. 13.5 we briefly describe the colored graph automorphism problem and the basic algorithm for solving it. This sets the stage, in Sec. 13.6, for the discussion on detecting the symmetries of CNF formulas by reduction to graph automorphism. The construction of symmetry breaking predicates is covered in Sec. 13.7. Sec. 13.8 describes the SAT-inspired **saucy** graph automorphism algorithm. Sec. 13.9 summarizes the whole symmetry detection and breaking flow, as well as offering some ideas on an alternative approach that requires further exploration. The chapter concludes in Sec. 13.10 with a historical review of relevant literature.

13.2. Preliminaries

Since we will be mostly concerned with symmetries in the context of Boolean satisfiability, it is useful to establish in this section the vocabulary of Boolean algebra to which we will make frequent reference. Specifically, we will be exclusively dealing with the 2-valued Boolean algebra, also known as propositional logic, which we define as follows:

Definition 13.2.1. (2-Valued Boolean Algebra) The 2-valued Boolean algebra is the algebraic structure $\langle \{0, 1\}, \cdot, +, ' \rangle$ where $\{0, 1\}$ is the set of *truth values*, and where the binary operators \cdot and $+$, and the unary operator $'$ are defined by the following rules:

- AND (logical conjunction): $0 \cdot 0 = 0 \cdot 1 = 1 \cdot 0 = 0, 1 \cdot 1 = 1$
- OR (logical disjunction): $0 + 0 = 0, 0 + 1 = 1 + 0 = 1 + 1 = 1$
- NOT (logical negation): $0' = 1, 1' = 0$

We will, on occasion, use other symbols to indicate these operators such as \wedge for AND, \vee for OR, and \neg for NOT. In addition, we will follow custom by indicating the AND operator with a simple juxtaposition of its arguments.

A Boolean *variable* is a variable whose domain is the set $\{0, 1\}$. Although not formally synonymous, we may at times refer to such variables as *binary* or as *propositional*. A Boolean *literal* is either a Boolean variable or the negation of a Boolean variable. The domain of a vector of n Boolean variables is the set

$\{0, 1\}^n$ whose elements are the 2^n ordered n -tuples, or combinations, of 0 and 1. In other words,

$$\{0, 1\}^n = \left\{ \underbrace{(0, 0, \dots, 0, 0)}_{n \text{ bits}}, \underbrace{(0, 0, \dots, 0, 1)}_{n \text{ bits}}, \dots, \underbrace{(1, 1, \dots, 1, 1)}_{n \text{ bits}} \right\}$$

Each of these combinations can also be interpreted naturally as an unsigned n -bit binary integer. Expressing each of these integers in decimal notation, we obtain the following equivalent representation of this domain:

$$\{0, 1\}^n = \{0, 1, 2, \dots, 2^n - 1\}$$

We will refer to elements of this set as *truth assignments* or “points” in the 2^n -dimensional Boolean space and identify each by its decimal “index”.

Individual Boolean variables will be denoted by lower-case letters, possibly with a numeric subscript, e.g., a, b, x_3 , etc. When speaking about the literals of a particular variable we will place a dot over the variable symbol. Thus, the literal \dot{a} stands for either a or a' . Vectors of Boolean variables will be denoted by upper case letters and, as above, interpreted as unsigned binary integers. Thus, $X = (x_{n-1}, x_{n-2}, \dots, x_0)$ is a vector of n Boolean variables representing an unsigned n -bit integer whose most significant bit is x_{n-1} and whose least significant bit is x_0 . An assignment $X = i$ to an n -variable Boolean vector where $0 \leq i \leq 2^n - 1$ is short-hand for assigning to the elements of X the appropriate bits of the binary integer corresponding to i . Thus, for $n = 3$, $X = 5$ means $x_2 = 1$, $x_1 = 0$ and $x_0 = 1$.

An n -variable Boolean function is defined by the map $\{0, 1\}^n \rightarrow \{0, 1\}$, i.e., each of the 2^n points in its domain is mapped to one of the two binary values. There are two classes of elementary Boolean functions: minterms and maxterms.

Definition 13.2.2. (Minterms and Maxterms) The i th n -variable *minterm function*, denoted by $m_i(X)$, maps point i in the 2^n -dimensional Boolean space to 1, and maps all other points to 0. The i th n -variable *maxterm function*, denoted by $M_i(X)$, maps point i in the 2^n -dimensional Boolean space to 0, and maps all other points to 1. Algebraically, an n -variable minterm function is an AND expression of n distinct literals, whereas an n -variable maxterm function is an OR expression of n distinct literals.

AND and OR expressions (not necessarily consisting of all n literals) are commonly referred to as *product* and *sum terms*, respectively.

Minterm and maxterm functions serve as building blocks for representing any n -variable Boolean function. For example, the function specified in Table 13.1 has the following *sum-of-minterm* and *product-of-maxterm* representations:

$$\begin{aligned} f(a, b, c) &= m_3 + m_5 = a'bc + ab'c \\ &= M_0 \cdot M_1 \cdot M_2 \cdot M_4 \cdot M_6 \cdot M_7 \\ &= (a + b + c)(a + b + c')(a + b' + c)(a' + b + c)(a' + b' + c)(a' + b' + c') \end{aligned}$$

Examination of the sum-of-minterms expression shows that it evaluates to 1 for combinations 3 and 5 on variables (a, b, c) and evaluates to 0 for all other combinations. Informally, we say that function f consists of minterms 3 and 5. Alternatively, we can say that f consists of maxterms 0, 1, 2, 4, 6, and 7. A commonly-used short-hand for representing Boolean functions this way is the following:

$$f(a, b, c) = \sum_{(a,b,c)} (3, 5) = \prod_{(a,b,c)} (0, 1, 2, 4, 6, 7)$$

Definition 13.2.3. (Implication) Given two Boolean functions $f(X)$ and $g(X)$, we say that $g(X)$ *implies* $f(X)$, written $g(X) \rightarrow f(X)$, if all of g 's minterms are also minterms of f .

Definition 13.2.4. (Implicants and Implicates) A product term $p(X)$ is an *implicant* of a function $f(X)$ if $p(X) \rightarrow f(X)$. A sum term $s(X)$ is an *implicate* of a function $f(X)$ if $f(X) \rightarrow s(X)$.

A function can have many implicants and implicates. In particular, a function's implicants include its minterms and its implicates include its maxterms.

Definition 13.2.5. (Disjunctive and Conjunctive Normal Forms) A *disjunctive normal form* (DNF) expression of a Boolean function is an OR of implicants. It is also known as a sum-of-products (SOP). A *conjunctive normal form* (CNF) expression of a Boolean function is an AND of implicates. It is also known as a product-of-sums (POS). It is customary to refer to the implicates in a CNF representation as *clauses*.

Definition 13.2.6. (Minimal DNF and CNF Expressions) The *cost* of a DNF or CNF expression $\varphi(X)$ is the tuple $(\text{terms}(\varphi), \text{literals}(\varphi))$ where $\text{terms}(\varphi)$ and $\text{literals}(\varphi)$ are, respectively, the number of terms (implicants or implicates) and total number of literals in the expression. We say that expression φ is *cheaper* than expression ϑ if $\text{terms}(\varphi) \leq \text{terms}(\vartheta)$ and $\text{literals}(\varphi) < \text{literals}(\vartheta)$. A DNF expression $\varphi(X)$ is minimal for function $f(X)$ if there are no other DNF expressions for $f(X)$ that are cheaper than $\varphi(X)$. Similarly, A CNF expression $\varphi(X)$ is minimal for function $f(X)$ if there are no other CNF expressions for $f(X)$ that are cheaper than $\varphi(X)$. Note that this definition of cost induces a partial order on the set of equivalent DNF (resp. CNF) expressions of a Boolean function.

Definition 13.2.7. (Prime Implicants and Prime Implicates) A *prime implicant* $p(X)$ of a function $f(X)$ is an implicant that is not contained in any other implicant of $f(X)$. In other words, $p(X)$ is a prime implicant of $f(X)$ if $p(X) \rightarrow f(X)$ and $p(X) \not\rightarrow q(X)$ where $q(X)$ is an implicant of $f(X)$. A *prime implicate* $s(X)$ of a function $f(X)$ is an implicate that does not contain any other implicate of $f(X)$. In other words, $s(X)$ is a prime implicate of $f(X)$ if $f(X) \rightarrow s(X)$ and $t(X) \not\rightarrow s(X)$ where $t(X)$ is an implicate of $f(X)$.

Theorem 13.2.1. (Prime Implicant/Prime Implicate Theorem [Qui52, Qui55, Qui59]) Any minimal DNF expression of a function $f(X)$ can only consist of prime implicants. Similarly, any minimal CNF expression can only consist of prime implicates. Minimal expressions are not necessarily unique.

Figure 13.2. A 4-bit comparator circuit

Definition 13.2.8. (leq predicate) The *less-than-or-equal* predicate in the 2^n -dimensional Boolean space is defined by the map

$$\begin{aligned} \text{leq}(X, Y) &= X \leq Y \\ &= \bigwedge_{i=0}^{n-1} \left[\left[\bigwedge_{j=i+1}^{n-1} (x_j = y_j) \right] \rightarrow (x_i \leq y_i) \right] \end{aligned} \quad (13.5)$$

This is a common arithmetic function that is usually implemented in a multi-level circuit similar to that shown in Fig. 13.2. In comparing the circuit to equation (13.5), note that $(x \rightarrow y) = (x \leq y) = (x' + y)$ and $(x = y)' = (x \oplus y)$, where \oplus denotes *exclusive OR*. Note also that the leq predicate imposes a total ordering on the 2^n truth assignments that conforms to their interpretation as unsigned integers. As will become clear later, the leq predicate provides one mechanism for breaking symmetries.

We close with a brief mention of set partitions since they arise in the context of describing and detecting the symmetries of a CNF formula.

Definition 13.2.9. (Partition) A partition π of a set X is a set of non-empty subsets of X , $\{X_i \mid X_i \subseteq X, i = 1, \dots, k\}$, such that:

$$\begin{aligned} X_i \cap X_j &= \emptyset, \text{ for } i \neq j \\ \bigcup_{1 \leq i \leq k} X_i &= X \end{aligned}$$

The elements of π are variously referred to as the *blocks*, *classes* or *cells* of the partition. A partition is *discrete* if all of its cells are singleton sets, and *unit* if it has only one cell (the whole set).

Two elements $x, y \in X$ are equivalent under partition π , written as $x \sim y$, if $x, y \in X_i$ for some $i \in [1, k]$.

A partition is usually written as a set of sets. For example, $\{\{1, 2\}, \{4\}, \{3, 5\}\}$ is a partition of $\{1, \dots, 5\}$. A slightly more compact notation for this partition uses vertical bars to separate the cells: $\{1, 2|4|3, 5\}$. When the order of the cells in a partition is important, curly brackets are replaced by square brackets. For example, $[1, 2|4|3, 5]$ is an *ordered partition* which is different from $[4|3, 5|1, 2]$.

Definition 13.2.10. (Lattice of Partitions [Can01]) Given two partitions π and π' of a set X , we say that π' is *finer* than π , written as $\pi' \leq \pi$, if every cell of π' is contained in some cell of π . The relation “is finer than” defines a *lattice* on the set of partitions whose top element is the unit partition and whose bottom element is the discrete partition. Given two partitions π_1 and π_2 , their *intersection*, $\pi_1 \cap \pi_2$, is the *largest* partition that refines both. Dually, the *union* of π_1 and π_2 , $\pi_1 \cup \pi_2$, is the *smallest* partition which is refined by both.

Example 13.2.1. Given $X = \{1, 2, \dots, 10\}$ and the two partitions

$$\begin{aligned}\pi_1 &= \{1, 2, 4|3|5|6, 7, 8|9, 10\} \\ \pi_2 &= \{1, 3, 4|2|5, 6, 7, 8|9|10\}\end{aligned}$$

their intersection and union are

$$\begin{aligned}\pi_1 \cap \pi_2 &= \{1, 4|2|3|5|6, 7, 8|9|10\} \\ \pi_1 \cup \pi_2 &= \{1, 2, 3, 4|5, 6, 7, 8|9, 10\}\end{aligned}$$

13.3. Group Theory Basics

The study of symmetries in Boolean functions and their various representations is greatly facilitated by understanding some basic notions from the vast field of group theory. In this section we cover only those aspects of group theory that are necessary to follow the development, in subsequent sections, of the symmetry detection and breaking approaches for CNF representations of Boolean functions. More comprehensive treatments of group theory are available in standard textbooks; a particularly accessible source is [Fra00] which we liberally borrow from in what follows.

13.3.1. Groups

We begin with the definition of a group as an abstract algebraic structure with certain properties.

Definition 13.3.1. (Group) A group is a structure $\langle G, * \rangle$, where G is a (non-empty) set that is closed under a binary operation $*$, such that the following axioms are satisfied:

- The operation is *associative*: for all $x, y, z \in G$, $(x * y) * z = x * (y * z)$
- There is an *identity* element $e \in G$ such that: for all $x \in G$, $e * x = x * e = x$
- Every element $x \in G$ has an inverse $x^{-1} \in G$ such that: $x * x^{-1} = x^{-1} * x = e$

We will typically refer to the group G , rather than to the structure $\langle G, * \rangle$, with the understanding that there is an associated binary operation on the set G . Furthermore, it is customary to write xy instead of $x * y$ and x^2 instead of $x * x$ much like we do with the multiplication operation on numbers.

This definition leads to a number of interesting properties that are easy to prove, including:

- **Uniqueness of the identity:** there is only one element $e \in G$ such that $e * x = x * e = x$ for all $x \in G$, and
- **Uniqueness of the inverse:** for each $x \in G$, there is only one element $x^{-1} \in G$ such that $x * x^{-1} = x^{-1} * x = e$.

The definition also does not restrict a group to be finite. However, for our purposes it is sufficient to focus on finite groups.

Definition 13.3.2. (Group Order) If G is a finite group, its *order* $|G|$ is the number of elements in (i.e., the cardinality of) the set G .

Under these two definitions, the set of transformations introduced in Sec. 13.1 is easily seen to be a group of order 4 with group operation $*$ as defined in Table 13.2. The identity element is the “do nothing” transformation ε and each of the four elements in the group is its own inverse. The associativity of the operation can be verified by enumerating all possible triples from $\{\varepsilon, \alpha, \beta, \gamma\}^3$. This group is known as the Klein 4-group V and is one of only two groups of order 4 [Fra00, p. 67].

Definition 13.3.3. (Group Isomorphism) Let $\langle G, * \rangle$ and $\langle G', *' \rangle$ be two groups. An *isomorphism* of G with G' is a one-to-one function ϕ mapping G onto G' such that:

$$\phi(x * y) = \phi(x) *' \phi(y) \text{ for all } x, y \in G$$

If such a map exists, then G and G' are *isomorphic groups* which we denote by $G \simeq G'$.

To illustrate group isomorphism, consider the following set of all possible negations (complementations) of two binary literals \dot{a}, \dot{b} :

Label	Negation
$\dot{a}\dot{b}$	Don't negate either literal
$\dot{a}'\dot{b}$	Only negate \dot{a}
$\dot{a}\dot{b}'$	Only negate \dot{b}
$\dot{a}'\dot{b}'$	Negate both \dot{a} and \dot{b}

The labels in the above table should be viewed as mnemonics that indicate the particular transformation on the two literals: a prime on a literal means the literal should be complemented by the transformation, and the absence of a prime means the literal should be left unchanged. As such, these transformations can

³Such enumeration is impractical or even infeasible for large groups. In general, proving that the group operation is associative is typically done by showing that the group is isomorphic (see Def. 13.3.3) to another group whose operation is *known* to be associative.

Table 13.4. Composition table for \mathcal{N}_2

$*'$	$\dot{a}\dot{b}$	$\dot{a}'\dot{b}$	$\dot{a}\dot{b}'$	$\dot{a}'\dot{b}'$
$\dot{a}\dot{b}$	$\dot{a}\dot{b}$	$\dot{a}'\dot{b}$	$\dot{a}\dot{b}'$	$\dot{a}'\dot{b}'$
$\dot{a}'\dot{b}$	$\dot{a}'\dot{b}$	$\dot{a}\dot{b}$	$\dot{a}'\dot{b}'$	$\dot{a}\dot{b}'$
$\dot{a}\dot{b}'$	$\dot{a}\dot{b}'$	$\dot{a}'\dot{b}'$	$\dot{a}\dot{b}$	$\dot{a}'\dot{b}$
$\dot{a}'\dot{b}'$	$\dot{a}'\dot{b}'$	$\dot{a}\dot{b}$	$\dot{a}'\dot{b}$	$\dot{a}\dot{b}'$

be combined. For example, negating both literals followed by negating only \dot{a} yields the same result as negating just \dot{b} . Denoting this operation by $*'$ we obtain the composition table in Table 13.4. Clearly, as defined, the set $\{\dot{a}\dot{b}, \dot{a}'\dot{b}, \dot{a}\dot{b}', \dot{a}'\dot{b}'\}$ along with the operation $*'$ is a group. Let's denote this group by \mathcal{N}_2 (for the *group of negations on two binary literals*). Close examination of Table 13.2 and Table 13.4 shows that, other than the particular labels used, they have identical structures. Specifically, we have the following map between the Klein 4-group V and the group of negations \mathcal{N}_2 :

$$\begin{array}{lcl}
 x \in V & \leftrightarrow & \phi(x) \in \mathcal{N}_2 \\
 \varepsilon & \leftrightarrow & \dot{a}\dot{b} \\
 \alpha & \leftrightarrow & \dot{a}'\dot{b} \\
 \beta & \leftrightarrow & \dot{a}\dot{b}' \\
 \gamma & \leftrightarrow & \dot{a}'\dot{b}'
 \end{array}$$

Thus V and \mathcal{N}_2 are isomorphic groups. In what follows we will use \mathcal{N}_n to denote the group of negations on n literals. This group has order 2^n .

13.3.2. Subgroups

Subgroups provide a way to understand the structure of groups.

Definition 13.3.4. (Subgroup) A non-empty subset H of a group G that is closed under the binary operation of G is itself a group and is referred to as a *subgroup* of G . We indicate that H is a subgroup of G by writing $H \leq G$. Additionally, $H < G$ shall mean that $H \leq G$ but $H \neq G$.

Definition 13.3.5. (Proper and Trivial Subgroups) If G is a group, then the subgroup consisting of G itself is the *improper subgroup* of G . All other subgroups are *proper subgroups*. The group $\{e\}$ is the *trivial subgroup* of G . All other subgroups are *non-trivial*.

We illustrate the notion of subgroups for the Klein 4-group introduced earlier. Specifically, this group has four non-trivial subgroups: $\{\varepsilon, \alpha\}$, $\{\varepsilon, \beta\}$, $\{\varepsilon, \gamma\}$, as well as the whole group itself. These groups are related according to the lattice structure shown in Fig. 13.3.

A subgroup H of a group G induces a partition of G whose cells are referred to as the *cosets* of H :

Definition 13.3.6. (Cosets) Let H be a subgroup of a group G . The *left coset* of H containing $x \in G$ is the subset $xH = \{xy | y \in H\}$ and the *right coset* of H containing $x \in G$ is the subset $Hx = \{yx | y \in H\}$.

Figure 13.3. Lattice diagram for the Klein 4-group V showing its subgroups.

For example, the left cosets of $H = \{\varepsilon, \alpha\}$ in the Klein-4 group $\{\varepsilon, \alpha, \beta, \gamma\}$ yield the partition $\{\{\varepsilon, \alpha\}, \{\beta, \gamma\}\}$.

It is easily shown that the number of elements in each coset of a subgroup H of a group G is the same as the number of elements of H [Fra00, p. 124]. This immediately leads to the following fundamental theorem of group theory:

Theorem 13.3.1. (Theorem of Lagrange) Let H be a subgroup of a finite group G . Then $|H|$ is a divisor of $|G|$.

13.3.3. Group Generators

Theorem 13.3.2. (Cyclic Subgroup) Let G be a group and let $x \in G$. Then

$$H = \{x^n \mid n \in \mathbb{Z}\}$$

i.e., the set of all (not necessarily distinct) powers of x , is a subgroup of G and is the smallest subgroup of G that contains x . This is referred to as the *cyclic subgroup of G generated by x* , and is denoted by $\langle x \rangle$.

Definition 13.3.7. (Generator; Cyclic Group) An element x of a group G *generates* G and is a *generator* for G if $\langle x \rangle = G$. A group G is *cyclic* if there is some element $x \in G$ that generates G .

Definition 13.3.8. (Group Generators) Let G be a group and let $H \subset G$ be a subset of the group elements. The smallest subgroup of G containing H is the *subgroup generated by H* . If this subgroup is all of G , then H *generates* G and the elements of H are *generators* of G . A generator is *redundant* if it can be expressed in terms of other generators. A set of generators for a group G is *irredundant* if it does not contain redundant generators.

An important property of irredundant generator sets of a finite group is that they provide an extremely compact representation of the group. This follows directly from the Theorem of Lagrange and the definition of irredundant generator sets:

Theorem 13.3.3. Any irredundant set of generators for a finite group G , such that $|G| > 1$, contains at most $\log_2 |G|$ elements.

Proof. Let $\{x_i \in G \mid 1 \leq i \leq n\}$ be a set of n irredundant generators for group G and consider the sequence of subgroups G_1, G_2, \dots, G_n such that group G_i is

generated by $\{x_j \in G \mid 1 \leq j \leq i\}$. Clearly, $G_1 < G_2 < \dots < G_n$ because of our assumption that the generators are irredundant. By the theorem of Lagrange, $|G_n| \geq 2|G_{n-1}| \geq \dots \geq 2|G_2| \geq 2|G_1|$, i.e., $|G_n| \geq 2^{n-1}|G_1|$. Noting that $G_n = G$ and that $|G_1| \geq 2$, we get $|G| \geq 2^n$. Thus, $n \leq \log_2 |G|$. \square

Returning to the Klein 4-group, we note that it has three sets of irredundant generators: $\{\alpha, \beta\}$, $\{\alpha, \gamma\}$, and $\{\beta, \gamma\}$. It can also be generated by the set $\{\alpha, \beta, \gamma\}$, but this set is redundant since any of its elements can be obtained as the product of the other two.

13.3.4. Permutation Groups

We turn next to an important class of groups, namely groups of permutations.

Definition 13.3.9. (Permutation) A permutation of a set A is a function $\phi : A \rightarrow A$ that is both one to one and onto (a bijection).

Permutations can be “multiplied” using function composition:

$$\sigma\tau(a) \equiv (\sigma \circ \tau)(a) = \sigma(\tau(a))$$

where σ and τ are two permutations of A and $a \in A$. The resulting “product” is also a permutation of A , since it is easily shown to be one to one and onto, and leads us to the following result:

Theorem 13.3.4. (Permutation Group) Given a non-empty set A , let S_A be the set of all permutations of A . Then S_A is a group under permutation multiplication.

Definition 13.3.10. (Symmetric Group) The group of all permutations of the set $\{1, 2, \dots, n\}$ ($n \geq 1$) is the *symmetric group on n letters*, and is denoted by S_n . For any non-empty set T , its symmetric group is denoted by $S_{|T|}(T)$.

Fig. 13.4 shows two example permutations of an 8-element set along with their products. Note that, in general, permutation multiplication is not commutative, i.e., $\sigma\tau \neq \tau\sigma$. The permutations in this figure are presented in a *tabular format* that explicitly shows how each element of the underlying set is mapped to a distinct element of the same set. For instance, element 3 is mapped by σ to 6: $\sigma(3) = 6$. This explicit format becomes cumbersome, however, when the cardinality of the set A is large, and especially when a permutation maps many of the elements of A to themselves. In such cases, the more compact *cycle notation* is preferred. Using cycle notation, the permutations in Fig. 13.4 can be expressed succinctly as follows⁴:

$$\begin{aligned} \sigma &= (1, 8) (3, 6) & \tau &= (2, 7, 8) (3, 5, 6) \\ \sigma\tau &= (1, 8, 2, 7) (3, 5) & \tau\sigma &= (1, 2, 7, 8) (5, 6) \end{aligned}$$

Each such permutation is a product of *disjoint cycles*, where a cycle (a, b, c, \dots, z) is understood to mean that the permutation maps a to b , b to c , and so on, finally

⁴Commas are frequently omitted from cycle notation, especially when the set being permuted consists of single digits. Thus $(2, 7, 8)$ would be written as (278) or $(2\ 7\ 8)$.

$$\sigma = \begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 8 & 2 & 6 & 4 & 5 & 3 & 7 & 1 \end{bmatrix} \quad \tau = \begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 1 & 7 & 5 & 4 & 6 & 3 & 8 & 2 \end{bmatrix}$$

$$\sigma\tau = \begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 8 & 7 & 5 & 4 & 3 & 6 & 1 & 2 \end{bmatrix} \quad \tau\sigma = \begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 2 & 7 & 3 & 4 & 6 & 5 & 8 & 1 \end{bmatrix}$$

Figure 13.4. Example permutations of the set $A = \{1, 2, 3, 4, 5, 6, 7, 8\}$ along with their products.

mapping the last element in the cycle z back to a . An element that does not appear in a cycle is understood to be left fixed (mapped to itself) by the cycle. The *length* of a cycle is the number of elements in the cycle; a cycle with k elements will be referred to as a k -cycle.

Definition 13.3.11. (Permutation Support) Given a permutation σ of a set A , its support consists of those elements of A that are not mapped to themselves by σ :

$$\text{supp}(\sigma) = \{a \in A \mid \sigma(a) \neq a\} \quad (13.6)$$

In other words, $\text{supp}(\sigma)$ are those elements of A that appear in σ 's cycle representation.

Permutation groups are in, some sense, fundamental because of the following result:

Theorem 13.3.5. (Cayley's Theorem) Every group is isomorphic to a group of permutations.

To illustrate, consider the following permutations defined on the Klein 4-group elements:

$$\lambda_\varepsilon = \begin{bmatrix} \varepsilon & \alpha & \beta & \gamma \\ \varepsilon & \alpha & \beta & \gamma \end{bmatrix} \quad \lambda_\alpha = \begin{bmatrix} \varepsilon & \alpha & \beta & \gamma \\ \alpha & \varepsilon & \gamma & \beta \end{bmatrix}$$

$$\lambda_\beta = \begin{bmatrix} \varepsilon & \alpha & \beta & \gamma \\ \beta & \gamma & \varepsilon & \alpha \end{bmatrix} \quad \lambda_\gamma = \begin{bmatrix} \varepsilon & \alpha & \beta & \gamma \\ \gamma & \beta & \alpha & \varepsilon \end{bmatrix}$$

The set of these four permutations along with permutation multiplication as the binary operation on the set satisfy the definition of a group. Additionally, the Klein 4-group is isomorphic to this permutation group using the mapping $\lambda_\varepsilon \leftrightarrow \varepsilon$, $\lambda_\alpha \leftrightarrow \alpha$, $\lambda_\beta \leftrightarrow \beta$, $\lambda_\gamma \leftrightarrow \gamma$.

It is useful at this point to recast the group of negations \mathcal{N}_n introduced earlier as a group of permutations of the set of positive and negative literals on n Boolean variables. Specifically, \mathcal{N}_2 can be expressed as a group of permutations of the set $\{a, a', b, b'\}$. Denoting these permutations by $\eta_\emptyset, \eta_{\{a, a'\}}, \eta_{\{b, b'\}}$ and $\eta_{\{a, a', b, b'\}}$ where η_S indicates that the literals in the set S should be complemented, we can readily write

$$\eta_\emptyset = \begin{bmatrix} a & a' & b & b' \\ a & a' & b & b' \end{bmatrix} \quad \eta_{\{a, a'\}} = \begin{bmatrix} a & a' & b & b' \\ a' & a & b & b' \end{bmatrix}$$

$$\eta_{\{b, b'\}} = \begin{bmatrix} a & a' & b & b' \\ a & a' & b' & b \end{bmatrix} \quad \eta_{\{a, a', b, b'\}} = \begin{bmatrix} a & a' & b & b' \\ a' & a & b' & b \end{bmatrix}$$

We should note that since the literals of each variable are complements of each other, the above permutations can be re-expressed by listing only the positive literals in the top row of each permutation (and by dropping the negative literals from the subscripts of η):

$$\eta_{\emptyset} = \begin{bmatrix} a & b \\ a & b \end{bmatrix}, \eta_{\{a\}} = \begin{bmatrix} a & b \\ a' & b \end{bmatrix}, \eta_{\{b\}} = \begin{bmatrix} a & b \\ a & b' \end{bmatrix}, \eta_{\{a,b\}} = \begin{bmatrix} a & b \\ a' & b' \end{bmatrix} \quad (13.7)$$

These same permutations can be expressed most succinctly in cycle notation as follows:

$$\eta_{\emptyset} = (), \eta_{\{a\}} = (a, a'), \eta_{\{b\}} = (b, b'), \eta_{\{a,b\}} = (a, a')(b, b') \quad (13.8)$$

where the identity permutation is denoted by $()$. In both (13.7) and (13.8) it is implicitly understood that the underlying set whose elements are being permuted is the set of literals $\{a, a', b, b'\}$.

13.3.5. Group of Negations and Permutations

We are now ready to discuss the group of most relevance to our study of symmetry and satisfiability, namely the group of negations *and* permutations of the literals of an n -variable CNF formula. We will denote this group by \mathcal{NP}_n and refer to it as the group of negations and permutations of n variables, with the understanding that its underlying set consists of $2n$ elements that correspond to the literals of n Boolean variables. Any permutation $\pi \in \mathcal{NP}_n$ must satisfy *Boolean consistency* which requires that when literal \hat{x} is mapped to literal \hat{y} , its negated literal \hat{x}' is also simultaneously mapped to literal \hat{y}' , i.e.,

$$\pi(\hat{x}_i') = [\pi(\hat{x}_i)]' \quad (13.9)$$

It is important to note that a group $G \leq S_{2n}$ that permutes the set of $2n$ literals without any restrictions may contain permutations that violate Boolean consistency; e.g. $(a, b')(a', c)$.

Group \mathcal{NP}_n has two important subgroups: the group of negations of n variables \mathcal{N}_n , and the group of permutations of n variables \mathcal{P}_n ⁵. Fig. 13.5 gives pictorial representations of \mathcal{NP}_2 as well as of its constituent subgroups \mathcal{N}_2 and \mathcal{P}_2 . By convention, when expressing the elements of these groups we will omit the mappings implied by Boolean consistency: thus we will write (a, b') rather than $(a, b')(a', b)$, the latter being implied by the former.

From Fig. 13.5 it is clear that each element of \mathcal{NP}_2 can be expressed as a pair (η, π) where $\eta \in \mathcal{N}_2$ and $\pi \in \mathcal{P}_2$. Furthermore, since both \mathcal{N}_2 and \mathcal{P}_2 are permutation groups, the element $(\eta, \pi) \in \mathcal{NP}_2$ is naturally interpreted as the composition of a negation η followed by a permutation π . For example, $((b, b'), (a, b))$ corresponds to negating b followed by swapping a and b yielding the permutation $(a, b) * (b, b') = (a, b, a', b')$ where the permutation composition operator $*$ is shown explicitly for added clarity.

⁵We prefer to denote the group of permutations of n variables by \mathcal{P}_n rather than by S_n to emphasize that its underlying set is the set of $2n$ literals and that its elements obey Boolean consistency (13.9). Other than that, \mathcal{P}_n and S_n are isomorphic groups.

(a) Group \mathcal{N}_2 : negations of two variables

(b) Group \mathcal{P}_2 : permutations of two variables

(c) Group \mathcal{NP}_2 : negations and permutations of two variables

Figure 13.5. Groups of (a) negations, (b) permutations, and (c) mixed negations and permutations of two variables.

More generally, the group \mathcal{NP}_n is the *semi-direct product* [Har63] of \mathcal{N}_n and \mathcal{P}_n , typically denoted by $\mathcal{N}_n \rtimes \mathcal{P}_n$, whose underlying set is the Cartesian product $\mathcal{N}_n \times \mathcal{P}_n = \{(\eta, \pi) | \eta \in \mathcal{N}_n, \pi \in \mathcal{P}_n\}$ and whose group operation $*$ is defined by:

$$(\eta_1, \pi_1) * (\eta_2, \pi_2) = \pi_1 \eta_1 \pi_2 \eta_2 \tag{13.10}$$

For example, $((a, a'), ()) * ((a, a'), (a, b)) = ()(a, a')(a, b)(a, a') = (a, b')$. Clearly, the order of \mathcal{NP}_n is $2^n \cdot n!$.

Returning to the example function in Sec. 13.1, we can express the four transformations that leave it invariant as the semi-direct product group

$$\begin{aligned} & \{(), (a, a')(b, b')\} \rtimes \{(), (a, b)\} \\ &= \{(), (), ((a, a')(b, b'), ()), ((), (a, b)), ((a, a')(b, b'), (a, b))\} \\ &= \{(), (a, a')(b, b'), (a, b), (a, b')\} \end{aligned} \tag{13.11}$$

Note that these four permutations do in fact constitute a group which, again, is easily seen to be isomorphic to the Klein 4-group.

13.3.6. Group Action on a Set

Finally, let's introduce the notion of a group *action* which is fundamental to the development of symmetry-breaking predicates for CNF formulas of Boolean functions.

Table 13.5. Action table of the group $\{(), (a, a')(b, b'), (a, b), (a, b')\}$ on the set $S = \{0, 1, 2, 3, 4, 5, 6, 7\}$ of truth assignments to a, b, c .

	0	1	2	3	4	5	6	7
$\gamma_0 = ()$	0	1	2	3	4	5	6	7
$\gamma_1 = (a, a')(b, b')$	6	7	4	5	2	3	0	1
$\gamma_2 = (a, b)$	0	1	4	5	2	3	6	7
$\gamma_3 = (a, b')$	6	7	2	3	4	5	0	1

Definition 13.3.12. (Group Action) An *action* of a group G on a set S is a map $G \times S \rightarrow S$ such that:

- $es = s$ for all $s \in S$
- $(g_1g_2)(s) = g_1(g_2s)$ for all $s \in S$ and all $g_1, g_2 \in G$.

The group action that we will be primarily concerned with is the action of a group of negations and permutations of the literals of a Boolean function on the set of points (i.e., truth assignments) in the function's domain. For example, Table 13.5 shows the action of the group of negations and permutations in (13.11) on the set of 8 truth assignments to the variables a, b , and c . It is customary to use superscript notation to indicate the action of a group element on an element of the set being acted on. Thus, e.g., $1^{\gamma_1} = 7$. The notation extends naturally to collections (sets, vectors, graphs, etc.), e.g., $\{0, 4, 6, 7\}^{\gamma_3} = \{0^{\gamma_3}, 4^{\gamma_3}, 6^{\gamma_3}, 7^{\gamma_3}\} = \{6, 4, 0, 1\}$.

A group action on a set induces an equivalence partition on the set according to the following theorem:

Theorem 13.3.6. (Group-Induced Equivalence Partition; Orbits) The action of a group G on a set S induces an equivalence relation on the set. Specifically, for $s_1, s_2 \in S$, let $s_1 \sim s_2$ if and only if there exists $g \in G$ such that $gs_1 = s_2$. Then \sim is an equivalence relation on S that partitions it into equivalence classes referred to as the *orbits* of S under G . The orbits of S under a particular group element $g \in G$ are those that satisfy $s_1 \sim s_2$ if and only if $s_2 = g^n s_1$ for some $n \in \mathbb{Z}$.

Using our running example, we can “extract” the orbits of the four permutations in Table 13.5 by inspection:

$$\begin{aligned}
 \text{orbits}(S, \gamma_0) &= \{0 \mapsto 0, 1 \mapsto 1, 2 \mapsto 2, 3 \mapsto 3, 4 \mapsto 4, 5 \mapsto 5, 6 \mapsto 6, 7 \mapsto 7\} \\
 \text{orbits}(S, \gamma_1) &= \{0 \mapsto 6 \mapsto 0, 1 \mapsto 7 \mapsto 1, 2 \mapsto 4 \mapsto 2, 3 \mapsto 5 \mapsto 3\} \\
 \text{orbits}(S, \gamma_2) &= \{0 \mapsto 0, 1 \mapsto 1, 2 \mapsto 4 \mapsto 2, 3 \mapsto 5 \mapsto 3, 6 \mapsto 6, 7 \mapsto 7\} \\
 \text{orbits}(S, \gamma_3) &= \{0 \mapsto 6 \mapsto 0, 1 \mapsto 7 \mapsto 1, 2 \mapsto 2, 3 \mapsto 3, 4 \mapsto 4, 5 \mapsto 5\}
 \end{aligned} \tag{13.12}$$

where $S = \{0, 1, 2, 3, 4, 5, 6, 7\}$ and $x \mapsto y$ means that x is mapped to y by the corresponding permutation. Using the more familiar partition notation, these

same orbits can be equivalently expressed as follows:

$$\begin{aligned}
 \text{partition}(S, \gamma_0) &= \{0|1|2|3|4|5|6|7\} \\
 \text{partition}(S, \gamma_1) &= \{0,6|1,7|2,4|3,5\} \\
 \text{partition}(S, \gamma_2) &= \{0|1|2,4|3,5|6|7\} \\
 \text{partition}(S, \gamma_3) &= \{0,6|1,7|2|3|4|5\}
 \end{aligned} \tag{13.13}$$

The *orbit partition* of S under the group $\{\gamma_0, \gamma_1, \gamma_2, \gamma_3\}$ is now simply the union of the orbits/partitions in (13.12)/(13.13):

$$\begin{aligned}
 \text{orbit partition}(S, \{\gamma_0, \gamma_1, \gamma_2, \gamma_3\}) &= \bigcup_{i \in \{0,1,2,3\}} \text{partition}(S, \gamma_i) \\
 &= \{0,6|1,7|2,4|3,5\}
 \end{aligned} \tag{13.14}$$

Given an element $s \in S$, its orbit under G is the cell in the orbit partition that contains s and is conventionally written as Gs . For example, from (13.14), we get $G0 = \{0,6\}$, $G7 = \{1,7\}$, etc.

A group action on a set distinguishes certain subgroups as *stabilizers*.

Definition 13.3.13. (Stabilizer Subgroup) Given $s \in S$, the subgroup of G that “fixes” s is denoted G_s and defined as $\{\gamma \in G | \gamma s = s\}$. G_s is referred to as the stabilizer of s .

Continuing with the example group in Table 13.5 we note that two of its three non-trivial subgroups are stabilizers. Specifically, $\{\gamma_0, \gamma_2\}$ stabilizes assignments 0, 1, 6, and 7, and can be equivalently denoted as G_0, G_1, G_6 , or G_7 . Similarly, $\{\gamma_0, \gamma_3\}$ stabilizes 2, 3, 4, and 5. The third subgroup $\{\gamma_0, \gamma_1\}$ is not a stabilizer.

13.4. CNF Symmetry

Symmetries of a Boolean function can be classified as being either *semantic* or *syntactic*. Semantic symmetries are intrinsic properties of the function that are independent of any particular representation we may choose for it. In contrast, syntactic symmetries correspond to specific algebraic representations of the function, e.g., an SOP, POS, or some nested expression that might correspond to a circuit representation. Our focus will be on the CNF representation of a function since it is the usual form that is processed by SAT solvers. We should note, however, that a given function can be represented by many equivalent CNF formulas. In particular, some of these formulas are unique representations and can, thus, be used to identify a function’s semantic symmetries. Examples of such unique CNF forms include the set of a function’s maxterms, the complete set of its prime implicants, or (if it exists) its unique minimal CNF expression. Such representations, however, are generally exponential in the number of variables rendering any attempt to analyze them intractable.

As mentioned in Sec. 13.3.5, we consider the invariance of an n -variable CNF formula $\varphi(X)$ under a) negation, b) permutation, and c) combined negation and permutation of its variables. We will refer to the symmetries that arise under

Table 13.6. Symmetries of different CNF formulas for the example function in (13.1). The formula in row 1 consists of the function’s maxterms, whereas that in row 2 is the function’s complete set of prime implicants. These two forms are unique and will always yield the function’s semantic symmetries. Other unique CNF representations, such as a unique minimal CNF form (which in the case of this function is the same as the complete set of prime implicants) will also yield the group of semantic symmetries. The remaining formulas will, generally, yield syntactic symmetries which are subgroups of the group of semantic symmetries.

(Equivalent) CNF Formulas	Symmetries			
	Identity ()	Variable (a, b)	Value (a, a')(b, b')	Mixed (a, b')
1. $(a + b + c)(a + b + c')(a + b' + c)$ $(a' + b' + c)(a' + b' + c')(a' + b + c)$	✓	✓	✓	✓
2. $(a + b)(a' + b')(c)$	✓	✓	✓	✓
3. $(a + b)(a' + b')(a' + c)(a + c)$	✓	✓	✓	✓
4. $(a + b)(a' + b' + c')(c)$	✓	✓		
5. $(a + c)(a' + c)(a' + b' + c')(a + b + c')$	✓		✓	
6. $(a + b)(a' + b')(a + b' + c)(c)$	✓			✓
7. $(a + b)(b' + c)(a' + b' + c)(c)$	✓			

these three types of transformation as *value*, *variable*, and *mixed* symmetries, respectively, and denote the resulting symmetry group by G_φ . Clearly, G_φ is a subgroup of \mathcal{NP}_n , i.e., $G_\varphi \leq \mathcal{N}_n \times \mathcal{P}_n$. The action of G_φ on the formula’s literals results in a re-ordering of the formula’s clauses and of the literals within the clauses while preserving Boolean consistency (13.9).

While it may be obvious, it is useful to demonstrate how different CNF formulas for the same function can have drastically different symmetries, or even no symmetries other than the identity. Table 13.6 gives the symmetries of seven different formulas for our example function (13.1). Clearly, a good *encoding* is necessary if we are to reap the benefits of symmetry detection and breaking.

13.5. Automorphism Group of a Colored Graph

So far we have been concerned with what groups are and what properties they have. Here we introduce one last group, the automorphism group of a colored graph, and sketch the basic procedure for computing it. As we show in Sec. 13.6, the symmetries of a CNF formula can be derived by computing the automorphism group of an associated graph. Efficient algorithms for graph automorphism are, thus, a critical link in the overall symmetry detection and breaking flow.

Definition 13.5.1. (Automorphism Group [McK81]) Given a graph⁶ $G = (V, E)$, with vertex set $V = \{1, 2, \dots, n\}$ and edge set E , along with a partition $\pi(V) = \{V_1 | V_2 | \dots | V_k\}$ of its vertices, its *automorphism group* $\text{Aut}(G, \pi)$ is $\{\gamma \in S_n | G^\gamma = G \text{ and } \pi^\gamma = \pi\}$, where $G^\gamma = (V^\gamma, E^\gamma)$ with $E^\gamma = \{(u^\gamma, v^\gamma) | (u, v) \in E\}$ and $\pi^\gamma = \{V_1^\gamma, \dots, V_k^\gamma\}$.

In other words, $\text{Aut}(G, \pi)$ is the set of permutations of the graph vertices that map edges to edges and non-edges to non-edges with the restriction that vertices

⁶The use of G and π in this definition to denote *graph* and *partition*, respectively, should not be confused with their earlier use to denote *group* and *permutation*.

in any given cell of π can only be mapped to vertices in that same cell. It is customary to consider the partition $\pi(V)$ as an assignment of k different colors to the vertices and to view it as a constraint that disallows permutations that map vertices of some color to vertices of a different color. We will be principally interested in *ordered partitions*, also called *colorings*, of the vertices. Thus, $\pi(V)$ will be specified with square, rather than curly, brackets: $\pi(V) = [V_1 | V_2 | \dots | V_k]$.

The importance of the graph automorphism problem in the context of symmetry detection for CNF formulas stems from the fact that it can be solved fairly efficiently for a large class of graphs. In fact, while this problem is known to be in the complexity class NP [GJ79], it is still an open question whether it is NP-complete or is in P. A straightforward, but hopelessly impractical, procedure for computing $\text{Aut}(G, \pi)$ is to explicitly enumerate all permutations in S_n and to discard those that are not symmetries of G . Efficient graph automorphism algorithms employ more intelligent implicit enumeration procedures that drastically reduce the number of individual permutations that must be examined. The kernel computation in such algorithms is an *ordered partition refinement* procedure similar to that used for state minimization of finite-state automata [AHU74], and their underlying data structure is a search tree whose nodes represent colorings of the graph vertices.

Definition 13.5.2. (Color-Relative Vertex Degree) Given a coloring $\pi(V) = [V_1 | V_2 | \dots | V_k]$ of the graph G and a vertex $v \in V$, let $d(v, V_i)$ be the number of vertices in V_i that are adjacent to v in G . Note that $d(v, V)$ is simply the degree of v in G .

Definition 13.5.3. (Stable/Equitable Coloring) A coloring π is *stable* (also referred to as equitable) if

$$d(u, V_i) = d(v, V_i), \quad 1 \leq i \leq |\pi|$$

for all pairs of vertices $u, v \in V_j, 1 \leq j \leq |\pi|$.

Ordered partition refinement transforms a given initial coloring π into a final *coarsest* stable coloring $\pi' \leq \pi$ by repeatedly splitting cells containing vertices with different vertex degrees (relative to the current coloring). Fig. 13.6 illustrates this procedure on a sample 2-colored graph with 9 vertices. The initial coloring π consists of two cells corresponding to the graph's two types of vertices (square and round). In the first refinement iteration, vertex 3 is split off from V_1 because its degree relative to V_2 is different from those of the two other vertices in V_1 . In other words, vertex 3 can be *distinguished* from vertices 1 and 2 and cannot possibly be mapped to either by a graph symmetry. Similarly, vertex 9 is split off from V_2 yielding the intermediate coloring $\hat{\pi}$. The second refinement iteration splits vertex 8 from V_3 yielding the final stable coloring π' .

If the refinement procedure returns a discrete coloring π' , i.e. every cell of the partition is a singleton, then all vertices can be distinguished, implying that G has no symmetries besides the identity. However, if π' is not discrete, then there is some non-singleton cell in π' representing vertices that could not be distinguished based on degree and are, thus, candidates for some symmetry. This is checked by

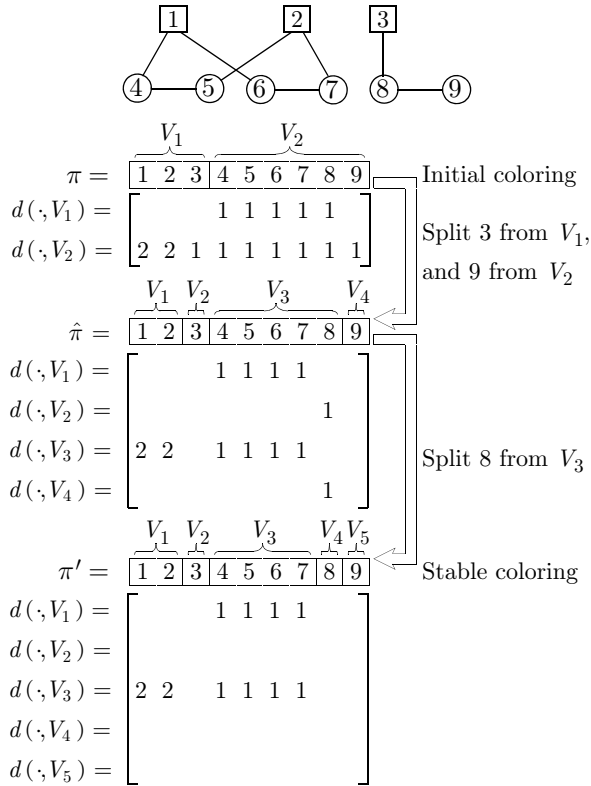

Figure 13.6. Illustration of ordered partition refinement. The “matrix” of vertex degrees is indicated under each coloring (zero entries are shown as blanks, and the degrees of singleton cells are not shown). Efficient implementations of this procedure compute only those vertex degrees necessary to trigger refinement.

selecting some non-singleton cell T of π' , called the *target cell*, and forming $|T|$ descendant colorings from π' , each identical to π' except that a distinct $t \in T$ is placed in front of $T - \{t\}$. Each of these colorings is subsequently refined, and further descendant colorings are generated if the refined colorings are not discrete; this process is iterated until discrete colorings are reached. The colorings explored in this fashion form a *search tree* with the discrete colorings at the leaves.

Fig.13.7 illustrates this process for an example 6-vertex graph. The initial coloring has a single cell since all vertices have the same color. Refinement yields a stable coloring with two non-singleton cells. At this point, the first cell is chosen as a target, and we branch by creating three descendant colorings. The process is now repeated (i.e., we refine each derived coloring and branch from it if it has non-singleton cells) in a depth-first manner until discrete colorings are reached. In this example, the search tree terminates in six leaves corresponding to six different discrete colorings.

The next step in the process is to derive from these colorings permutations

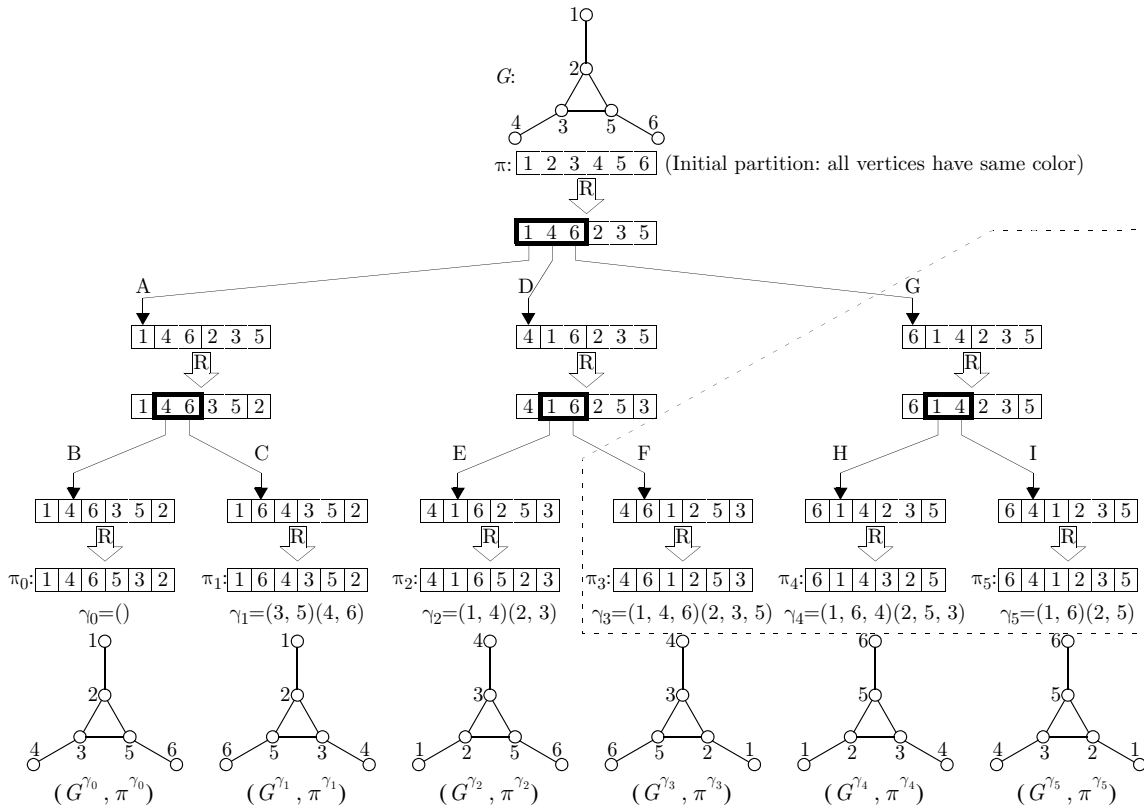

Figure 13.7. Basic flow of the ordered partition refinement procedure for computing the automorphism group of an example 6-vertex single-colored graph. Each node in the search tree is a sequence of ordered partitions (obtained using the partition refinement procedure illustrated in Fig. 13.6 and indicated by the fat arrows labeled with ‘R’) ending with a stable coloring. The tree is traversed in the order A-B-C-D-E-F-G-H-I.

Table 13.7. Automorphism results on a sample of very large sparse graphs (sorted in descending order by number of vertices) using a modern graph automorphism tool. The *bigblue* and *adaptec* graphs are derived from circuits used in the ISPD 2005 placement competition [ISP]. The *CA* and *FL* graphs represent, respectively, the road networks of California and Florida [U.S]. The *Internet* graph represents the interconnections of the major routers on the Internet's North American backbone [CBB00, GT00]. Note the extreme sparsity of each of these graphs and of their symmetry generators. Note also the astronomical orders of the graphs' automorphism groups. These data are from [DSM08].

of the graph vertices that correspond to graph symmetries. This is done by choosing one of these colorings as a reference, and computing the permutations that transform it to the other colorings. For the example of Fig.13.7, we chose the left-most coloring π_0 as the reference; the permutations that convert it to the other colorings, including itself, are labeled γ_0 to γ_5 . Each such permutation γ_i is now checked to determine if it is a graph symmetry, i.e., if $G^{\gamma_i} = G$. In this example all six permutations are indeed symmetries of the graph, yielding $\text{Aut}(G) = \{\gamma_0, \gamma_1, \gamma_2, \gamma_3, \gamma_4, \gamma_5\}$. A permutation that does not correspond to a symmetry of the graph triggers backtracking in the search tree so that other branches can be explored.

While the above sketch of graph automorphism algorithms is sufficient for a basic understanding of how they operate, we should note that their performance in practice depends critically on aggressive pruning of the search tree to avoid deriving permutations that can be obtained as the product of other permutations that have already been found. For our running example, the portion of the search tree enclosed by the dashed outline (nodes F, G, H, and I) can be safely pruned away since the permutations identified at its leaves can be expressed in terms of permutations γ_1 and γ_2 . Ideally, the output of a graph automorphism algorithm should be a *minimal* set of irredundant generators. In practice, however, the overhead of performing the group-theoretic pruning necessary to guarantee this outcome tends to be excessive. Instead, graph automorphism tools are designed to produce at most $n - 1$ generators for an input graph with n vertices, providing an exponentially smaller but not necessarily minimal representation of the complete set of symmetries.

Modern implementations of graph automorphism can process graphs with millions of vertices in a matter of seconds on commodity personal computers. Key to this remarkable performance is the extreme *sparsity* of both the graphs themselves and the generators of their symmetry groups. In this context, sparsity is taken to mean that the average vertex degree in the graph and the average

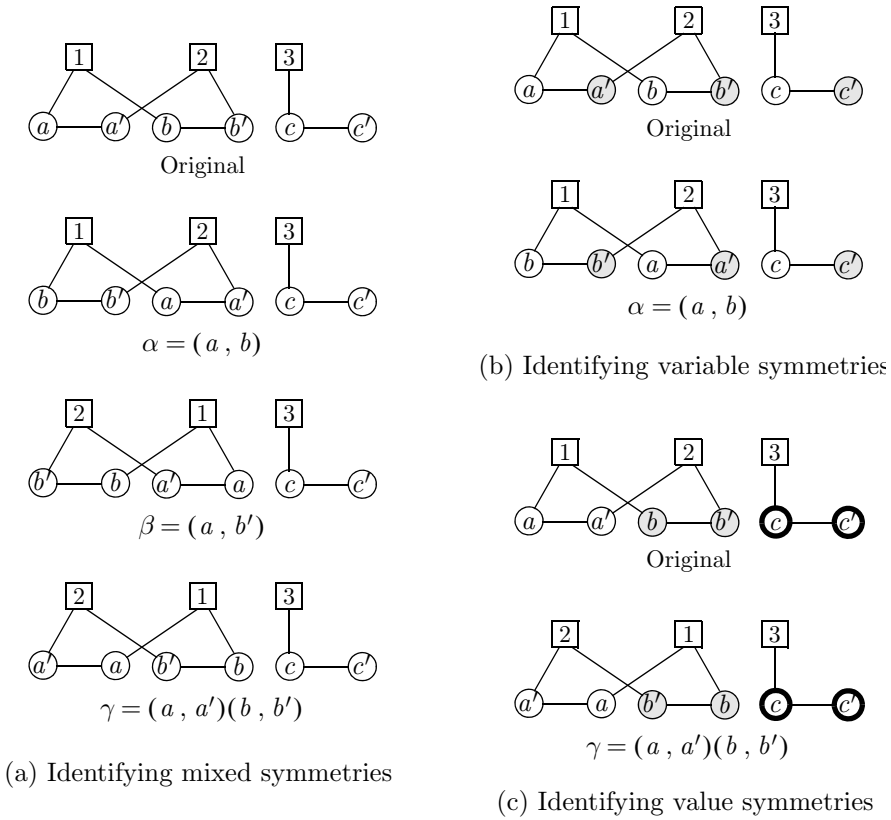

Figure 13.8. Colored graph constructions and resultant symmetries for the example formula $(a + b)(a' + b')(c)$. (a) Using two colors (square vertices: color 0; circle vertices: color 1) yields the symmetry group $G = \{(), (a, b), (a, b'), (a, a')(b, b')\}$. (b) Using three colors (shaded circles: color 2) yields the symmetry group $G = \{(), (a, b)\}$. (c) Using four colors (bolded circles: color 3) yields the symmetry group $G = \{(), (a, a')(b, b')\}$.

support of the resulting symmetry generators are both much smaller than the number of graph vertices. Incorporating knowledge of both types of sparsity in the basic automorphism algorithm can result in substantial pruning of the search tree, essentially yielding a tree whose size is linear, rather than quadratic, in the total support of the symmetry generators [DSM08]. Table 13.7 provides empirical evidence of these observations on a number of very large sparse graphs.

13.6. Detection of CNF Symmetries

The basic approach for identifying the symmetries of a CNF formula is through reduction to, and solution of, an associated colored graph automorphism problem. Specifically, given a CNF formula consisting of m clauses and l (total) literals over n variables, construct a corresponding colored graph with $m + 2n$ vertices and

$l + n$ edges as follows:

- **Clause vertices:** represent each of the m clauses by a vertex of color 0
- **Positive literal vertices:** represent each of the n positive literals by a vertex of color 1
- **Negative literal vertices:** represent each of the n negative literals by a vertex of color 1
- **Clause edges:** represent each of the m clauses by a set of edges that connect the clause vertex to the vertices of the literals that appear in the clause
- **Boolean consistency edges:** connect each pair of literal vertices that correspond to the same variable by an edge

The choice of two vertex colors insures that clause vertices can only be mapped to clause vertices and literal vertices can only be mapped to literal vertices. Using one color for all literal vertices also makes it possible to detect the mixed symmetries of the formula. Pure variable and pure value symmetries can be identified by using more colors for the literal vertices. Specifically, variable symmetries can be identified by using two colors: color 1 for positive literal vertices and color 2 for negative literal vertices. Identifying pure value symmetries requires n colors: color 1 for the literals of the first variable, color 2 for the literals of the second variable, and so on. This construction, thus, is general enough to identify variable, value, and mixed symmetries by a suitable assignment of colors to literal vertices. Fig. 13.8 illustrates these variants, along with the symmetries they yield, for the three-variable CNF formula $(a + b)(a' + b')(c)$ of our example function in (13.1).

Noting that graph automorphism algorithms tend to be more sensitive to the number of vertices of an input graph than to the number of its edges, the above construction can be optimized to reduce the number of graph vertices while preserving its automorphism group. Specifically, single-literal clauses can be eliminated through Boolean Constraint Propagation (BCP) yielding an equivalent formula that has only clauses with 2 or more literals each. A further reduction in the number of graph vertices is achieved by modeling binary clauses (i.e., 2-literal clauses) using graph edges instead of graph vertices. As we demonstrate shortly, the CNF formulas used to model problems from a variety of application domains tend to have a large fraction of binary clauses. Thus, this optimization is particularly significant for the overall efficiency of symmetry detection. Care must be taken, however, when applying this optimization since it may, on rare occasions, lead to spurious symmetries that result from unintended mappings between binary clause edges and Boolean consistency edges. Such symmetries violate the Boolean consistency requirement (13.9) and, as shown in [ARMS03], arise when the CNF formula contains chains of implications such as $(x'_1 + x_2)(x'_2 + x_3) \cdots (x'_k + x_1)$. The set of generators returned by a graph automorphism program must, thus, be checked for members that violate (13.9) before reporting the results back. Several options of how to filter these spurious symmetries are described in [ARMS03].

The results of applying the above graph construction to detect the symmetries of a selection of CNF instances are given in Table 13.8. These instances are drawn from the following six benchmark families.

- **Hole:** This is the family of unsatisfiable pigeon-hole instances. Instance ‘hole n ’ corresponds to placing $n + 1$ pigeons in n holes [DIM].
- Difficult CNF instances that represent the routing of wires in integrated circuits [ARMS02, ARMS03]. This family includes three members: the first two share the characteristic of the pigeon-hole family (namely placing n objects in m slots such that each object is in a slot and no two objects are in the same slot) whereas the third member is based on the notion of *randomized flooding*:
 - **ChnlRoute:** This is a family of unsatisfiable channel routing instances. Instance ‘chnl n _ m ’ models the routing of m wires through n tracks in a routing channel.
 - **FPGARoute:** This is a family of satisfiable instances that model the routing of wires in the channels of field-programmable integrated circuits [NASR01]. Instance ‘fpga n _ m ’ models the routing of m wires in channels of n tracks.
 - **GRoute:** This is a family of randomly-generated satisfiable instances that model the routing of global wires in integrated circuits. Instance ‘sn- m - c - k ’ corresponds to global routing of wires on an n -by- m grid with *edge capacity* between grid cells equal to c tracks. The last integer k in the instance name serves as the instance identifier.
- **Urq:** This is the family of unsatisfiable randomized instances based on expander graphs [Urq87].
- **XOR:** This is a family of various *exclusive or* chains from the SAT’02 competition [SAT].
- **Pipe:** This is a family of difficult unsatisfiable instances that model the functional correctness requirements of modern out-of-order microprocessor CPUs [VB01].

The results in Table 13.8 were generated by a) constructing three colored graphs for each CNF instance and, b) using the **saucy** graph automorphism program [DLSM04] to obtain corresponding sets of generators for the graphs’ automorphism groups. These generators were then postprocessed (by dropping cycles that permute clause vertices, and by relabeling negative literal vertices to relate them back to their positive literals) to obtain the symmetry generators of the CNF instance. The generator sets corresponding to the three graph variants identify, respectively, a formula’s mixed, variable, and value symmetries. The experiments were conducted on a 3GHz Intel Xeon workstation with 4GB RAM running the Redhat Linux Enterprise operating system.

For each benchmark instance, the table lists the following data:

- Instance parameters: family, name, number of variables, total number of clauses, number of binary clauses, number of literals, and number of vertices in the corresponding colored graph.
- Symmetry group characteristics for each of the three variants of the colored graph: group order, number of generators along with their total support, and symmetry detection time.

Examination of the data in Table 13.8 leads to the following general observations:

- Except for the Pipe microprocessor verification benchmarks which only have a handful of symmetries, the number of symmetries in these instances is extremely large.
- Symmetry detection is very fast, in most cases taking only tiny fractions of a second. The notable exceptions are the GRoute benchmarks and the larger Urq benchmarks which require on the order of a few seconds. This is partly explained by the large graphs used to model them which, unlike those of the other instances, have thousands rather than hundreds of vertices. On the other hand, the fast detection times for the Pipe instances, despite their large graphs, can be attributed to the small number of symmetries in those graphs.
- While **saucy** guarantees that the maximum number of generators it outputs will be no more than the number of graph vertices minus one, in all cases the number of produced generators is much less. In fact, the logarithmic upper bound given in Theorem 13.3.3 for the size of an irredundant set of generators is reached only for the Urq and Pipe benchmarks. The number of generators in other cases is less than this bound, sometimes by a large factor.
- The Hole and wire routing benchmarks exhibit only pure variable symmetries. This is to be expected as these benchmarks essentially involve some sort of capacity constraint on a set of interchangeable variables. Note also that the two varieties of colored graphs corresponding to mixed and variable symmetries yield the same number of generators in all cases.
- The Urq and XOR benchmarks, except for x1_16, exhibit only pure value symmetries. Again the graphs for mixed and value symmetries yield the same number of generators in those cases. But note that the support of these generators is different suggesting that **saucy** is producing different sets of mixed and value symmetry generators. The x1_16 instance is the only one in the entire set of benchmarks in the table to have all types of symmetry: 2 variable permutations, $6.55E+4$ variable negations, and their composition.
- The Pipe benchmarks do not have any value symmetries, but do have variable symmetries and mixed symmetries that involve simultaneous variable permutations and negations.
- Finally, the support of the symmetry generators in all cases is a very small fraction of the total number of variables, ranging from 4% to 29% with a mean of 13%. In other words, the generators are extremely sparse.

We should note that these benchmarks are relatively small and that it is quite conceivable that other benchmark families might yield a different set of results. However, it seems safe to assume that the detection of the symmetries of CNF formulas through reduction to graph automorphism is computationally quite feasible using today's graph automorphism programs, and that the use of such programs as pre-processors for SAT solvers can be a viable approach in many cases.

Table 13.9. Symmetries of the formula $\varphi(a, b, c) = (a + b' + c')(a + b + c)(a' + b + c')$ along with their orbits and lex-leader predicates (the lex-leaders in each orbit are shown in bold.) Note that we have omitted the identity permutation π_0 since each of the 8 truth assignments will be in its own orbit yielding a lex-leader predicate which is the constant 1 function.

Permutation	Orbits	Lex-Leader Predicate
$\pi_1 = (a, b)$	$\{\mathbf{0} \mapsto 0, \mathbf{1} \mapsto 1, \mathbf{2} \mapsto 4 \mapsto 2, \mathbf{3} \mapsto 5 \mapsto 3, \mathbf{6} \mapsto 6, \mathbf{7} \mapsto 7\}$	$\sum_{(a,b,c)} (0, 1, 2, 3, 6, 7) = (a' + b)$
$\pi_2 = (a, c')$	$\{\mathbf{0} \mapsto 5 \mapsto 0, \mathbf{1} \mapsto 1, \mathbf{2} \mapsto 7 \mapsto 2, \mathbf{3} \mapsto 3, \mathbf{4} \mapsto 4, \mathbf{6} \mapsto 6\}$	$\sum_{(a,b,c)} (0, 1, 2, 3, 4, 6) = (a' + c')$
$\pi_3 = (b, c')$	$\{\mathbf{0} \mapsto 3 \mapsto 0, \mathbf{1} \mapsto 1, \mathbf{2} \mapsto 2, \mathbf{4} \mapsto 7 \mapsto 4, \mathbf{5} \mapsto 5, \mathbf{6} \mapsto 6\}$	$\sum_{(a,b,c)} (0, 1, 2, 4, 5, 6) = (b' + c')$
$\pi_4 = (a, b, c')$	$\{\mathbf{0} \mapsto \mathbf{3} \mapsto 5 \mapsto 0, \mathbf{1} \mapsto 1, \mathbf{2} \mapsto 7 \mapsto 4 \mapsto 2, \mathbf{6} \mapsto 6\}$	$\sum_{(a,b,c)} (0, 1, 2, 3, 6) = (a' + b)(a' + c')$
$\pi_5 = (a, c', b)$	$\{\mathbf{0} \mapsto 5 \mapsto 3 \mapsto 0, \mathbf{1} \mapsto 1, \mathbf{2} \mapsto \mathbf{4} \mapsto 7 \mapsto 2, \mathbf{6} \mapsto 6\}$	$\sum_{(a,b,c)} (0, 1, 2, 4, 6) = (a' + c')(b' + c')$
Group	Equivalence Classes	Lex-Leader Predicate
$\{\pi_0, \pi_1, \pi_2, \pi_3, \pi_4, \pi_5\}$	$\{\mathbf{0}, \mathbf{3}, \mathbf{5} \mid \mathbf{1} \mid \mathbf{2}, \mathbf{4}, \mathbf{7} \mid \mathbf{6}\}$	$\sum_{(a,b,c)} (0, 1, 2, 6) = (a' + b)(b' + c')$

13.7. Symmetry Breaking

Given a CNF formula $\varphi(X)$ along with its group of symmetries G_φ the goal now is to augment $\varphi(X)$ with additional predicates that break all of its symmetries. Recall that G_φ induces an equivalence relation on the set of truth assignments, i.e., it partitions the space of possible assignments into equivalence classes. Complete symmetry breaking amounts to constructing predicates that select exactly one representative assignment from each equivalence class. The most common approach for accomplishing this objective is to order the assignments numerically, and to use the *leq* predicate introduced in Sec. 13.2 to choose the least assignment in each equivalence class. Specifically, let $\text{PP}(\pi; X)$ denote the *permutation predicate* of permutation $\pi \in G_\varphi$ defined as:

$$\begin{aligned} \text{PP}(\pi; X) &= \text{leq}(X, X^\pi) \\ &= \bigwedge_{i=0}^{n-1} \left[\bigwedge_{j=i+1}^{n-1} (x_j = x_j^\pi) \right] \rightarrow (x_i \leq x_i^\pi) \end{aligned} \quad (13.15)$$

$\text{PP}(\pi; X)$ is a Boolean function that evaluates to 1 for each assignment X^* such that $X^* \leq \pi(X^*)$ and evaluates to 0 otherwise. More specifically, let $X_0^* \mapsto X_1^* \mapsto \dots \mapsto X_{k-1}^* \mapsto X_0^*$ be an orbit of π , i.e. π maps each assignment X_i^* to the next assignment $X_{(i+1) \bmod k}^*$; then $\text{PP}(\pi; X)$ is true for only those assignments that are numerically smaller than their successor assignments as we traverse the orbit. In particular, $\text{PP}(\pi; X)$ will be true for the smallest assignment in the orbit. We will refer to $\text{PP}(\pi; X)$ as a *lex-leader predicate* for permutation π . We can now construct a Boolean predicate that breaks *every* symmetry in G_φ by conjoining all of its permutation predicates:

$$\rho(G_\varphi; X) = \bigwedge_{\pi \in G_\varphi} \text{PP}(\pi; X) \quad (13.16)$$

This symmetry-breaking predicate (SBP) will be true for exactly the least assignment in each equivalence class induced by G_φ on the set of truth assignments. An example illustrating the construction of this predicate is shown in Table 13.9.

Using the SBP in (13.16), we can now determine the satisfiability of $\varphi(X)$ by invoking a SAT solver on the formula

$$\psi(X) \equiv \varphi(X) \wedge \rho(G_\varphi; X) \quad (13.17)$$

Clearly, if $\varphi(X)$ is unsatisfiable, then so is $\psi(X)$. On the other hand, if $\varphi(X)$ is satisfiable then its restriction by $\rho(G_\varphi; X)$ preserves only those solutions that are *numerically least* in their orbits. Either way, we can determine the satisfiability of $\varphi(X)$ by, instead, checking the satisfiability of $\psi(X)$.

To apply a SAT solver to (13.17), the permutation predicates in (13.15) must first be converted to CNF. A simple way to accomplish this is to introduce n auxiliary *equality* variables

$$e_i \equiv (x_i = x_i^\pi), \quad 0 \leq i \leq n-1 \quad (13.18)$$

allowing us to re-write (13.15) as

$$\text{PP}(\pi; X) = \bigwedge_{i \in [0, n-1]} (e'_{i+1} + e'_{i+2} + \cdots + e'_{n-1} + x'_i + x_i^\pi) \quad (13.19)$$

This leads to a CNF representation of the permutation predicate whose size is

$$\begin{aligned} \text{clauses}(\text{PP}(\pi; X)) &= 5n \\ \text{literals}(\text{PP}(\pi; X)) &= 0.5(n^2 + 27n) \end{aligned} \quad (13.20)$$

Table 13.10. Comparison of CNF formula size and permutation predicate size from (13.20)

The size of a single permutation predicate can, thus, significantly exceed the size of the original formula! Table 13.10 compares the size of each benchmark in Table 13.8 to the size of a single permutation predicate as formulated in (13.18) and (13.19). In practice, this dramatic increase in the size of the formula negates much of the hoped-for reduction in the search space due to symmetry breaking. This is further compounded by the fact that full symmetry breaking requires adding, according to (13.16), a quadratically-sized predicate *for each permutation in the symmetry group*. As the data in Table 13.8 clearly demonstrate, the orders of the symmetry groups for most benchmarks are exponential in the number of variables, rendering direct application of (13.18)-(13.19) infeasible.

This analysis may suggest that we have reached an impasse: the theoretical possibility of significantly pruning the search space by breaking a formula's symmetries seems to be at odds with the need to add an exponentially-sized SBP to the formula causing a SAT solver to grind to a halt. We show next a practical approach to resolve this impasse and demonstrate its effectiveness on the benchmark families analyzed in Sec. 13.6. The approach rests on two key ideas: a) reducing the size of the permutation predicate so that it becomes sub-linear, rather than quadratic, in the number of variables, and b) relaxing the requirement to break all symmetries and opting, instead, to break "enough" symmetries to reduce SAT search time.

13.7.1. Efficient Formulation of the Permutation Predicate

To obtain an efficient CNF representation of the permutation predicate in (13.15) it is necessary to introduce some additional notation that facilitates the manipulation of various subsets of the variables $\{x_i | 0 \leq i \leq n - 1\}$. Let I_n denote the integer set $\{0, 1, \dots, n - 1\}$, and let upper-case "index variables" I and J denote non-empty subsets of I_n as appropriate. Given an index set I and an index $i \in I$, define the *index selector* functions:

$$\begin{aligned} \text{pred}(i, I) &= \{j \in I \mid j < i\} \\ \text{succ}(i, I) &= \{j \in I \mid j > i\} \end{aligned} \tag{13.21}$$

A permutation is said to be a *phase-shift* permutation if it contains one or more 2-cycles that have the form (x_i, x'_i) , i.e., cycles that map a variable to its complement. Such cycles will be referred to as *phase-shift cycles*. Given a permutation π , we now define

$$\text{ends}(\pi) = \{i \in I_n \mid i \text{ is the smallest index of a literal in a non-phase-shift cycle of } \pi\} \tag{13.22}$$

and

$$\text{phase-shift}(\pi) = \max \{i \in I_n \mid x_i^\pi = x'_i\} \tag{13.23}$$

In other words, based on the assumed total ordering $x_{n-1} \succ x_{n-2} \succ \dots \succ x_0$, $\text{ends}(\pi)$ identifies the *last* literal in each non-phase-shift cycle of π whereas $\text{phase-shift}(\pi)$ identifies the literal of the *first* phase-shift cycle.

We begin the simplification of the permutation predicate in (13.15) by rewriting it as a conjunction of *bit predicates*:

$$\text{BP}(\pi; x_i) = \left[\bigwedge_{j \in \text{succ}(i, I_n)} (x_j = x_j^\pi) \right] \rightarrow (x_i \leq x_i^\pi) \quad (13.24)$$

$$\text{PP}(\pi; X) = \bigwedge_{i \in I_n} \text{BP}(\pi, x_i) \quad (13.25)$$

Minimization of the CNF representation of the permutation predicate is based on two key optimizations. The first utilizes the *cycle structure* of a permutation to eliminate tautologous bit predicates and is accomplished by replacing I_n in (13.24) and (13.25) with $I \subset I_n$ where $|I| \ll n$. This optimization can be viewed as replacing n in (13.20) by a much smaller number m . The second optimization decomposes the multi-way conjunction in (13.24) into a chain of 2-way conjunctions to yield a CNF formula whose size is linear, rather than quadratic, in m . Fig. 13.9 provides an example illustrating these optimizations.

Elimination of redundant BPs. Careful analysis of (13.24) reveals three cases in which a BP is tautologous, and hence redundant. The first corresponds to bits that are mapped to themselves by the permutation, i.e., $x_i^\pi = x_i$. This makes the consequent of the implication in (13.24), and hence the whole bit predicate, unconditionally true. With a slight abuse of notation, removal of such BPs is easily accomplished by replacing the index set I_n in (13.24) and (13.25) with $\text{supp}(\pi)$ ⁷. For sparse permutations, i.e., permutations for which $|\text{supp}(\pi)| \ll n$, this change alone can account for most of the reduction in the CNF size of the PP.

The second case corresponds to the BP of the last bit in each non-phase-shift cycle of π . “Last” here refers to the assumed total ordering on the variables. Assume a cycle involving the variables $\{x_j | j \in J\}$ for some index set J and let $e = \min(J)$. Such a cycle can always be written as (x_s, \dots, x_e) where $s \in J$. Using equality propagation, the portion of the antecedent in (13.24) involving the variables of this cycle can, thus, be simplified to:

$$\left[\bigwedge_{j \in J - \{e\}} (x_j = x_j^\pi) \right] = (x_s = x_e)$$

and since $(x_s = x_e) \rightarrow (x_e \leq x_s)$ is a tautology, the whole bit predicate becomes tautologous. Elimination of these BPs is accomplished by a further restriction of the index set in (13.24) and (13.25) to just $\text{supp}(\pi) - \text{ends}(\pi)$ and corresponds to a reduction in the number of BPs from n to $m = |\text{supp}(\pi)| - \text{cycles}(\pi)$ where $\text{cycles}(\pi)$ is the number of non-phase-shift cycles of π .

The third and last case corresponds to the BPs of those bits that occur after the first “phase-shifted variable.” Let i be the index of the first variable for which $x_i^\pi = x_i'$. Thus, $e_i = 0$ and all BPs for $j < i$ have the form $0 \rightarrow (x_j \leq x_j^\pi)$ making them unconditionally true.

⁷Technically, we should replace I_n with $\{i \in I_n | \dot{x}_i \in \text{supp}(\pi)\}$.

$$\pi = \begin{pmatrix} x_9 & x_8 & x_7 & x_6 & x_5 & x_4 & x_3 & x_2 & x_1 & x_0 \\ x_6 & x_8 & x_2 & x_9 & x'_5 & x'_7 & x_3 & x'_4 & x_1 & x_0 \end{pmatrix} = (x_9, x_6)(x_7, x_2, x'_4)(x_5, x'_5)$$

$$\text{supp}(\pi) = \{2, 4, 5, 6, 7, 9\}, \text{phase-shift}(\pi) = 5, \text{ends}(\pi) = \{2, 6\}$$

$$I = \text{supp}(\pi) - \text{ends}(\pi) - \text{pred}(\text{phase-shift}(\pi), I_{10}) = \{5, 7, 9\}$$

(a) Permutation in tabular and cycle notation, along with various associated index sets.

$$\text{BP}(\pi, x_9) = (x_9 \leq x_6)$$

$$\boxed{\text{BP}(\pi, x_8) = (x_9 = x_6) \rightarrow (x_8 \leq x_8)}$$

$$\text{BP}(\pi, x_7) = (x_9 = x_6)(x_8 = x_8) \rightarrow (x_7 \leq x_2)$$

$$\boxed{\text{BP}(\pi, x_6) = (x_9 = x_6)(x_8 = x_8)(x_7 = x_2) \rightarrow (x_6 \leq x_9)}$$

$$\text{BP}(\pi, x_5) = (x_9 = x_6)(x_8 = x_8)(x_7 = x_2)(x_6 = x_9) \rightarrow (x_5 \leq x'_5)$$

$$\boxed{\text{BP}(\pi, x_4) = (x_9 = x_6)(x_8 = x_8)(x_7 = x_2)(x_6 = x_9)(x_5 = x'_5) \rightarrow (x_4 \leq x'_7)}$$

$$\boxed{\text{BP}(\pi, x_3) = (x_9 = x_6)(x_8 = x_8)(x_7 = x_2)(x_6 = x_9)(x_5 = x'_5)(x_4 = x'_7) \rightarrow (x_3 \leq x_3)}$$

$$\boxed{\text{BP}(\pi, x_2) = (x_9 = x_6)(x_8 = x_8)(x_7 = x_2)(x_6 = x_9)(x_5 = x'_5)(x_4 = x'_7)(x_3 = x_3) \rightarrow (x_2 \leq x'_4)}$$

$$\boxed{\text{BP}(\pi, x_1) = (x_9 = x_6)(x_8 = x_8)(x_7 = x_2)(x_6 = x_9)(x_5 = x'_5)(x_4 = x'_7)(x_3 = x_3)(x_2 = x'_4) \rightarrow (x_1 \leq x_1)}$$

$$\boxed{\text{BP}(\pi, x_0) = (x_9 = x_6)(x_8 = x_8)(x_7 = x_2)(x_6 = x_9)(x_5 = x'_5)(x_4 = x'_7)(x_3 = x_3)(x_2 = x'_4)(x_1 = x_1) \rightarrow (x_0 \leq x_0)}$$

(b) Permutation's bit predicates. BPs enclosed in boxes with square corners are tautologous because π maps the corresponding bits to themselves. BPs enclosed in boxes with rounded corners are tautologous because they correspond to cycle "ends." The BPs for bits 4 to 0 are tautologous because π maps bit 5 to its complement.

$$\begin{aligned} \text{PP}^*(\pi; X) &= (l_9)(p_9 \rightarrow l_7)(p_7 \rightarrow l_5)(g_9 \rightarrow p_9)(p_9 g_7 \rightarrow p_7) \\ &= (x'_9 + x_6)(p'_9 + x'_7 + x_2)(p'_7 + x'_5)(x'_9 + p_9)(x_6 + p_9)(p'_9 + x'_7 + p_7)(p'_9 + x_2 + p_7) \end{aligned}$$

(c) Linear formulation of the (relaxed) permutation predicate using the chaining 'p' variables.

Figure 13.9. Illustration of the formulation of the permutation predicate according to (13.26) and (13.32).

Taken together, the redundant BPs corresponding to these three cases can be easily eliminated by setting the index set in (13.24) and (13.25) to:

$$I = \text{supp}(\pi) - \text{ends}(\pi) - \text{pred}(\text{phase-shift}(\pi), I_n) \quad (13.26)$$

In the sequel we will refer to the bits in the above index set as “irredundant bits” and use $I = \{i_1, i_2, \dots, i_m\}$, with $i_1 > i_2 > \dots > i_m$, to label them. Note that the presence of a phase-shifted variable early in the total order can lead to a drastic reduction in the number of irredundant bits. For example, if $\pi = (x_{n-1}, x'_{n-1}) \dots$ then $\text{PP}(\pi; X)$ is simply (x'_{n-1}) regardless of how many other variables are moved by π .

Linear construction of PPs through chaining. Elimination of the redundant bit predicates yields the following reduced expression for $\text{PP}(\pi; X)$:

$$\text{PP}(\pi; X) = \bigwedge_{1 \leq k \leq m} \left\{ \left[\bigwedge_{1 \leq j \leq k-1} (x_{i_j}^\pi = x_{i_j}) \right] \rightarrow (x_{i_k}^\pi \leq x_{i_k}) \right\} \quad (13.27)$$

where the outer conjunction is now over the irredundant index set $\{i_1, \dots, i_m\}$. We show next how to convert (13.27) to a CNF formula whose size is linear in m . The first step in this conversion is to eliminate the equalities in the inner conjunction. Specifically, we introduce the “ordering” predicates $l_{i_j} = (x_{i_j} \leq x_{i_j}^\pi)$ and $g_{i_j} = (x_{i_j} \geq x_{i_j}^\pi)$ to re-write (13.27) as:

$$\text{PP}(\pi; X) = \bigwedge_{1 \leq k \leq m} \left\{ \left[\bigwedge_{1 \leq j \leq k-1} l_{i_j} g_{i_j} \right] \rightarrow l_{i_k} \right\} \quad (13.28)$$

The next step utilizes the following easily-proved lemma:

Lemma 13.7.1. (Elimination of Redundant Premise)

$$(a \rightarrow b) \wedge \bigwedge_{i \in I} (abc_i \rightarrow d_i) = (a \rightarrow b) \wedge \bigwedge_{i \in I} (ac_i \rightarrow d_i)$$

Repeated application of this lemma to (13.28) leads to the successive elimination of the “less-than-or-equal” predicates in the inner conjunction:

$$\begin{aligned} & \text{PP}(\pi; X) \\ &= (1 \rightarrow l_{i_1}) (l_{i_1} g_{i_1} \rightarrow l_{i_2}) (l_{i_1} g_{i_1} l_{i_2} g_{i_2} \rightarrow l_{i_3}) \dots (l_{i_1} g_{i_1} \dots l_{i_{m-1}} g_{i_{m-1}} \rightarrow l_{i_m}) \\ &= (1 \rightarrow l_{i_1}) (g_{i_1} \rightarrow l_{i_2}) (g_{i_1} l_{i_2} g_{i_2} \rightarrow l_{i_3}) \dots (g_{i_1} l_{i_2} g_{i_2} \dots l_{i_{m-1}} g_{i_{m-1}} \rightarrow l_{i_m}) \\ &= (1 \rightarrow l_{i_1}) (g_{i_1} \rightarrow l_{i_2}) (g_{i_1} g_{i_2} \rightarrow l_{i_3}) \dots (g_{i_1} g_{i_2} \dots l_{i_{m-1}} g_{i_{m-1}} \rightarrow l_{i_m}) \quad (13.29) \\ &= \dots \\ &= (1 \rightarrow l_{i_1}) (g_{i_1} \rightarrow l_{i_2}) (g_{i_1} g_{i_2} \rightarrow l_{i_3}) \dots (g_{i_1} g_{i_2} \dots g_{i_{m-1}} \rightarrow l_{i_m}) \\ &= \bigwedge_{1 \leq k \leq m} \left\{ \left[\bigwedge_{1 \leq j \leq k-1} g_{i_j} \right] \rightarrow l_{i_k} \right\} \end{aligned}$$

Next, we decompose the multi-way conjunctions involving the “greater-than-or-equal” predicates by introducing m auxiliary *chaining* variables⁸ defined by:

$$\begin{aligned}
 p_{i_0} &= 1 \\
 p_{i_1} &= p_{i_0} \wedge g_{i_1} = g_{i_1} \\
 p_{i_2} &= p_{i_1} \wedge g_{i_2} = g_{i_1} \wedge g_{i_2} \\
 &\dots \\
 p_{i_{m-1}} &= p_{i_{m-2}} \wedge g_{i_{m-1}} = \bigwedge_{1 \leq j \leq m-1} g_{i_j}
 \end{aligned} \tag{13.30}$$

Substituting these definitions, along with those of the ordering predicates, yields the following final expression for the permutation predicate

$$\text{PP}(\pi; X) = \left[\bigwedge_{1 \leq k \leq m} (p_{i_{k-1}} \rightarrow (x_{i_k} \leq x_{i_k}^\pi)) \right] \wedge \left[\bigwedge_{1 \leq k \leq m-1} (p_{i_k} = p_{i_{k-1}} \wedge (x_{i_k} \geq x_{i_k}^\pi)) \right] \tag{13.31}$$

which can be readily converted to a CNF formula consisting of, approximately, $4m$ 3-literal clauses and m 2-literal clauses for a total of $14m$ literals. A further reduction is possible by replacing the equalities in the second conjunction in (13.31) with one-way implications, effectively relaxing the permutation predicate to

$$\text{PP}^*(\pi; X) = \left[\bigwedge_{1 \leq k \leq m} (p_{i_{k-1}} \rightarrow (x_{i_k} \leq x_{i_k}^\pi)) \right] \wedge \left[\bigwedge_{1 \leq k \leq m-1} (p_{i_{k-1}} \wedge (x_{i_k} \geq x_{i_k}^\pi) \rightarrow p_{i_k}) \right] \tag{13.32}$$

Since $\text{PP}(\pi; X) \leq \text{PP}^*(\pi; X)$, it is now possible for $\text{PP}^*(\pi; X)$ to have solutions that violate $\text{PP}(\pi; X)$. These solutions follow the pattern:

$$\begin{array}{ccc}
 p_{i_{k-1}} & g_{i_k} & p_{i_k} \\
 0 & 0 & 1 \\
 0 & 1 & 1 \\
 1 & 0 & 1
 \end{array}$$

In other words, p_{i_k} is 1 when either $p_{i_{k-1}}$ or g_{i_k} is 0. Each such solution, however, can be modified to a solution that does satisfy $\text{PP}(\pi; X)$ by simply changing the value of p_{i_k} from 1 to 0. We can thus use $\text{PP}^*(\pi; X)$ without compromising correctness; this predicate consists of $3m$ 3-literal clauses for a total of $9m$ literals.

13.7.2. Partial Symmetry Breaking

By filtering all but the least assignment in each orbit of the symmetry group G_φ , the SBP in (13.16) is able to break every symmetry of the associated CNF formula

⁸Actually, we only need $m - 1$ auxiliary variables since p_{i_0} stands for the constant 1.

$\varphi(X)$. For exponentially large symmetry groups, however, such *full symmetry breaking* is infeasible. Even when it is possible to construct a full SBP, its ability to prune away symmetric assignments in the search space will be overwhelmed by a drastic increase in search time caused by the sheer size of the formula that must be processed by the SAT solver. The only option left in such situations is to abandon the goal of full symmetry breaking and to re-phrase the objective of the exercise as that of minimizing SAT search time by breaking some, but not necessarily all, symmetries. Like a full SBP, a *partial* SBP selects the least assignment in each orbit of the symmetry group but may include other assignments as well. Formally, if \hat{G}_φ is a subset of G_φ then

$$\rho(G_\varphi; X) \leq \rho(\hat{G}_\varphi; X) \tag{13.33}$$

A natural choice for \hat{G}_φ is any set of irredundant generators for the group. Such a set is computationally attractive because, by Theorem 13.3.3, it is guaranteed to be exponentially smaller than the order of the symmetry group. Additionally, the independence of the generators in an irredundant set (i.e., the fact that none of the generators can be expressed in terms of any others) suggests that their corresponding SBP may block more symmetric assignments than that, say, of an equally-sized set of randomly-chosen elements of G_φ .

Table 13.11 lists the nine sets of irredundant generators for the symmetry group of the example function from Table 13.9 along with their corresponding SBPs. Three of these generator sets yield full SBPs, whereas the remaining six produce partial SBPs. Interestingly, the set $\{\pi_4, \pi_5\}$ which does not generate the group also yields a full SBP! Thus, choosing to break the symmetries of a set of irredundant generators must be viewed as a heuristic whose effectiveness can only be judged empirically.

Table 13.11. Symmetry-breaking predicates of different generator sets for the symmetry group of the CNF formula in Table 13.9. Note that the SBPs of three generator sets achieves full symmetry breaking, whereas those of the remaining six achieve only partial symmetry breaking.

Generator Set	Lex-Leader Predicate	Symmetry Breaking
$\{\pi_1, \pi_2\}$	$\sum_{(a,b,c)} (0, 1, 2, 3, 6) = (a' + b)(a' + c')$	Partial
$\{\pi_1, \pi_3\}$	$\sum_{(a,b,c)} (0, 1, 2, 6) = (a' + b)(b' + c')$	Full
$\{\pi_1, \pi_4\}$	$\sum_{(a,b,c)} (0, 1, 2, 3, 6) = (a' + b)(a' + c')$	Partial
$\{\pi_1, \pi_5\}$	$\sum_{(a,b,c)} (0, 1, 2, 6) = (a' + b)(b' + c')$	Full
$\{\pi_2, \pi_3\}$	$\sum_{(a,b,c)} (0, 1, 2, 4, 6) = (a' + c')(b' + c')$	Partial
$\{\pi_2, \pi_4\}$	$\sum_{(a,b,c)} (0, 1, 2, 3, 6) = (a' + b)(a' + c')$	Partial
$\{\pi_2, \pi_5\}$	$\sum_{(a,b,c)} (0, 1, 2, 4, 6) = (a' + c')(b' + c')$	Partial
$\{\pi_3, \pi_4\}$	$\sum_{(a,b,c)} (0, 1, 2, 6) = (a' + b)(b' + c')$	Full
$\{\pi_3, \pi_5\}$	$\sum_{(a,b,c)} (0, 1, 2, 4, 6) = (a' + c')(b' + c')$	Partial

13.7.3. Experimental Evaluation of Symmetry Breaking

The impact of symmetry breaking on SAT search time for the benchmark instances in Table 13.8 is shown in Table 13.12. For each instance, the table lists the following data:

(1, -1) (5, -5) (12, -12) (13, -13) (19, -19)
 (13, -13) (22, -22) (31, -31) (39, -39) (45, -45)

(b) Generators for Value Symmetries with corresponding SBP $\bigwedge_{i \in S} x'_i$ where
 $S = \{1-22, 24, 25, 27, 29, 30, 32, 36\}$

Figure 13.10. Generators for the Urq3.5 benchmark

- Instance parameters: family, name, number of variables, number of clauses, and number of literals
- SAT search time without symmetry breaking
- SBP size for each variant (mixed, variable, and value): number of variables, number of clauses, and number of literals
- SAT search time when the instance is conjoined with each of the three SBP variants

The SBPs in these experiments were created using the optimization described in [ASM03] which yields a permutation predicate consisting of $4|I|$ clauses and $14|I|$ literals where I is the index of irredundant bits specified in (13.26). SAT checking was carried out using the RSAT solver [RSA] which won the gold medal in the industrial category in the SAT'07 competition [SAT]. The experiments were performed on a 3GHz Intel Xeon workstation with 4GB RAM running the Redhat Linux Enterprise operating system. Each instance was allowed to run for up to 1000 seconds; times-outs are indicated in the table by '-'.²

Close examination of these results leads to the following general observations:

- On average, the size of the SBP-augmented formula (number of variables and number of literals) is slightly more than twice the size of the original formula. The largest increase in size (about 3.4X for variables and 4X for literals) occurred for the Hole, FPGARoute, and ChnlRoute benchmarks; the smallest (about 1.3X for variables and 1.1X for literals) was for the Urq and Pipe benchmarks. These are relatively modest increases that should not tax the abilities of modern SAT solvers.
- Generally, but not always, the addition of the SBP helps to reduce the time to perform the SAT check. Specifically,
 - The Hole, ChnlRoute, Urq, and XOR instances all benefited from the addition of the SBP, even when the symmetry detection time was factored in. This was especially true for instances which could not be solved within the time-out limit.
 - The FPGARoute instances were quite easy to solve without the addition of the SBPs. There was a marginal speed-up in search time when the SBPs were added. However, when symmetry detection times were factored in, the net effect was a marked slow-down.
 - The results for the GRoute instances were mixed. The addition of SBPs improved search times in some cases but worsened it in others. When symmetry detection times were added in, however, the net effect was a noticeable slow-down.
 - The Pipe instances all suffered increases in search times when SBPs were added, even without considering symmetry detection times.
- In cases where only pure variable symmetries are present (Hole, ChnlRoute, FPGARoute, and GRoute), comparable search times were obtained for the two variants of an augmented instance (namely the instance augmented with the variable symmetry SBP and the one augmented with the mixed symmetry SBP).
- However, in cases where only pure value symmetries are present (Urq and all but the smallest XOR), the search times for instances augmented with

Table 13.12. SAT search times (in seconds) with and without symmetry breaking.

Benchmark		Symmetry Breaking Predicate

mixed symmetry SBPs were worse (some timing out) than the search times for the same instances augmented with value symmetry SBPs. The only plausible explanation of such divergent behaviors is that the mixed and value symmetry SBPs are derived from two different sets of generators. This turned out to be the case as illustrated in Fig. 13.10. The figure shows the generators returned by **saucy** for the 46-variable Urq3.5 benchmark: part (a) shows the generators obtained for mixed symmetries and part (b) gives the generators obtained for value symmetries. In both cases, the generators consist of phase-shift permutations (as expected), but the two sets are different. This leads to different SBPs which, in this case, are simply conjunctions of negative literals that correspond to the phase-shift cycle of the variable that occurs first in the assumed variable ordering. Clearly, the generators obtained for value symmetries lead to a SBP that is superior to that obtained from the generators for mixed symmetries. Specifically, the SBP for value symmetries “fixes” 29 out of the 46 variables compared to the SBP for mixed symmetries which fixes only 12 variables. This difference in pruning power was not sufficient to cause the search times to be substantially different for this particular instance. For the larger instances, however, the pruning ability of the SBPs derived from value symmetries is clearly evident; in fact the SBPs derived from mixed symmetries were unsuccessful in helping the SAT solver prove the unsatisfiability of their corresponding instances within the 1000 second time-out.

13.8. From Symmetry to Satisfiability and Back⁹

While the intuition behind exploiting symmetry to speed up SAT search is compelling, as of this writing the empirical evidence is still inconclusive and this quest remains an active research area. On the other hand, and in an unexpected twist, this line of inquiry led to a re-examination of established algorithms for symmetry detection and to their re-formulation as *search* for graph automorphisms in the *space of vertex permutations* yielding orders-of-magnitude improvements in capacity and performance over traditional approaches.

The initial trigger was the black-box use of the **nauty** graph automorphism and canonical labeling package [McK81, McK] to detect the symmetries in CNF formulas as described in Section 13.6. It quickly became apparent, however, that the graphs of typical CNF formulas were too large (hundreds of thousands to millions of vertices) and unwieldy for **nauty** which was geared more towards small dense graphs (hundreds of vertices). The obvious remedy, changing the data structure for storing graphs from an incidence matrix to a linked list, yielded the **saucy** system which demonstrated the viability of graph automorphism detection on very large sparse graphs [DLSM04]. Unlike **nauty**, which also solved the canonical labeling problem, **saucy** was limited to just finding an irredundant set of symmetry generators. Canonical labeling seeks to assign a unique signature to a graph that captures its structure and is invariant under all possible labelings of its vertices. The **bliss** tool [JK07] adopted, and improved upon, **saucy**'s sparse data

⁹Material in this section is based on [KSM10].

structures and solved both the symmetry detection and canonical labeling problems for small dense and large sparse graphs. Close analysis of the search trees used in **nauty** and **bliss** revealed that they were primarily designed to solve the canonical labeling problem, and that symmetry generators were detected “along the way.” Both tools employed sophisticated group-theoretic pruning heuristics to narrow the search for the canonical labeling of an input graph. The detection of symmetries benefited from these pruning rules, but discovered symmetries also helped prune the “canonical labeling” tree since labelings that are related by a symmetry yield the same signature.

Recognizing this, the next version of **saucy** [DSM08] replaced the canonical labeling tree (see Fig. 13.7) with a *permutation search tree* in order to process vertex permutations directly without being constrained by the need to also solve the canonical labeling problem. Instead of a tree of single ordered partitions, the nodes in the **saucy** tree are *ordered partition pairs* that represent partial permutations in analogy with partial Boolean assignments in a SAT search tree. Partial permutations allow the encoding of *sets* of permutations and enable significant additional pruning of the search tree beyond what’s possible with group-theoretic pruning.

De-linking the search for symmetries from the search for a canonical labeling was a major algorithmic change that yielded a remarkable 1000-fold improvement in run time for many large sparse graphs with sparse symmetry generators, i.e., generators that “move” only a tiny fraction of the graph’s vertices. This change also made the search for symmetries resemble, at least superficially, the search for satisfying assignments by a SAT solver.

13.8.1. Implicit Representation of Permutation Sets

Searching the space of a graph’s vertex permutations is greatly facilitated by the adoption of a data structure that compactly represents not just single but also sets of permutations.

Definition 13.8.1. (Ordered Partition Pair or OPP) An *ordered partition pair* Π is specified as

$$\Pi = \begin{bmatrix} \pi_T \\ \pi_B \end{bmatrix} = \begin{bmatrix} T_1 | T_2 | \cdots | T_m \\ B_1 | B_2 | \cdots | B_k \end{bmatrix} \quad (13.34)$$

with π_T and π_B referred to, respectively, as its top and bottom ordered partitions. An OPP is *isomorphic* if $m = k$ and $|T_i| = |B_i|$ for $i = 1, \dots, m$; otherwise it is *non-isomorphic*. In other words, it is isomorphic if its top and bottom partitions have the same number of cells, and corresponding cells have the same cardinality. An isomorphic OPP

$$\Pi = \begin{bmatrix} T_1 & T_2 & \cdots & T_m \\ B_1 & B_2 & \cdots & B_m \end{bmatrix} \quad (13.35)$$

can be further classified, based on the structure and content of its corresponding cells, as:

$$\text{Unmapped: } \bigwedge_{1 \leq i \leq m} (T_i = B_i) \quad (13.36)$$

$$\text{Matching: } \bigvee_{i \in \text{Singletons}(\Pi)} (T_i \neq B_i) \wedge \bigwedge_{i \notin \text{Singletons}(\Pi)} (T_i = B_i) \quad (13.37)$$

$$\text{Non-Matching: } \bigvee_{i \in \text{Singletons}(\Pi)} (T_i \neq B_i) \wedge \bigvee_{i \notin \text{Singletons}(\Pi)} (T_i \neq B_i) \quad (13.38)$$

where $\text{Singletons}(\Pi) = \{i \mid |T_i| = 1\}$. Finally an OPP is discrete (resp. unit) if its top and bottom partitions are discrete (resp. unit).

An isomorphic OPP is an implicit compact representation of a set of $\prod_{1 \leq i \leq m} |T_i|!$ permutations. Thus, a unit OPP represents all $n!$ permutations of V , and a discrete OPP represents just one permutation. On the other hand, it is not possible to obtain well-defined mappings between the top and bottom partitions of a non-isomorphic OPP. Thus, non-isomorphic OPPs conveniently serve as empty sets of permutations.

An OPP can be viewed as a generalization of the tabular format for representing single permutations. Specifically, the set of permutations corresponding to an unmapped OPP can be expressed as

$$\Pi = \bigcirc_{1 \leq i \leq m} S_{|T_i|}(T_i) \quad (13.39)$$

where function composition \bigcirc is naturally extended from single permutations to sets of permutations. The set of permutations corresponding to a matching OPP can also be expressed succinctly as

$$\Pi = \gamma(\text{Singletons}(\Pi)) \circ \bigcirc_{i \notin \text{Singletons}(\Pi)} S_{|T_i|}(T_i) \quad (13.40)$$

where $\gamma(\text{Singletons}(\Pi))$ is the permutation formed from the singleton cells of Π . Fig. 13.11 shows several different examples of OPPs and the permutation sets they represent.

13.8.2. Permutation Search Tree

OPP's play a role similar to partial variable assignments in CNF-SAT solvers. Recall that a partial variable assignment on n Boolean variables can be encoded by an n -element array whose i th element indicates the value of the i th variable: 0, 1, or X for *unassigned*. A *complete* assignment is one in which all variables have been assigned a binary value; otherwise the assignment is *partial* and corresponds to a set of complete assignments that can be enumerated by considering all possible 0, 1 combinations of the unassigned variables. A backtracking SAT solver extends a given partial assignment by choosing an unassigned variable and assigning to it one of the two binary values. This is referred to as a *decision* step and SAT solvers use a variety of decision heuristics to determine which variable to assign next and what value to assign to it. SAT solvers also employ *propagation* to avoid making decisions on variables whose values are implied (forced) by prior decisions. Finally, SAT solvers backtrack from conflicts, i.e. assignments that cause the formula being checked to become unsatisfied.

$$\begin{aligned}
 \text{(a)} \quad & \left[\begin{array}{c|c|c|c} 3 & 1 & 2 & 4 \\ 2 & 3 & 1 & 4 \end{array} \right] = \{(1\ 3\ 2)\} \\
 \text{(b)} \quad & \left[\begin{array}{c|c} 1, 2, 3 \\ 1, 2, 3 \end{array} \right] = S_3(\{1, 2, 3\}) = \{\iota, (1\ 2), (1\ 3), (2\ 3), (1\ 2\ 3), (1\ 3\ 2)\} \\
 \text{(c)} \quad & \left[\begin{array}{c|c|c} 1, 3 & 2, 5 & 4 \\ 1, 3 & 2, 5 & 4 \end{array} \right] = S_2(\{1, 3\}) \circ S_2(\{2, 5\}) = \{\iota, (1\ 3), (2\ 5), (1\ 3)(2\ 5)\} \\
 \text{(d)} \quad & \left[\begin{array}{c|c|c|c} 2 & 6 & 1, 3, 5 & 4 \\ 4 & 6 & 1, 3, 5 & 2 \end{array} \right] = (2\ 4) \circ S_3(\{1, 3, 5\}) \\
 \text{(e)} \quad & \left[\begin{array}{c|c|c} 4 & 1, 2 & 3 \\ 2 & 4, 1 & 3 \end{array} \right] = \{(2\ 4), (1\ 4\ 2)\} \\
 \text{(f)} \quad & \left[\begin{array}{c|c} 1, 3 | 2 \\ 2 | 3, 1 \end{array} \right] = \left[\begin{array}{c|c} 3 | 1 | 2 \\ 2 | 3, 1 \end{array} \right] = \emptyset
 \end{aligned}$$

Figure 13.11. Example OPPs and the permutation sets they represent: (a) discrete, (b) unit, (c) unmapped, (d) matching, (e) non-matching, (f) non-isomorphic. The OPPs (a)-(e) are all isomorphic.

The basic skeleton of a permutation enumeration algorithm can thus be patterned after a backtracking SAT algorithm that finds *all* satisfying assignments to a given CNF formula. The decision step in such an algorithm starts with an isomorphic OPP and refines it by:

- choosing a non-singleton cell (the *target* cell) from the top partition
- choosing a vertex from the target cell (the *target* vertex), and
- mapping the target vertex to a vertex (the *mapped* vertex) from the corresponding cell (the *mapped* cell) of the bottom partition.

The mapping step is accomplished by simultaneously splitting the target vertex from the target cell and the mapped vertex from the mapped cell and placing them in their own singleton cell. Symbolically, given the isomorphic OPP in (13.35) assume that the i th cell is the target cell and let $j \in T_i$ be the target vertex. Mapping j to $k \in B_i$ refines the m -cell OPP Π to the following $(m+1)$ -cell OPP Π' :

$$\Pi' = \left[\begin{array}{c|c|c|c|c|c|c} T'_1 & T'_2 & \cdots & T'_i & T'_{i+1} & \cdots & T'_{m+1} \\ B'_1 & B'_2 & \cdots & B'_i & B'_{i+1} & \cdots & B'_{m+1} \end{array} \right]$$

where

$$\begin{aligned}
 T'_l &= T_l & B'_l &= B_l & l &= 1, \dots, i-1 \\
 T'_i &= T_i - \{j\} & B'_i &= B_i - \{k\} \\
 T'_{i+1} &= \{j\} & B'_{i+1} &= \{k\} \\
 T'_l &= T_{l-1} & B'_l &= B_{l-1} & l &= i+2, \dots, m+1
 \end{aligned}$$

To illustrate, consider the search tree in Fig. 13.12(a) which enumerates all

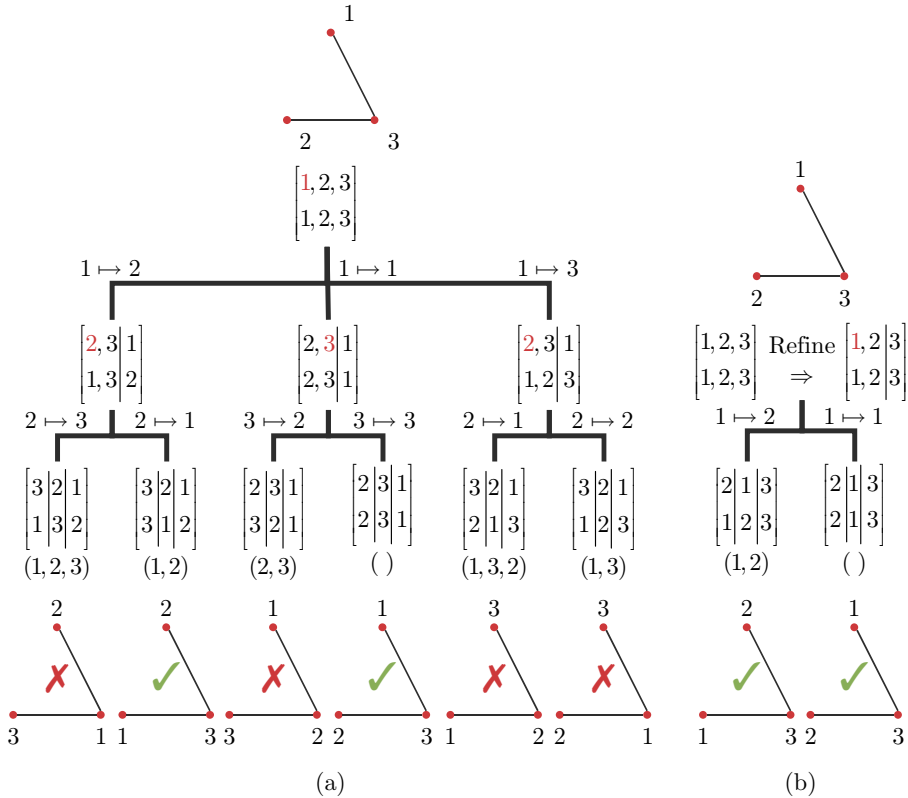

Figure 13.12. Search trees for the automorphisms of a 3-vertex “line” graph. The target vertex (“decision variable”) at each tree node is highlighted in red. (a) without partition refinement. (b) with partition refinement.

permutations of $V = \{1, 2, 3\}$ and checks which are valid symmetries of the indicated 3-vertex 2-edge graph. Each node of the search tree corresponds to an OPP which is the root of a subtree obtained by mapping a target vertex in all possible ways. For example, the unit OPP at the root of the search tree is extended into a 3-way branch by mapping target vertex 1 to 2, 1, and 3. It is important to point out that the choice of target vertex at each tree node and the order in which each of its possible mappings are processed does not affect the final set of permutations produced at the leaves of the search tree. It does, however, alter the order in which these permutations are produced. Note that valid permutations, i.e. permutations that satisfy the graph’s edge relation, can be viewed as satisfying assignments whereas invalid ones are analogous to SAT conflicts.

The permutation search tree can be pruned significantly by performing *partition refinement* [AHU74, DLMS04, McK81] before selecting and branching on a target vertex. This is analogous to Boolean constraint propagation in the SAT space and is standard in all algorithms for graph automorphism and canonical labeling. In the present context, partition refinement is applied *simultaneously* to the top and bottom partitions of the current OPP. This is illustrated in Fig. 13.12(b) where vertex 3 is split from vertices 1 and 2 because it has a

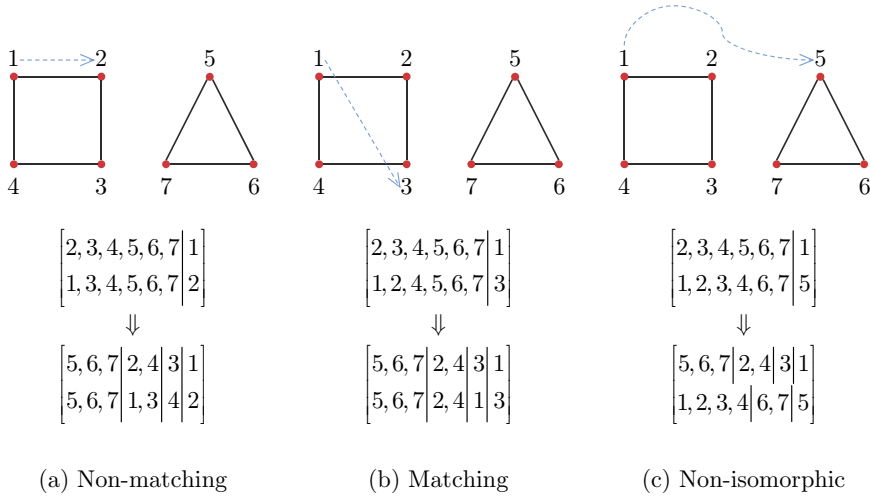

Figure 13.13. Possible outcomes of three different mappings and subsequent refinement of the unit OPP $\left[\begin{array}{c} 1,2,3,4,5,6,7 \\ 1,2,3,4,5,6,7 \end{array} \right]$. In (a) mapping vertex 1 to vertex 2 leads to a non-matching OPP that requires further branching before discovering a potential symmetry. In (b) mapping vertex 1 to vertex 3 leads to a matching OPP that corresponds to the 12 valid permutations $(1\ 3) \circ S_2(\{2,4\}) \circ S_3(\{5,6,7\})$ all of which require the swap of vertices 1 and 3. In this case, we can prune further branching since the matching non-singleton cells can be viewed as “don’t care’s.” In (c), mapping vertex 1 to vertex 5 causes the top and bottom partitions to split non-isomorphically into 4 and 3 cells, respectively, allowing us to immediately conclude that there are no valid permutations in this branch.

different degree.

As in SAT search, partition refinement is invoked after each mapping decision to determine the consequences of that decision. In the SAT case, the consequences are implied assignments to other variables that move the search from its current *decision* state to one of the following three states:

- A new decision state if there are still unassigned variables after propagation.
- A *solution* state if all variables have been assigned; this would be a satisfying assignment.
- A *conflict* state in which a variable is assigned opposing values.

The consequences of a decision in the permutation search tree is a refinement of an isomorphic OPP that moves the search from its current decision state to one of the following three states:

- A new decision state if the resulting OPP is non-matching.
- A solution state if the resulting OPP is matching. Unlike the SAT case, this state corresponds to a partial assignment that represents many solutions¹⁰.

¹⁰This is similar to how the original Grasp SAT solver [MSS96, MSS99] terminated the search: it stopped when it detected that all clauses are satisfied by the current partial assignment. Modern CDCL SAT solvers that employ Chaff’s two-watched literal scheme [MMZ⁺01] terminate

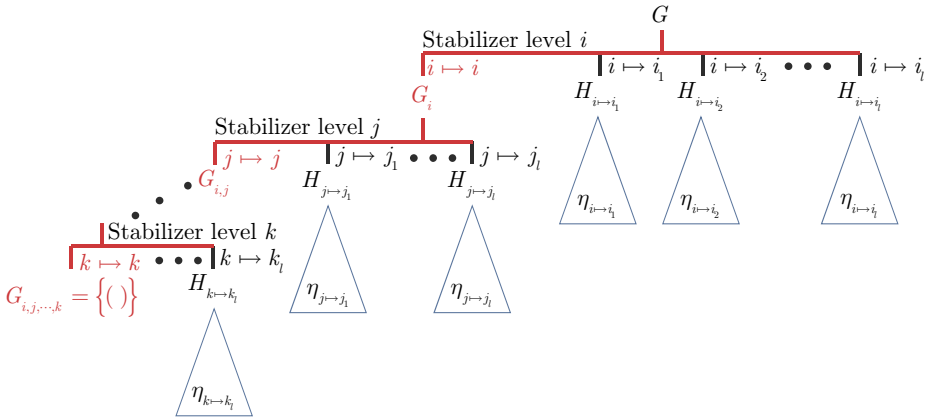

Figure 13.14. Structure of the **saucy** permutation search tree. The highlighted branching levels correspond to subgroup stabilizers. The triangles correspond to permutation sets that are either empty or that represent cosets of the stabilizer subgroup in the left-most branch.

- A conflict state if the corresponding OPP is non-isomorphic.

These three cases are illustrated in Fig. 13.13 for an example 7-vertex graph. The occurrence of matching and non-isomorphic OPPs during the search for automorphisms can be used to define two OPP-based pruning rules that significantly reduce unnecessary exploration of the permutation search tree:

- **Matching OPP pruning** which avoids further branching by mapping matching cells identically and returning an automorphism based on the singleton cells.
- **Non-isomorphic OPP pruning** which indicates that all permutations in the subtree rooted at that node violate the graph’s edge relation.

13.8.3. Group-Theoretic Pruning: Finding a Group’s Generators

Enumerating all automorphisms of a given graph is, in general, intractable but also unnecessary. Instead, a graph automorphism algorithm simply needs to find a set of irredundant generators for the graph’s automorphism group. This is achieved by applying two rules for pruning the permutation search tree that are anchored in group theory: *coset* pruning and *orbit* pruning. These two rules are orthogonal to, and work in concert with, the above-mentioned OPP-based pruning rules.

To enable coset and orbit pruning, branching decisions along the left-most path in the permutation tree are restricted to be identity mappings. This results in a decomposition of the graph’s automorphism group G into a sequence of stabilizer subgroups ending in the identity permutation. As shown in Fig. 13.14, this restriction structures the tree into a sequence of stabilizer levels corresponding to the sequence of stabilized vertices along the left-most path. Each level is

when all variables are assigned.

a multi-way branch whose left-most node is a stabilizer subgroup and whose remaining nodes are possible cosets of that subgroup.

For example, stabilizer level i in Fig. 13.14 corresponds to the multi-way branch that maps vertex i to vertices i, i_1, i_2, \dots, i_l in that order. The left-most node at this level represents the permutation subset corresponding to the mapping $i \mapsto i$, namely the subgroup G_i that stabilizes i . The other nodes at this level correspond to the mappings $i \mapsto i_x$ for $x = 1, \dots, l$ and represent permutation subsets that will be denoted as $H_{i \mapsto i_x}$.

Now assume that Z is a set of irredundant generators for G_i . A set of generators for the parent group G can be obtained by augmenting Z with a *single* representative from each coset of G_i . This set may, however, contain redundant generators that must be eliminated with the aid of the orbit partition.

To find coset representatives, we must solve up to l independent problems where problem $i \mapsto i_x$ seeks to determine whether the set of permutations $H_{i \mapsto i_x}$ is a coset of G_i . This is accomplished by searching $H_{i \mapsto i_x}$ for a *single permutation* that satisfies the graph edge relation, i.e., a permutation that is an automorphism of the graph. If no such permutation exists, then $H_{i \mapsto i_x}$ is “unsatisfiable”, i.e., it is not a coset of G_i . This problem is remarkably similar, structurally, to the problem of finding a satisfying assignment to a CNF formula or proving that no such assignment exists.

Let permutation $\eta_{i \mapsto i_x}$ denote a solution to problem $i \mapsto i_x$. Clearly, $\eta_{i \mapsto i_x}$ serves as a coset representative for $H_{i \mapsto i_x}$ and is added to the set of generators for G . Additionally, the orbit partition is updated by merging the orbits of i and i_x . Thus, if the orbit of i_x contains vertex i_y with $y > x$, then problem $i \mapsto i_y$ can be skipped since its corresponding coset must necessarily contain redundant generators.

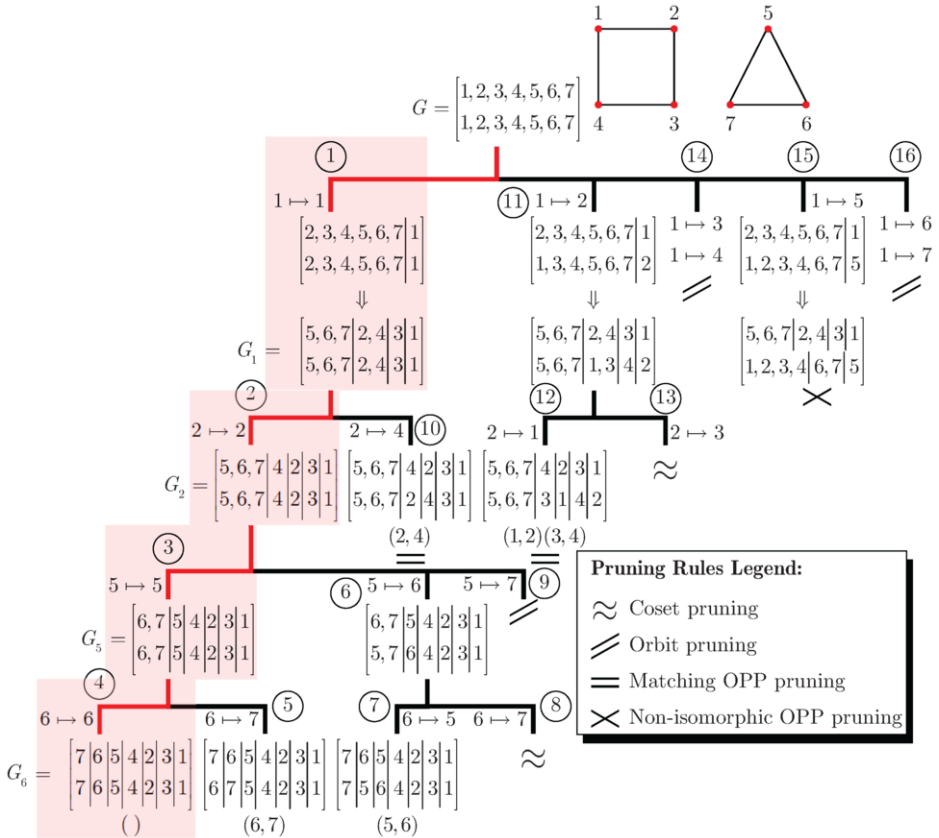

To summarize, the two group-theoretic pruning rules that guarantee the production of an irredundant set of group generators are:

- **Coset pruning** which terminates the search in a coset subtree as soon as a coset representative is found.
- **Orbit pruning** which avoids searching the subtree of $H_{i \mapsto i_x}$ if i_x is already in i 's orbit or in the orbit of a vertex i_y that was previously shown to lead to a violation of the graph's edge relation under the mapping $i \mapsto i_y$.

Finding a coset representative for problem $H_{i \mapsto i_x}$, or proving that the problem is not a coset, is greatly facilitated by the two OPP-based pruning rules. Specifically, a coset representative is found as soon as a node in the search tree becomes matching. When this happens at a shallow level in the tree, a potentially exponential amount of work is avoided. Similarly, encountering a non-isomorphic node eliminates the need for further branching. When this happens at the level of stabilizer subgroup G_i , i.e., when attempting to solve problem $H_{i \mapsto i_x}$, it immediately indicates that this problem is not a coset of G_i .

13.8.4. Putting it All Together

We now have all the ingredients needed to sketch the **saucy** algorithm. Given a colored graph, the algorithm produces a) a set Z of (no more than $n - 1$)

Initialization: $\pi = \{1 | 2 | 3 | 4 | 5 | 6 | 7\}$, $Z = \emptyset$

1. Fix vertex 1 and refine
2. Fix vertex 2
3. Fix vertex 5
4. Fix vertex 6; $G_6 = \{()\}$
5. Search for representative of coset $H_{6 \rightarrow 7}$;
 $Z = \{(6, 7)\}$; $\pi = \{1 | 2 | 3 | 4 | 5 | 6, 7\}$; $|G_5| = |G_6| \cdot |G_6| = 1 \cdot 2 = 2$
6. Search for representative of coset $H_{5 \rightarrow 6}$
7. Found representative of coset $H_{5 \rightarrow 6}$;
 $Z = \{(6, 7), (5, 6)\}$; $\pi = \{1 | 2 | 3 | 4 | 5, 6, 7\}$
8. **Coset pruning**: no need to explore since we have already found a coset representative for $H_{5 \rightarrow 6}$
9. **Orbit pruning**: no need to explore since 7 is already in the orbit of 5
 $|G_2| = |G_5| \cdot |G_5| = 2 \cdot 3 = 6$
10. Search for representative of coset $H_{2 \rightarrow 4}$;
Matching OPP pruning: found representative of coset $H_{2 \rightarrow 4}$

14. **Orbit pruning**: no need to explore since 3 and 4 are already in the orbit of 1
15. **Non-isomorphic OPP pruning**: 1 cannot map to 5
16. **Orbit pruning**: no need to explore since 6 and 7 are already in the orbit of 5
 $|G| = |G_1| \cdot |G_1| = 12 \cdot 4 = 48$

Figure 13.15. Search tree for graph automorphisms of the “square and triangle” graph and relevant computations at each node. The shaded region corresponds to subgroup decomposition.

irredundant generators for the graph's automorphism group G , b) the group's orbit partition π , and c) the order $|G|$ of the group .

The algorithm starts out with an empty set of generators $Z = \emptyset$ and an orbit partition where each graph vertex i is in its own cell, $G_i = \{i\}$. The algorithm then proceeds with a depth-first traversal of the tree to obtain a stabilizer subgroup decomposition of G . This is followed by repeatedly processing each stabilizer level, in reverse order, to compute Z , π , and $|G|$.

This computation is best understood by considering two adjacent stabilizer levels i and j in the permutation search tree (see Fig. 13.14). Let Z_i (resp. π_i) and Z_j (resp. π_j) denote the set of generators (resp. orbit partitions) at levels i and j . In addition, let B_j denote the set of vertices that result in non-isomorphic OPPs when j is mapped to any one of them; these are “bad” vertices. The computation at stabilizer level j can now be summarized as follows:

1. $Z_i = Z_j$; $\pi_i = \pi_j$; $B_j = \emptyset$; // Initialize
2. for $x = 1$ to l // Process mappings of j
3. if $\neg[(j_x \in Gj) \vee (\exists j_y \in B_j : j_x \in Gj_y)]$ // Orbit pruning
4. if SAT($H_{j \rightarrow j_x}$) { // Found symmetry $\eta_{j \rightarrow j_x}$
5. $Z_i = Z_i \cup \{\eta_{j \rightarrow j_x}\}$ // Update generators
6. Update π_i by merging Gj and Gj_x } // Update orbit partition
7. else $B_j = B_j \cup \{j_x\}$ // Record bad mapping
8. $|G_i| = |G_j| \cdot |G_j|$ // Compute order of G_i

The check on line 3 implements orbit pruning by ensuring that the mapping $j \mapsto j_x$ can be skipped if either j_x is already in j 's orbit or it is in the orbit of a vertex in j 's bad set. The SAT check on line 4 utilizes the two OPP pruning rules to quickly find an automorphism or to prove that none exist for the given mapping.

A trace of this (informally presented) algorithm illustrating all four pruning rules is shown in Fig. 13.15. Fig. 13.16 shows its run time performance as implemented in the **saucy** symmetry detection tool on the complete set of 1183 SAT 2009 competition benchmarks. As the figure shows, there is a weak trend towards larger run times for larger graphs. However, run time seems to also depend on other attributes of a graph besides its absolute size (number of vertices.) Overall, the algorithm seems to be quite scalable: it solved the largest benchmark **post-cbmc-zfcp-2.8-u2-noholes**, an application instance with about 11 million variables and 33 million clauses, whose graph encoding has over 32 million vertices, in about 231 seconds. It is also extremely fast, finishing in less than one second on 93% (1101) of all benchmarks.

13.9. Summary and a Look Forward

This chapter was concerned with recognizing symmetry in CNF formulas and exploiting it in the context of satisfiability checking. The particular approach we described for utilizing symmetry in SAT solving is sometimes referred as *static symmetry breaking* because it modifies the input to the SAT solver rather than modifying the SAT solver itself. Given a CNF formula $\varphi(X)$, static symmetry breaking consists of the following steps:

Figure 13.16. saucy 2.1 run time, in seconds, as a function of graph size for the SAT 2009 competition benchmarks. A time-out of 500 seconds was applied.

1. Converting the formula to a colored graph whose symmetries are isomorphic to the symmetries of the formula.
2. Computing the automorphism group G_φ of the graph and returning a set of generators $\hat{G}_\varphi \subset G_\varphi$ for it using a suitable graph automorphism program.
3. Mapping the returned generators back to symmetries of the formula.
4. Constructing an appropriate symmetry-breaking predicate $\rho(\hat{G}_\varphi; X)$ in CNF and conjoining it to the formula.
5. Checking $\varphi(X) \wedge \rho(\hat{G}_\varphi; X)$ using a suitable SAT solver.

The attractiveness of this approach stems from the fact that it can be used with *any* SAT solver and can, thus, automatically benefit from improvements in SAT solving technology. On the other hand, the method has a number of drawbacks that can limit its effectiveness in some cases. The method's inherent disadvantage is that the SBP created in step 4 relates to the *global symmetries* of the original formula. During SAT search, particular partial assignments to the variables may give rise to additional *local symmetries*, also known as *conditional symmetries* [BS07], that offer the possibility of further pruning of the search space. A pre-processing approach cannot utilize such symmetries. Computationally, even after applying the optimizations described in Sec. 13.7.1, the size of the SBP (expressed as a CNF formula) might still be too large to be effectively handled by a SAT solver. Furthermore, the pruning ability of the SBP depends on the generator set used to derive it and, as we have seen experimentally, can vary widely. Finally, the assumed, and essentially arbitrary, ordering of the variables to create the SBP

may be at odds with the SAT solver's branching strategy; this limitation, however, is not as severe as the other two since modern SAT solvers employ adaptive decision heuristics that are insensitive to the initial static ordering of the variables. It may be useful, however, to explore orderings on the truth assignments that are not lexicographic. For example, orderings in which successive assignments have a Hamming distance of 1 (i.e., differ in only one bit position) might yield better SBPs because of better clustering of "least" assignments. Despite these shortcomings, static symmetry breaking is currently the most effective approach for exploiting symmetry in SAT search.

An alternative approach is to break symmetries *dynamically* during the search. In fact, one of the earliest references to utilizing symmetry in SAT advocated such an approach [BFP88]. However, except for a brief follow-up to this work in [LJPJ02], the early contributions of Benhamou et al in [BS92, BS94], and the more recent contribution of Sabharwal in [Sab05], there is practically little mention in the open literature of dynamic symmetry breaking in SAT. The situation is completely different in the domain of constraint satisfaction problems (CSP) where breaking symmetries during search has been a lively research topic for the past few years. One conjecture that might explain this anomaly is that modern implementations of conflict-driven backtrack SAT solvers are based on highly-optimized and finely-tuned search engines whose performance is adversely affected by the introduction of expensive symmetry-related computations in their innermost kernel.

The potential benefits of dynamic symmetry breaking are too compelling, however, to completely give up on such an approach. These benefits include the ability to identify local symmetries, and the possibility of boosting the performance of conflict-driven learning by recording the symmetric equivalents of conflict-induced clauses. Dynamic symmetry breaking is also appealing because it avoids the creation, as in static symmetry breaking, of potentially wasteful symmetry breaking clauses that drastically increase the size of the CNF formula while only helping marginally (or not at all) in pruning the search space. To realize these benefits, however, the integration of symmetry detection and symmetry breaking must be considered carefully. An intriguing possibility is to *merge* the graph automorphism and SAT search engines so that they can work simultaneously on the CNF formula as the search progresses. The recent improvements in graph automorphism algorithms, tailored specifically to the sparse graphs that characterize CNF formulas, suggest that this may now be a practical possibility. Further advances, including incremental updating of the symmetry group (through its generators) in response to variable assignments, are necessary, however, to make such a scheme effective on large CNF instances with many local symmetries. In short, this is an area that is ripe for original research both in the graph automorphism space as well as in the SAT search space.

13.10. Bibliographic Notes

13.10.1. Theoretical Considerations

The study of symmetry in Boolean functions has a long history. Early work was primarily concerned with counting the number of symmetry types of Boolean functions of n variables. Assuming invariance under variable permutation and/or complementation, the 2^{2^n} possible functions of n variables can be partitioned into distinct equivalence classes. Slepian [Sle54] gave a formula for the number of such classes as a function of n . Slepian also related this to earlier work by Pólya [Pól40] and Young [You30], and noted that the group of permutations and/or complementations is isomorphic to the hyperoctahedral group (the automorphism group of the hyperoctahedron in n -dimensional Euclidean space) as well as to the group of symmetries of the n -dimensional hypercube. These investigations were further elaborated by Harrison [Har63] who gave formulas for separately counting the number of equivalence classes of Boolean functions under three groups: complementation, permutation, and combined complementation and permutation. He also pointed out that the combined group is the semi-direct, rather than the direct, product¹¹ of the other two. More recently, Chen [Che93] studied the *cycle structure* of the hyperoctahedral group by representing it using *signed permutations*, i.e., permutations on $\{1, 2, \dots, n\}$ “with a + or – sign attached to each element $1, 2, \dots, n$.”

13.10.2. Symmetry in Logic Design

Symmetry of Boolean functions was also studied in the context of logic synthesis. Motivated by the desire to create efficient realizations of relay circuits for telephone switching exchanges, Shannon [Sha38, Sha49] developed a notation to describe and logically manipulate symmetric functions based on their so-called “a-numbers.” Specifically, Shannon showed that a function which is symmetric in all of its variables (i.e., a function which remains invariant under all permutations of its variables) can be specified by a subset of integers from the set $\{0, 1, \dots, n\}$. Such functions were termed *totally symmetric* in contrast with *partially symmetric* functions that remain invariant under permutation of only a *subset* of their variables. For example, $f(a, b, c) = ab + ac + bc$ is a totally symmetric function specified as $S_{\{2,3\}}(a, b, c)$ and interpreted to mean that f is equal to 1 when exactly 2 or exactly 3 of its variables are 1. The notation extends naturally when some variables need to be complemented before being permuted. Thus $f(a, b, c) = ab'c + a'bc + a'b'c'$ is specified as $S_{\{0,1\}}(a, b, c')$ meaning that f is equal to 1 when exactly 0 or exactly 1 of the literals from the set $\{a, b, c'\}$ is equal to 1. The specification of partially symmetric functions is more involved. Let $f(X, Y)$ be such a function where $\{X, Y\}$ is a partition of its variables such that the function remains invariant under all permutations of the X variables.

¹¹A discussion of direct and semi-direct group products will take us too far afield. For current purposes, it is sufficient to note that a direct product is a special type of a semi-direct product. Specifically, the direct product of two groups G and H is the group whose underlying set is $G \times H$ and whose group operation is defined by $(g_1, h_1)(g_2, h_2) = (g_1g_2, h_1h_2)$ where $g_1, g_2 \in G$ and $h_1, h_2 \in H$.

Using the elementary symmetric functions¹² $S_{\{i\}}(X)$ for $i = 0, \dots, |X|$ as an orthonormal basis, f can be specified as:

$$f(X, Y) = \sum_{0 \leq i \leq |X|} S_{\{i\}}(X) R_i(Y)$$

where $R_i(Y)$ is the *residual* function corresponding to $S_{\{i\}}(X)$.

Shannon's definition of symmetry yields a partition of a function's literals such that literals in a given cell of the partition can be permuted arbitrarily without causing the function to change. A variety of schemes were subsequently developed to derive this partition. All of these schemes are based on finding pairs of equivalent literals using the following "Boole/Shannon" expansion:

$$f(\dots, x, \dots, y, \dots) = x'y'f_{x'y'} + x'yf_{x'y} + xy'f_{xy'} + xyf_{xy}$$

where $f_{x'y'}, \dots, f_{xy}$ are the *cofactors* of f with respect to the indicated literals [BCH⁺82]. For example, $f_{x'y} = f(\dots, 0, \dots, 1, \dots)$, i.e., f is restricted by the assignment of 0 to x and 1 to y . It is now straightforward to see that f remains invariant under a swap of x and y if and only if $f_{x'y} = f_{xy'}$. Similarly, f will be invariant under a swap of x and y' (resp. x' and y) if and only if $f_{x'y'} = f_{xy}$. In cycle notation,

$$\begin{aligned} (f_{x'y} = f_{xy'}) &\Leftrightarrow (x, y) \\ (f_{x'y'} = f_{xy}) &\Leftrightarrow (x, y') \end{aligned}$$

Larger sets of symmetric literals can now be built from symmetric pairs using transitivity. The computational core in all of these schemes is the check for equivalence between the cofactor functions. Early work [Muk63] employed *decomposition charts* which, essentially, are truth tables in which the four combinations of the variable pair being checked for equivalence are listed row-wise whereas the combinations of the remaining variables are listed column-wise. Equality of cofactors is now detected as identical rows in the charts. Such a scheme, obviously, is not scalable and subsequent symmetry detection algorithms mirrored the evolution, over time, of more efficient representations for Boolean functions as cube lists (that encode functions in SOP form) [DS67], in terms of various spectral transforms [EH78, RF98], using Reed-Muller forms [TMS94], and finally as binary decision diagrams (BDDs) [MMW93, PSP94]. Most recently, the problem of detecting the symmetries of large Boolean functions was addressed by employing a portfolio of representations and algorithms including circuit data structures, BDDs, simulation, and (interestingly) satisfiability checking [ZMBCJ06].

It is important to note that the symmetries we have been discussing in this brief historical review are *semantic* rather than syntactic, i.e., symmetries that are independent of a function's particular representation. Detection of these symmetries, thus, requires some sort of *functional* analysis that checks various cofactors for logical equivalence¹³. Furthermore, we may view the resulting partition of a

¹² $S_A(X)$ is an elementary symmetric function if $|A| = 1$, i.e., the set of a-numbers A is a singleton.

¹³As mentioned in Sec. 13.4, semantic symmetries can also be found by structural analysis of certain CNF representations of a function such as those that include a function's maxterms or its prime implicates. However, since these representations tend to be exponential in the number of variables, they are rarely used to find a function's semantic symmetries.

function's literals into subsets of symmetric literals as an implicit compact representation of the function's symmetries. This is in contrast with the use of a set of irredundant generators to represent a group of symmetries. We should note, however, that a partition of the function's literals may not capture all possible symmetries of the function. This fact was "discovered" in the context of checking the logical equivalence of two functions with unknown correspondence between their inputs [MMM95], and led to augmenting Shannon's *classical symmetries*, which are based on a flat partitioning of a function's literals, with additional *hierarchical symmetries* that involve simultaneous swaps of sets of literals. These symmetries were further generalized in [KS00] where classical *first-order* symmetries (based on variable swaps) formed the foundation for *higher-order* symmetries that involve the swaps of both ordered and un-ordered sets of literals. These two extensions to Shannon's original definition of functional symmetry allowed the detection of many more function-preserving literal permutations in benchmark circuits. Still, such swap-based representations are inherently incapable of capturing arbitrary permutations such as $(a, b, c)(d, f, e)(g, h, m)(i, j, k)$ which is a symmetry of the function $ab + ac + af + aj + bc + be + bk + cd + ci + dk + ej + fi + gi + hj + km$ [Kra01].

13.10.3. Symmetry in Boolean Satisfiability Problems

Whereas interest in semantic symmetries, as noted above, was primarily motivated by the desire to optimize the design of logic circuits or to speed up their verification, interest in syntactic symmetries, i.e., symmetries of CNF formulas, arose in the context of constraint solving, specifically Boolean satisfiability checking. The earliest reference to the potential benefits of invoking symmetry arguments in logical reasoning is traditionally attributed to Krishnamurthy [Kri85] who introduced the notions of global and local "symmetry rules" that can be used to significantly shorten (from exponential to polynomial) the proofs of certain propositions such as the pigeon-hole principle. Another early reference to the use of symmetry in backtrack search is [BFP88] where symmetries are used *dynamically* by the search algorithm to restrict its search to the equivalence classes induced by the formula's symmetries (which are assumed to be given). In the same vein, Benhamou and Sais [BS92, BS94] described a modification to backtrack search that prunes away symmetric branches in the decision tree. Their method for detecting symmetries worked directly on the CNF formula and derived formula-preserving variable permutations incrementally through pair-wise substitutions. In [Sab05], Sabharwal described an interesting modification to the zChaff [MMZ⁺01] SAT solver that allows it to branch on a set of symmetric variables rather than on single variables. For instance, given a set $\{x_1, x_2, \dots, x_k\}$ of k symmetric variables, a $k + 1$ -way branch sets x_1, \dots, x_i to 0 and x_{i+1}, \dots, x_k to 1 for each $i \in [0, k]$. This reduces the number of partial assignments that must potentially be explored from 2^k to $k + 1$. The identification of symmetric variables is assumed to be available from high-level descriptions of a problem (e.g., variables denoting pigeons in a pigeon-hole are all symmetric) and provided to the solver as an additional input.

The first complete exposition of the use of symmetries in a pre-processing step to prune the search space of SAT solvers must, however, be credited to

Crawford et al. [Cra92, CGLR96]. In [Cra92], Crawford laid the theoretical foundation for reasoning by symmetry by showing that symmetry detection can be polynomially reduced to the problem of colored graph automorphism. The subsequent paper [CGLR96] detailed the basic flow of symmetry detection and breaking and introduced the following computational steps which, with some modification, still constitute the elements of the most successful approach, at least empirically, for the application of symmetry reasoning in SAT. Given a CNF formula:

1. Convert the formula to a colored graph whose automorphisms correspond to the symmetries of the formula.
2. Identify a set generators of the graph automorphism group using the **nauty** graph automorphism package [McK, McK81].
3. Using the generators, create a *lex-leader*¹⁴ symmetry-breaking predicate from one of the following alternative sets of symmetries:
 - just the generators.
 - a subset of symmetries obtained from a truncated *symmetry tree* constructed from the generators.
 - a set of random group elements obtained from the generators.

The symmetry tree data structure in this flow was proposed as a mechanism to reduce the observed duplication in the SBP for problems with a large number of symmetries. However, except for some special cases (e.g., the full symmetry group of order $n!$ has a pruned symmetry tree with n^2 nodes), the size of the symmetry tree remains exponential in the number of variables.

The symmetry detection and breaking approach we described in Sec. 13.6 and Sec. 13.7 is based on [ARMS02, AMS03, ASM03] which extended Crawford's methodology in the following important ways:

- Crawford's graph construction in [CGLR96] used three vertex colors (for clauses, positive literals, and negative literals, respectively) and was, thus, limited to discovering variable symmetries. By using one color for both positive and negative literals, it was shown in [ARMS02] that additional symmetries can be found, namely value symmetries and their composition with variable symmetries. The restriction to just value symmetries by the use of a distinct color for each literal pair, as described in Sec. 13.6, is a further extension of these ideas that shows the versatility of the colored graph construction as a mechanism for studying the symmetries in a CNF formula.
- The size of Crawford's lex-leader SBP for breaking a single symmetry is quadratic in the number of variables. The optimizations introduced in [ARMS02, AMS03], and particularly in [ASM03], reduced this dependence to linear in a much smaller number that reflects the cycle structure of a symmetry as well as the presence of phase shifts in it. The relaxed permutation predicate in (13.32) represents a further optimization that

¹⁴The term lex-leader indicates a lexicographic ordering of the truth assignments that is induced by an assumed ordering of the variables; it is the same as the numeric ordering in (13.5) corresponding to the interpretation of the truth assignments as unsigned integers.

shrinks the size of the SBP from $14|I|$ to $9|I|$ where I is the index set of irredundant bits defined by (13.26).

- The use of edges to represent binary clauses was suggested by Crawford to improve the efficiency of graph automorphism. The possibility that this optimization to the colored graph construction may produce spurious symmetries was noted in [ARMS03] and attributed to the presence of circular chains of implications in the CNF formula. Alternative constructions were also offered in [ARMS03] to deal with this problem, as well as suggestions for how to filter out the spurious symmetries when they arise.
- Finally, the work in [ARMS02, AMS03, ASM03] provided the first empirical large-scale validation of the feasibility of static symmetry breaking. This approach was validated empirically on a large number of different benchmark families.

Recent applications of this general symmetry breaking approach included its use in decision and optimization problems that involve pseudo-Boolean constraints (linear inequalities on Boolean variables) [ARSM07], and in deciding the satisfiability of quantified Boolean formulas [AJS07].

13.10.4. Symmetry in Constraint Satisfaction Problems

Research on the use of symmetry in constraint programming is too voluminous to adequately cover in a few paragraphs. Instead, we refer the reader to the excellent recent (and largely current) survey in [GPP06]¹⁵ and briefly highlight a few connections to similar issues in the context of Boolean satisfiability.

One of the questions that has preoccupied the constraint programming community over the past several years has been definitional: what exactly are the symmetries of a constraint programming problem? This question was largely settled in [CJJ⁺05] which provided a comprehensive taxonomy that encompassed most of the previous notions of CSP symmetry. In a nutshell, the type of symmetry in a CSP is classified based on:

- What is being permuted:
 - variables (yielding *variable* symmetries)
 - values (yielding *value* symmetries)
 - variable/value pairs
- What is invariant:
 - set of solutions (yielding *solution* symmetries)
 - set of constraints (yielding *constraint* symmetries)

This classification is essentially the same as the one we used to categorize the symmetries of CNF formulas. Specifically, a CNF's semantic and syntactic symmetries correspond, respectively, to a CSP's solution and constraint symmetries. Furthermore, viewing a CSP's variable/value pair as a *literal*, we note that a CNF's variable, value, and mixed symmetries have their corresponding CSP counterparts. The similarity extends to the graph constructions used to extract the symmetries of a problem instance. For example, the constraint symmetries of a

¹⁵This survey also has pointers to key references on the use of symmetry in integer programming, planning, theorem proving, and model checking.

CSP instance correspond to automorphisms of the associated *microstructure* [J93] which is the analog of the CNF formula graph we used in Sec. 13.6 to find the formula's syntactic symmetries.

There are some important differences, however. Symmetries tend to be easier to spot and describe in the CSP specifications of many problems than in the corresponding CNF encodings of these problems (the pigeon-hole problem being an obvious example.) There is room, thus, for hybrid approaches, along the lines of [Sab05], that combine high-level specifications of a problem's symmetries with a modern SAT solver's powerful search algorithms. Furthermore, many of the techniques for dynamic symmetry breaking that have been studied extensively in the CSP domain have yet to be fully explored in the CNF SAT context.

13.10.5. Graph Automorphism

Crawford's proposal in [CGLR96] for detecting and breaking the symmetries of CNF formulas included the use of McKay's graph isomorphism package, **nauty** [McK, McK81]. **nauty** had, by then, been the dominant publicly-available tool for computing automorphism groups, as well as for canonical labeling, of graphs. It was, thus, the natural choice for symmetry detection in subsequent extensions to Crawford's work in both the SAT and CSP domains. However, it quickly became clear that **nauty** was not optimized for the large sparse graphs constructed from CNF formulas that model design or verification problems. Specifically, the significant reductions in SAT search time that became possible because of SBP pruning were more than offset by **nauty**'s runtime for the detection of symmetries. This prompted the development of **saucy** [DLSM04] whose data structures were designed to take advantage of the sparsity in the graphs constructed from CNF formulas. **saucy** achieved significant speed-ups over **nauty** on such graphs and established the viability, at least for certain classes of problems, of the static symmetry detection and breaking approach. More enhancements along these lines were recently proposed in [JK07] which introduced the **bliss** tool for canonical labeling of large and sparse graphs. The latest offering in this space is a major enhancement to **saucy** that not only takes advantage of the sparsity of the input graph but also of the symmetry generators themselves [DSM08].

13.10.6. Canonical Labeling

While the main concern in this chapter is symmetry detection to speed up SAT solving, the accidental discovery of fast graph automorphism algorithms that de-link symmetry detection from canonical labeling opened the possibility of also re-thinking the architecture of canonical labeling tools. Katebi et al. [KSM12] showed that by carefully integrating **saucy** with **bliss**, canonical labeling can be done much faster. Specifically, by synchronizing the stabilizer subgroup decomposition between **saucy** and **bliss**, symmetry detection is quickly carried out by **saucy** which it forwards to **bliss** as orbit partitions at each stabilizer level. This eliminates the need for **bliss** to perform any symmetry processing since it now has all the information necessary to quickly find a canonical labeling.

Acknowledgments

Many people helped in shaping the content of this chapter. I want to thank Igor Markov for nudging me to explore group theory as a way to describe and analyze symmetries of Boolean functions. Fadi Aloul was tremendously helpful in providing the experimental data for the mixed, variable, and value symmetries of CNF formulas. Paul Darga helped improve the description of the basic graph automorphism algorithm. Mark Liffiton provided the examples used to illustrate the various concepts. Zaher Andraus provided detailed comments from a careful reading of the manuscript. Hadi Katebi and Paolo Codenotti contributed to the development of the latest version of **saucy** and its integration with **bliss** to enable fast canonical labeling. I would also like to thank my editor Toby Walsh for his insightful feedback. This work was completed during the author's sabbatical leave at Carnegie Mellon in Qatar and was supported, in part, by the National Science Foundation under ITR grant No. 0205288.

Chapter 14

Minimal Unsatisfiability and Autarkies

Hans Kleine Büning and Oliver Kullmann

The topic of this chapter is the study of certain forms of “redundancies” in propositional conjunctive normal forms and generalisations. In Sections 14.1 - 14.7 we study “minimally unsatisfiable conjunctive normal forms” (and generalisations), unsatisfiable formulas which are irredundant in a strong sense, and in Sections 14.8 - 14.13 we study “autarkies”, which represent a general framework for considering redundancies. Finally in Section 14.14 we collect some main open problems.

14.1. Introduction

A literal is a variable or a negated variable. Let X be a set of variables, then $\text{lit}(X)$ is the set of literals over the variables in X . Clauses are disjunctions of literals. Clauses are also considered as sets of literals. A propositional formula in conjunctive normal form (CNF) is a conjunction of clauses. CNF formulas will be considered as multi-sets of clauses. Thus, they may contain multiple occurrences of clauses. The set of all variables occurring in a formula φ is denoted as $\text{var}(\varphi)$. Next we introduce formally the notion of *minimal unsatisfiability*. Please note that in some of the older papers minimal unsatisfiable formulas are sometimes called “critical satisfiable”.

Definition 14.1.1. A set of clauses $\{f_1, \dots, f_n\} \in \text{CNF}$ is called *minimal unsatisfiable* if $\{f_1, \dots, f_n\}$ is unsatisfiable and for every clause f_i ($1 \leq i \leq n$) the formula $\{f_1, \dots, f_{i-1}, f_{i+1}, \dots, f_n\}$ is satisfiable. The set of minimal unsatisfiable formulas is denoted as MU.¹

The complexity class D^P is the set of problems which can be described as the difference of two NP-problems, i.e., a problem Z is in D^P iff $Z = X - Y$ where X and Y are in NP. The D^P completeness of MU has been shown by a reduction of the D^P -complete problem UNSAT-SAT [PW88]. UNSAT-SAT is the set of pairs (F, G) for which F is unsatisfiable and G is satisfiable.

¹Depending on the author, instead of “minimal unsatisfiable formulas” also “minimally unsatisfiable formulas” can be used (or is preferable).

Theorem 14.1.1. [PW88] MU is D^P -complete.

The idea of the proof is as follows. At first, we show that MU is in D^P . Let Y be the set of satisfiable CNF and let X be the set of CNF such that after removal of any clause they are satisfiable. Then we obtain $MU = X - Y$ and therefore MU is in D^P . For the hardness we assign to every pair of 3-CNF formulas (F, G) a formula $H(F, G)$, such that (F, G) is in UNSAT-SAT if and only if $H(F, G)$ is minimal unsatisfiable:

- Let $F = \{f_1, \dots, f_n\}$ be in 3-CNF with $f_i = (L_{i,1} \vee L_{i,2} \vee L_{i,3})$.
- For new variables x_1, \dots, x_n let $\pi_i = (x_1 \vee \dots \vee x_{i-1} \vee x_{i+1} \vee \dots \vee x_n)$.
- We define

$$H_1(F) = \bigwedge_{1 \leq i \leq n} (f_i \vee \pi_i) \wedge \bigwedge_{1 \leq i \leq n, 1 \leq j \leq 3} (\neg L_{i,j} \vee \pi_i \vee \neg x_i) \wedge \bigwedge_{1 \leq i < j \leq n} (\neg x_i \vee \neg x_j).$$

- Let $G = \{g_1, \dots, g_m\}$ be in 3-CNF with $g_i = (L'_{i,1} \vee L'_{i,2} \vee L'_{i,3})$.
- For new variables y_1, \dots, y_m let $\varphi_i = (y_1 \vee \dots \vee y_{i-1} \vee y_{i+1} \vee \dots \vee y_m)$.
- We define

$$H_2(G) = \bigwedge_{1 \leq i \leq n} (g_i \vee \varphi_i) \wedge \bigwedge_{1 \leq i \leq m, 1 \leq j \leq 3} (\neg L'_{i,j} \vee \varphi_i \vee \neg x_i) \wedge \bigwedge_{1 \leq i < j \leq m} (\neg y_i \vee \neg y_j) \wedge (y_1 \vee \dots \vee y_m).$$

- Then we have $H_2(G)$ is unsatisfiable. Moreover, F is unsatisfiable if and only if $H_1(F) \in MU$, and G is satisfiable if and only if $H_2(G) \in MU$.
- For $H_1(F) = \bigwedge_i \sigma_i$ and $H_2(G) = \bigwedge_j \tau_j$ we define $H(F, G) = \bigwedge_{i,j} (\sigma_i \vee \tau_j)$.
- Then (F, G) is in UNSAT-SAT if and only if $H(F, G)$ is in MU.

14.2. Deficiency

A very interesting measure for the complexity of formulas in CNF is the so-called “deficiency” which indicates the difference between the number of clauses and the number of variables.

Definition 14.2.1. Let F be a formula in CNF with n clauses and k variables. Then the *deficiency* of F is defined as $d(F) = n - k$. Further, we define the *maximal deficiency* as $d^*(F) = \max\{d(G) \mid G \subseteq F\}$.

Let k -CNF be the set of CNF-formulas with deficiency (exactly) k . Then the satisfiability problem for k -CNF is NP-complete. That can be shown easily by a reduction to SAT. Similarly, let $CNF^*(k)$ be the set of formulas with maximal deficiency k , i.e. $\{F \in CNF : d^*(F) = k\}$. In [FKS02] it has been shown that the satisfiability problem for these classes is solvable in polynomial time.

The set of minimal unsatisfiable formulas with deficiency k is denoted as $MU(k)$. It has been shown in [AL86] that any minimal unsatisfiable formula has a deficiency greater than 0, that means, every minimal unsatisfiable formula contains more clauses than variables. With respect to deficiency, one of the main results is the following

Theorem 14.2.1. [FKS02] For fixed integer k the problem $\text{MU}(k)$ is solvable in polynomial time.

Instead of asking whether a formula is in $\text{MU}(k)$ we may be interested in whether a formula contains a $\text{MU}(k)$ -subformula. This problem (i.e., the set of formulas) is denoted by $\text{sup-MU}(k)$ and is NP-complete [Sze01, KZ02a].

Formulas in conjunctive normal form can be represented as matrices (“variable-clause matrices”). The columns are the clauses and for each variable there is a row.

Example 14.2.1. For example, the formula $F = (x_1 \vee x_2 \vee x_3) \wedge (x_1 \vee \neg x_3) \wedge (\neg x_2 \vee x_3) \wedge (\neg x_1 \vee x_3) \wedge (\neg x_1 \vee \neg x_2 \vee \neg x_2)$ can be written as

$$\begin{pmatrix} x_1 & x_1 & & \neg x_1 & \neg x_1 \\ x_2 & & \neg x_2 & x_2 & \neg x_2 \\ x_3 & \neg x_3 & x_3 & & \neg x_3 \end{pmatrix}$$

If the order of the variables is fixed then sometimes we replace the positive occurrence of a variable by the symbol ‘+’ and the negative occurrence by the symbol ‘-’. For the fixed order x_1, x_2, x_3 and the formula given above, we have

$$\begin{pmatrix} + & + & & - & - \\ + & & - & + & - \\ + & - & + & & - \end{pmatrix}.$$

The transposed of the variable-clause matrix is called the “clause-variable matrix”, and is studied further (as a matrix over $\{-1, 0, +1\}$) in [Kul03]; see Subsection 14.11.3.2 for further details on matrix representations of formulas.

14.2.1. Splitting

For a formula $F \in \text{MU}$ and a variable x we can assign the value true to x and reduce the formula by removing any clause with x and deleting any occurrence of $\neg x$. The formula we obtain is unsatisfiable and therefore contains at least one minimal unsatisfiable formula. If we perform the assignment also for $\neg x$ then we get two MU -formulas (a choice for each branch), and in this sense the assignment and the reduction splits the formula F into two MU -formulas. The splitting can be used to investigate the structure of MU -formulas and is a helpful tool for proofs; for an early reference see [KB99].

Definition 14.2.2. For $F \in \text{MU}$ and a variable x of F there exist formulas $B_x, C, B_{\neg x}$ in which neither x nor $\neg x$ occur such that

1. the formula F can be represented as

$$F = \{x \vee f_1, \dots, x \vee f_s\} \cup B_x \cup C \cup B_{\neg x} \cup \{\neg x \vee g_1, \dots, \neg x \vee g_t\};$$

2. $\{f_1, \dots, f_s\} \cup B_x \cup C$, denoted by F_x , is in MU , and $\{g_1, \dots, g_t\} \cup B_{\neg x} \cup C$, denoted by $F_{\neg x}$, is in MU . F_x and $F_{\neg x}$ may consist of the empty clause only.

We call $(F_x, F_{\neg x})$ a *splitting* of F on x .

Example 14.2.2. Continuing Example 14.2.1, we obtain the splitting

$$\begin{aligned} F_{\neg x_1} &= (x_2 \vee x_3) \wedge (\neg x_3) \wedge (\neg x_2 \vee x_3) \\ F_{x_1} &= (\neg x_2 \vee x_3) \wedge (x_2) \wedge (\neg x_2 \vee \neg x_3). \end{aligned}$$

The corresponding matrix representations are

$$\begin{pmatrix} x_2 & \neg x_2 \\ x_3 & \neg x_3 & x_3 \end{pmatrix}, \begin{pmatrix} \neg x_2 & x_2 & \neg x_2 \\ x_3 & & \neg x_3 \end{pmatrix}.$$

For all k , all $F \in \text{MU}(k)$, all variables x in F and all splittings $(F_x, F_{\neg x})$ of F on x we have:

1. $d(F_x), d(F_{\neg x}) \leq k$ (see Corollary 7.10 in [Kul03], considering the larger class of “matching lean” clause-sets as discussed later in Subsection 14.11.2).
2. If all variables occur positively as well as negatively at least twice, then $d(F_x), d(F_{\neg x}) < k$ (Theorem 2 in [KB00]; see Lemma 3.9 in [Kul00a] for a somewhat stronger statement, also considering the larger class of “lean” clause-sets as discussed later in Subsection 14.8.3).
3. If $k \geq 2$, then (by Lemma 3.10 in [Kul00a]) there is some variable x' such that for some splitting $(F_{x'}, F_{\neg x'})$ we have $d(F_{x'}) < k$ and $d(F_{\neg x'}) < k$. Such a variable can be computed in polynomial time.

That by splitting the deficiency can be reduced has to do with the “expansion” of variables, and is discussed further in Section 4.4 in [Kul07a]. If the common part of both formulas, C , is empty, we call the splitting *disjunctive*. We say a formula has a *unique splitting* for a variable x , if there exists exactly one pair of splitting formulas $(F_x, F_{\neg x})$. In general, splittings are not unique. If a MU-formula F has a disjunctive splitting on x then however the disjunctive splitting on x is unique. See Section 3 in [KZ03] for further investigations into splittings.

14.2.2. Structure of MU(1) and MU(2)

A class of MU-formulas with deficiency 1 is the set Horn-MU of minimal unsatisfiable Horn formulas. That together with the linear-time decidability can easily be shown by an induction on the number of variables. But MU(1) contains more formulas. The structure of MU(1)-formulas is well understood. Every MU(1)-formula can be represented as a *basic matrix* and vice versa [DDKB98]. Basic matrices are defined inductively as follows:

1. $(+ \ -)$ is a basic matrix.
2. If B is a basic matrix then

$$\begin{pmatrix} B & 0 \\ b_1 & + \end{pmatrix}, \begin{pmatrix} B & 0 \\ b_2 & - \end{pmatrix}$$

are basic matrices, where b_1, b_2 are non-null row vectors without $+$ resp. without $-$.

3. If B_1 and B_2 are basic matrices and b_1, b_2 are as above, then

$$\begin{pmatrix} B_1 & 0 \\ b_1 & b_2 \\ 0 & B_2 \end{pmatrix}$$

is a basic matrix.

Here, “+” represents a positive literal, and “−” a negative literal. We usually omit zeros and write them as blank fields. The rows belong to the variables and the columns to the clauses.

Example 14.2.3. The formula $x \wedge \neg x$ has the basic matrix $(+ -)$. For the formula $(x_1 \vee x_2) \wedge (\neg x_1) \wedge (\neg x_2 \vee x_3) \wedge (\neg x_2 \vee \neg x_3)$ we have the basic matrix

$$\begin{pmatrix} + & - & & \\ + & & - & - \\ & & + & - \end{pmatrix}.$$

Since basic matrices have a disjunctive splitting, we can always find a disjunctive splitting for MU(1)-formulas. Moreover, it is easy to see that any minimal unsatisfiable Horn formula is in MU(1), whereas for 2-CNF minimal unsatisfiable formulas with an arbitrary deficiency can be constructed. For an approach based on a tree representation of the elements of MU(1) see [Kul00a]. We remark that the class MU(1) has been studied rather extensively from the point of view of “qualitative matrix analysis”; see Subsection 14.12.1 for some general introduction.

With respect to the structure of the matrices for greater deficiencies only very few results are known. For example, every MU(2)-formula in which each literal occurs at least twice has the following form except for renaming [KB00]:

$$\begin{pmatrix} x_1 & \neg x_1 & \neg x_2 & \cdots & \neg x_{n-1} & \neg x_n & \neg x_1 \\ x_2 & x_2 & x_3 & \cdots & x_n & x_1 & \neg x_2 \\ x_3 & & & & & & \neg x_3 \\ \vdots & & & & & & \vdots \\ x_n & & & & & & \neg x_n \end{pmatrix}$$

See [SD97] for some initial study on MU(3) and MU(4).

14.3. Resolution and Homomorphism

It is well-known that in the worst-case resolution refutations of unsatisfiable formula require super-polynomially many resolution steps. For fixed deficiency, for each $F \in \text{MU}(k)$ there is a resolution refutation with not more than $2^{k-1}n$ resolution steps. The proof follows immediately by splitting property 3 from Section 14.2.1 together with the characterisation of MU(1) from Subsection 14.2.2.

It is easy to see that MU(k) is closed under $(1, *)$ -resolution (also called *singular DP-resolution*) for every k . That means, if $F = \{L \vee f, \neg L \vee g_1, \neg L \vee g_2, \dots, \neg L \vee g_s\} + F'$ \in MU(k) and L as well as $\neg L$ do not occur in F' , then

$\{f \vee g_1, f \vee g_2, \dots, f \vee g_s\} + F' \in \text{MU}(k)$. Please note that the literal L occurs only once in the formula, and that we simultaneously resolve on all clauses with literal L . In that sense, $(1, *)$ -resolution is a restricted version of hyperresolution.

We say a formula is *read-once refutable* if the formula has a resolution refutation tree in which each input clause is used at most once, and such a refutation is called a *read-once refutation*. ROR is the class of read-once refutable formulas and known to be NP-complete [IM95]. The following example is a formula for which a read-once refutation exists, no proper subformula has a read-once refutation, but the formula is not minimal unsatisfiable.

$$\left(\begin{array}{cccccccc} z & u & \neg x & \neg x & \neg a & \neg a & a & y & \neg z & \neg u \\ & & \neg y & \neg b & \neg y & \neg b & x & b & y & a \\ & & & & & & & & b & \neg x \end{array} \right).$$

Let $\text{ROR-MU}(k)$ be the set of minimal unsatisfiable formulas with deficiency k for which a read-once refutation exists. $\text{ROR-MU}(k)$ is decidable in polynomial time for any fixed k [KZ02a]. For the class $\text{Sup-ROR-MU}(k) := \{F \mid \exists G \in \text{ROR-MU}(k) : G \subseteq F\}$ it has been shown in [KZ02a, Sze01] that the decision problem is NP-complete. In [FSW06] it has been shown that the *Short Resolution Refutation* (SRR) and the *Small Unsatisfiability Subset* (SUS) problems are likely not fixed-parameter tractable, however the restrictions to planar formulas or to formulas with fixed bounds on clause-length and variable-occurrence are fixed-parameter tractable. Here SRR is the problem whether for a parameter t a refutation with at most t steps exists, and SUS is the problem of deciding whether a formula contains an unsatisfiable sub-formula with at most t clauses.

In [Sze01] homomorphisms for CNF-formulas have been introduced as a tool for proving the unsatisfiability of formulas. For CNF-formulas H and F , a mapping $\phi : \text{lit}(H) \rightarrow \text{lit}(F)$ is called a *homomorphism* from H to F if $\phi(\neg x) = \neg\phi(x)$ for every variable x , and $\phi(H) = \{\phi(h) \mid h \in H\} \subseteq F$, where $\phi(h) = \{\phi(L_1), \dots, \phi(L_m)\}$ for a clause $h = \{L_1, \dots, L_m\}$. According to [Sze01], for every tree resolution proof T one can find in polynomial time a formula $H \in \text{MU}(1)$ and a homomorphism $\phi : H \rightarrow \text{pre}(T)$, where $\text{pre}(T)$ is the set of all premises of T (i.e., the clauses labelling the leaves) such that $\phi(H) = \text{pre}(T)$, and $|H|$ equals the number of leaves of T .

Let \mathcal{C} be a class of CNF-formulas. We define $\mathcal{HOM}(\mathcal{C})$ as the set of pairs (F, G) of CNF-formulas such that a homomorphism from F to G exists with image all of G . The problem $\mathcal{HOM}(\text{Horn-MU})$ is NP-complete. Clearly, the problem is in NP. The completeness can be shown by a reduction to the 3-colouring problem for graphs. Furthermore, for fixed $k \geq 1$ the problem $\mathcal{HOM}(\text{MU}(k))$ is NP-complete, even we allow another fixed parameter $t \geq 1$ and consider all pairs (F, G) with $F \in \text{MU}(k)$ and $G \in \text{MU}(t)$ [KX05].

We say (H, ϕ) is a *representation* of F if $\phi : H \rightarrow F$ is a homomorphism with $\phi(H) = F$; so $\mathcal{HOM}(\mathcal{C})$ is the set of all pairs (F, G) such that F can be made a representation of G . Let (H, ϕ) be a representation of F , where F and H are minimal unsatisfiable formulas. If the shortest resolution refutation of F requires m steps then the shortest refutation for H needs at least m steps [KZ02b]. For all $k, t \geq 1$ and for all $F \in \text{MU}(k)$ a representation of F by a $\text{MU}(t)$ -formula can be computed in polynomial time.

A homomorphism ϕ with $\phi(H) = F$ is termed *clause-preserving* for H and F if H and F have the same number of clauses. As a consequence of results shown in [Sze01] and [KZ02b], we have that for every formula F for which a disjunctive splitting tree exists, we can find a formula $H \in \text{MU}(1)$ for which a clause-preserving homomorphism ϕ with $\phi(H) = F$ exists, and vice versa.

14.4. Special Classes

In this section we present some MU-problems for restricted classes of formulas and some additional constraints.

14.4.1. 2-CNF-MU

For every $k \geq 1$ there is a formula $F \in \text{2-CNF-MU}(k)$, the set of minimal unsatisfiable formulas with deficiency k consisting of 2-clauses. Whether a 2-CNF-formula is in MU can be decided in linear time. In a 2-CNF-MU formula, each literal occurs at most twice. Every 2-CNF-MU formula can be reduced by iterative (1,*)-resolution in linear time to a 2-CNF-MU formula in which each literal occurs exactly twice. These formulas have the following structure except for renaming

$$\begin{pmatrix} x_1 \neg x_2 \cdots \neg x_{n-1} \neg x_n \neg x_1 & x_2 \cdots x_{n-1} & x_n \\ x_2 & x_3 \cdots x_n & x_1 \neg x_2 \neg x_3 \cdots \neg x_n \neg x_1 \end{pmatrix}.$$

14.4.2. Hitting Formulas

Let $\text{HIT} := \{F \in \text{CNF} \mid \forall f, g \in F, f \neq g \exists L \in f : \neg L \in g\}$ denote the set of “hitting formulas”, formulas in which every pair of clauses has a complementary pair of literals. Let HIT-MU be the set of minimal unsatisfiable hitting formulas. In [Iwa89], a satisfiability algorithm has been introduced which counts for a given formula the number $\phi(F)$ of falsifying truth assignments (total assignments which for at least one clause falsify every literal in it). If the number is $\phi(F) = 2^n$, where n is the number of variables, then the formula is unsatisfiable, and otherwise satisfiable. The idea of this counting is based on “independent” sets of clauses. A set of clauses S is termed *independent* if every pair of (different) clauses contains no complementary pair of literals. The calculation of $\phi(F)$ can be expressed as follows for a formula $F = \{f_1, \dots, f_m\}$:

$$\phi(F) = \sum_{1 \leq i \leq m} \sum_{S \in \text{IND}_i(F)} (-1)^{i-1} \cdot 2^{n-|\text{var}(S)|}$$

where $\text{IND}_i(F) := \{S \subseteq F \mid S \text{ independent and } |S| = i\}$. F is a hitting formula if and only if $\text{IND}_i(F) = \emptyset$ for $i \geq 2$; thus for $F \in \text{HIT}$ we have

$$\phi(F) = \sum_{f \in F} 2^{n-|f|}.$$

It follows for F in HIT:

1. $\sum_{f \in F} 2^{-|f|} \leq 1$;
2. $\sum_{f \in F} 2^{-|f|} < 1 \iff F \in \text{SAT}$;
3. $\sum_{f \in F} 2^{-|f|} = 1 \iff F \in \text{MU}$.

A special class of hitting clause-sets are k -regular hitting clause-sets, where between two different clauses always *exactly* k complementary (or “clashing”) pairs of literals exist. A k -regular hitting clause-set for $k \neq 1$ is satisfiable, due to the completeness of resolution. The unsatisfiable 1-regular hitting clause-sets have been characterised in [Kul04a] as those elements of $\text{MU}(1)$ which are “saturated” or “maximal” (see below); an alternative combinatorial proof (not using methods from linear algebra as in [Kul04a]) has been given in [SST07].

14.4.3. Stronger forms of minimal unsatisfiability

Let $A \leq_p B$ denote the polynomial reducibility between A and B (i.e., A can be polynomially reduced to B), while $A =_p B$ is an abbreviation for $A \leq_p B$ and $B \leq_p A$. It is known that MARG-MU , MAX-MU and Almost-Unique-MU are D^P -complete, while $\text{Unique-MU} =_p \text{Unique-SAT} \leq_p \text{Dis-MU}$, where these classes are defined as follows:

1. *Maximal formulas* MAX-MU : A clause f of an MU -formula F is called *maximal* in F if for any literal L occurring neither positively nor negatively in f the formula obtained from F by adding L to f is satisfiable. Then $F \in \text{MAX-MU}$ if f is maximal in F for any $f \in F$. Another notion used in the literature is “saturated clause-sets”
2. *Marginal formulas* MARG-MU : A formula $F \in \text{MU}$ is called *marginal* w.r.t. a literal L if removing an arbitrary occurrence of L from F produces a non-minimal unsatisfiable formula. We say F is *marginal* if F is marginal w.r.t. all literals occurring in F . Or in other words, a formula is marginal if and only if removing an arbitrary literal always leads to a non-minimal unsatisfiable formula. The set of marginal formulas is denoted as MARG-MU .
3. *Unique minimal unsatisfiable formulas* Unique-MU : Based on the well-known concept of Unique-SAT , the set of formulas having exactly one satisfying truth assignment, we define the class Unique-MU as the class of MU -formulas F for which for any clause $f \in F$ we have $F - \{f\} \in \text{Unique-SAT}$.
4. *Almost unique formulas* Almost-Unique-MU : A weaker notion which demands that except for one clause f , the reduced formula $F - \{f\}$ must be in Unique-SAT .
5. *Disjunctive Formulas* Dis-MU : We define $F \in \text{Dis-MU}$ if $F \in \text{MU}$ and for any $x \in \text{var}(F)$ every splitting of F on x is disjunctive. Please note, that in case of a disjunctive splitting on a variable x the splitting on x is unique.

See [KZ07a] for more information on these classes.

14.4.4. Regarding the number of literal occurrences

For fixed $k \geq 3$, the problem “ k -CNF-MU”, recognising minimal unsatisfiable formulas in k -CNF, remains D^P -complete. The D^P -completeness of k -CNF-MU follows from the D^P -completeness of MU. We only have to replace longer clauses with shorter clauses by introducing new variables and by splitting the long clauses. Let k -CNF p be the class of k -CNF-formulas in which each literal occurs at least p times. It has been shown in [KBZ02] that 3-CNF-MU 3 , and for any fixed $k \geq 4$ and any $p \geq 2$ the classes k -CNF-MU p are D^P -complete. But whether a formula in 3-CNF-MU exists in which each literal in F occurs at least 5 times is not known. More results can be found for example in [KZ02a].

14.4.5. Complement-invariant formulas

A formula F is *complement-invariant* if for every clause $\{L_1, \dots, L_k\} \in F$ also the complemented clause is in F , that is $\{\neg L_1, \dots, \neg L_k\} \in F$. A complement-invariant F , which additionally consists only of positive and negative clauses, can be identified with the underlying variable-hypergraph $\mathfrak{H}(F)$, whose vertices are the variables of F while the hyperedges are the variable-sets of clauses of F . It is easy to see that such F is satisfiable if and only if $\mathfrak{H}(F)$ is 2-colourable (i.e., vertices can be coloured using two colours such that no hyperedge is monochromatic), while F is minimally unsatisfiable if and only if $\mathfrak{H}(F)$ is minimally non-2-colourable (or “critically 3-colourable”), i.e., G is not 2-colourable but removing any hyperedge renders it 2-colourable. In this way critical-3-colourability of hypergraphs is embedded into the study of minimal unsatisfiable formulas. Complement-invariant formulas have been studied at various places, but apparently the first systematic treatment is in [Kul07b]. The deficiency of complement-invariant formulas F is less useful here, but the *reduced deficiency* $d_r(F) := d(\mathfrak{H}(F))$ is the central notion, where the deficiency $d(G)$ of a hypergraph is the difference of the number of hyperedges and the number of vertices. As shown in [Sey74] (translated to our language), the reduced deficiency of minimally unsatisfiable $F(G)$ is at least 0. Solving a long outstanding open question, in [RST99, McC04] it was shown (again, in our language) that the decision problem whether a complement-invariant formula is minimally unsatisfiable with reduced deficiency 0 is decidable in polynomial time; more on the strong connections to the satisfiability problem the reader finds in [Kul07b], while in Subsection 14.12.2 of this chapter we further discuss this problem from the point of view of autarky theory.

14.4.6. Weaker forms of minimal unsatisfiability

The question whether an arbitrarily given formula can be transformed into a minimal unsatisfiable formula by replacing some literals with their complements has been studied in [Sze05]. It has been shown in [Sze05] that the problem whether a formula is satisfiable and remains satisfiable under such replacements is Π_2^P -complete.

The class of formulas which are the union of minimally unsatisfiable formulas has been studied at different places; see for example [KLMS06, Kul07a]. A generalisation of minimal unsatisfiability based on autarkies is discussed in Subsection 14.4.7.

14.4.7. Generalising minimal unsatisfiability for satisfiable formulas

Similarly to minimal unsatisfiable formulas, where removing a clause leads to a satisfiable formula, we say a formula F is *clause-minimal* (or “irredundant”) if removing a clause f from F results in a formula not equivalent to F , i.e. $F - \{f\} \not\equiv F$. Let $\text{CL-MIN} := \{F \in \text{CNF} \mid \forall f \in F : F - \{f\} \not\equiv F\}$ and $\text{CL-MIN}(k)$ the set of CL-MIN-formulas with deficiency k . The problems CL-MIN and $\text{SAT} \cap \text{CL-MIN}$ are known to be NP-complete [PW88]. Furthermore, we have $\text{MU} = \text{UNSAT} \cap \text{CL-MIN}$, and for any fixed k the problem $\text{CL-MIN}(k)$ is NP-complete [KZ05]. Further results one finds in [Kul07a].

14.4.8. Extending minimal unsatisfiable formulas

The extension problem is the problem of determining whether for pairs of formulas (F, H) there is a formula G for which $F + G \equiv H$ and $\text{var}(G) \subseteq \text{var}(H + F)$. Without any restriction this question is equivalent to whether $H \models F$ (that is, whether H implies F). The latter problem is known to be coNP-complete. Now we are looking for extensions for MU-formulas. Let $\text{MU-EXT} = \{F \mid \exists G : F + G \in \text{MU} \text{ and } \text{var}(G) \subseteq \text{var}(F)\}$. Then we have $\text{MU-EXT} = \text{CL-MIN}$. Suppose, a CNF-formula F can be extended to a minimal unsatisfiable formula. Then it is easy to see that F is clause minimal. For the inverse direction suppose $F \in \text{CL-MIN}$ is satisfiable. Let $\{t_1, \dots, t_r\}$ be the set of satisfying (total) truth assignments for F and let G consist of the r clauses exactly falsified by the assignments t_i ; then $F + G$ is in MU. More details and further classes can be found in [KZ05]

14.5. Extension to non-clausal formulas

In this section, we will extend the notion of “minimal unsatisfiability” and “deficiency” to non-clausal propositional formulas, where for the sake of a simplified representation we only allow the operations “binary and”, “binary or” and “not”. Furthermore we study only formulas in “negation normal form”, where we have negations only at the leaves, i.e., we study binary nested and’s and or’s of literals. The length of a propositional formula is the number of occurrences of literals. More formally, the length can be defined as $\ell(L) = 1$ for a literal L and $\ell(F \wedge G) = \ell(F \vee G) = \ell(F) + \ell(G)$. The number of occurrences of \wedge -symbols in a formula F is denoted by $\#\wedge(F)$, whereas $\#\vee(F)$ is the number of \vee -symbols. Obviously, we have $\ell(F) = 1 + \#\wedge(F) + \#\vee(F)$ (since the operations are binary). Following [KZ07b], we define:

Definition 14.5.1. Let F be a propositional formula in negation normal form with $n(F)$ variables. The *cohesion* $D(F)$ is defined as $D(F) = 1 + \#\wedge(F) - n(F)$.

Example 14.5.1. The formula $F = (x \wedge y) \vee (\neg x \wedge (z \vee \neg y))$ has the cohesion $D(F) = 1 + \#\wedge(F) - n(F) = 1 + 2 - 3 = 0$. An application of the distributive law $F \wedge (G \vee H) \equiv (F \wedge G) \vee (F \wedge H)$ may change the cohesion. For example, from $F = z \wedge (x \vee y)$ we obtain the formula $F' = (z \wedge x) \vee (z \wedge y)$. The cohesion of F is -1 and the cohesion of F' is 0 .

For propositional formulas in negation normal form the so-called ‘‘Tseitin procedure’’ generates satisfiability-equivalent formulas in CNF. Two formulas F and G are satisfiability-equivalent, if F is satisfiable if and only if G is satisfiable. For F a propositional formula in negation normal form, the Tseitin procedure replaces step by step subformulas of the form $(F_1 \wedge F_2) \vee F_3$ by the formula $(z \vee F_1) \wedge (z \vee F_2) \wedge (\neg z \vee F_3)$ for a new variable z . Let $\text{ts}(F)$ denote a formula in CNF obtained from F by this Tseitin procedure, eliminating the non-determinism in the procedure in some (arbitrary) way. Because the Tseitin procedure adds as many \wedge -symbols as new variables, we obtain $D(\text{ts}(F)) = D(F)$.

Lemma 14.5.1. *Let F be a propositional formula in negation normal form. Then we have $D(F) = \ell(F) - \#\vee(F) - n(F)$. and if $F \in \text{CNF}$, then $D(F) = d(F)$.*

Minimal unsatisfiability is defined for formulas in conjunctive normal form. The formulas are unsatisfiable, and after eliminating an arbitrary clause the formulas are satisfiable. In non-clausal formulas, instead of the deletion of a clause we will remove so-called ‘‘or-subformulas’’ based on a representation of formulas as trees:

- If the formula is a literal L , the associated tree T_L is a node labelled with L .
- For a formula $F \wedge G$ (resp. $F \vee G$) let T_F and T_G be the associated trees. Then we have a root labelled with \wedge (resp. \vee) and the subtrees T_F and T_G . That means, the successor nodes of the \wedge -node (resp. \vee -node) are the roots of T_F and T_G .

Please notice that the leaves of the tree are labelled with the literals of the formula. Let T be the associated tree of a formula. An *or-subtree* of T is a subtree T' , whose root is either an \vee -node or a literal which is successor of an \wedge -node. An or-subtree T' of T is again a representation of a propositional formula, say $F_{T'}$, which is a subformula of the propositional formula of F . The formula $F_{T'}$ is called an *or-subformula* of F . In case of formulas in conjunctive normal form, the or-subformulas are exactly the clauses.

Example 14.5.2. For the formula $(\neg y) \wedge ((x \vee y) \wedge a) \vee \neg z$ the associated tree

is

and the four or-subformulas are $(\neg y)$, $((x \vee y) \wedge a) \vee (\neg z)$, $(x \vee y)$, and a .

In case of a propositional formula F (as always in negation normal form), an or-subformula of F is a subformula of F . For formulas in conjunctive normal form, that is a conjunction of clauses, a satisfiable formula remains satisfiable after the deletion of any clause. Similarly, after the deletion of an or-subtree in a satisfiable formula the formula is still satisfiable. That follows from the definition of or-subtrees, because the predecessor node of an or-subtree is an \wedge -node, and so the deletion of an or-subtree does not decrease the truth-value of the formula at that \wedge -node, while the formulas are in negation normal form and thus all operations are monotonically increasing.

Definition 14.5.2. A propositional formula F in negation normal form is in MU^* if F is unsatisfiable and eliminating an arbitrary or-subformula yields a satisfiable formula. The set of formulas in MU^* with cohesion (exactly) k is denoted by $MU^*(k)$.

It can easily be shown that for a CNF-formula being minimally unsatisfiable and being element of MU^* are equivalent properties. By the property of the Tseitin procedure, and the results known for MU and $MU(k)$ the following theorem holds [KZ07b].

Theorem 14.5.2. *The following holds for the notion of minimal unsatisfiable propositional formulas according to Definition 14.5.2:*

1. MU^* is D^P -complete.
2. For $F \in MU^*$ we have $D(F) \geq 1$.
3. For fixed k , $MU^*(k)$ is decidable in polynomial time.

There is an alternative definition of the class MU^* , based on the complementation of literal occurrences. Let MU_L be the set of unsatisfiable formulas F such that for all literal occurrences of F its replacement by its complement renders the formula satisfiable. Obviously, for formulas in CNF, any formula in MU_L is in MU and vice versa. For the general case, $MU^* = MU_L$ can be shown by an analysis of the Tseitin procedure $ts(F)$.

14.6. Minimal Falsity for QBF

The concept of minimal unsatisfiability for CNF can be extended to QCNF, the class of closed quantified Boolean formulas in prenex form and with matrix in CNF; see Chapter 7 in [KBL99] for a general introduction to quantified propositional logic. All formulas F in QCNF have the form $F = Q_1x_1 \cdots Q_nx_nf$, where $Q_i \in \{\exists, \forall\}$ and f is a propositional formula in conjunctive normal form using (only) the variables x_1, \dots, x_n . $Q_1x_1 \cdots Q_nx_n$ is the *prefix* of F , and f is called the *matrix* of F . The set of existential variables is denoted by $\text{var}_{\exists}(F)$, while $\text{var}(F)$ is the set of all variables. Let $F = Q_1x_1 \cdots Q_nx_nf$, $F' = Q_1x_1 \cdots Q_nx_nf'$ be two QCNF formulas with the same prefix. We say that F' is a *subformula* of F , denoted by $F' \subseteq F$, if f' is a subformula of f . Let Qf be a formula in QCNF with prefix Q . Then $f_{|\exists}$ is the conjunction of clauses we obtain after the deletion of all occurrences of literals with universal variables from f . Please note, that the propositional formula $f_{|\exists}$ may contain multiple occurrence of clauses. A formula $Q(f_1 \wedge \cdots \wedge f_n)$ in QCNF is called *minimal false*, if the formula is false and for any clause f_i the formula $Q(f_1 \wedge \cdots \wedge f_{i-1} \wedge f_{i+1} \wedge \cdots \wedge f_n)$ is true. The class of minimal false formulas is denoted as MF.

The minimal falsity problem MF is PSPACE-complete [KZ06]. That can easily be shown by means of the PSPACE-completeness of the satisfiability problem for QCNF. Since the satisfiability problem for quantified Boolean Horn formulas (QHORN) and formulas with matrix in 2-CNF (Q2-CNF) is solvable in polynomial time, the minimal falsity problems for both classes are solvable in polynomial time, too. The notion of deficiency and maximal deficiency can be extended to QCNF, taking only the existential variables into account.

Definition 14.6.1. [KZ06]

1. Let $F = Qf \in \text{QCNF}$ with m clauses. The deficiency is defined as $d(F) = m - |\text{var}_{\exists}(f)|$.
2. The maximal deficiency of F is defined as $d^*(F) := \max\{d(F') : F' \subseteq F\}$.
3. Let k be fixed. The set of minimal false formulas with deficiency k is defined as $\text{MF}(k) = \{F : F \in \text{MF} \text{ and } d(F) = k\}$.

Some of the methods and techniques well-known for $\text{MU}(k)$ can be adapted in order to prove similar results. For example, a formula F is termed *stable* if for any proper subformula $F' \subset F$, $d(F') < d(F)$. The notion of stable QCNF formulas can be understood as a generalisation of matching lean CNF formulas [Kul03]. A formula $F \in \text{CNF}$ is matching lean if and only if $d(F') < d(F)$ for each proper subformula $F' \subset F$; see Subsection 14.11.2. By Definition 14.6.1, F is stable if and only if $F_{|\exists}$ is matching lean. Corollary 7.12 in [Kul03] says that the largest matching lean subformula can be computed in polynomial time. This implies that the largest stable subformula can also be computed in polynomial time.

Theorem 14.6.1. [KZ08a] *Let $F = Qf$ be a formula in QCNF.*

1. *If $f_{|\exists}$ is satisfiable or $d^*(F) \leq 0$, then F is true.*
2. *If $F \in \text{MF}$, then F is stable.*
3. *Any minimal false formula has deficiency strictly greater than 0.*

Besides MF(1), which is solvable in polynomial time as shown later in this section, the computational complexity of MF(k) is open, where only some non-trivial upper bounds are known.

Theorem 14.6.2. [KZ06] *Let k be fixed.*

1. *The satisfiability problem for QCNF with maximal deficiency k is in NP.*
2. *The minimal falsity problem MF(k) for QCNF is in D^P .*

The proof of Theorem 14.6.2 makes use of the size of models of satisfiable formulas in QCNF with maximal deficiency k . Let $F = \forall x_1 \exists y_1 \forall x_2 \exists y_2 \cdots \forall x_k \exists y_k f$ be a formula in QCNF. The formula is true if and only if there are Boolean functions (formulas) $\rho_i : \{0, 1\}^i \rightarrow \{0, 1\}$ for $i \in \{1, \dots, k\}$ (depending on x_1, \dots, x_i) such that

$$\forall x_1 \cdots \forall x_k f[y_1/\rho_1(x_1), \dots, y_k/\rho_k(x_1, \dots, x_k)]$$

is true. $f[y_1/\rho_1, \dots, y_k/\rho_k]$ denotes the formula obtained by simultaneously replacing in the matrix the occurrences of the existential variables y_i by the formulas ρ_i . In general a sequence of Boolean functions $M = (\rho_1, \dots, \rho_k)$ is called a *model* for F if the formula is true for these functions. We assume that the Boolean functions ρ_i are represented as propositional formulas. If the Boolean functions ρ_i are given as CNF-formulas, then we call M a *CNF-model* for F .

Theorem 14.6.3. [KZ08a] *For any $k \geq 1$ and any true QCNF formula $F = Qf$ with maximal deficiency $d^*(F) = k$, there is a set U with at most $2^{4k/3}$ universal variables such that F has a CNF-model $M = (\rho_1, \dots, \rho_m)$ where the formulas ρ_i are constants or fulfil $\text{var}(\rho_i) \subseteq U$ and have at most 2^k clauses.*

The size of the model functions only depends on k . By guessing a set U of size less than or equal to $2^{4k/3}$ and model formulas ρ_i , and replacing x_i by ρ_i , we obtain a universally quantified formula with universal variables in U . Since k is fixed, the satisfiability of these formulas can thus be decided in polynomial time.

QEHORN (QE2-CNF respectively) is the set of formulas in QCNF with $F = Qf$ for which $f_{|\exists}$ is a Horn formula (2-CNF formula respectively). That means, the existential part of the matrix is in HORN (2-CNF respectively). The satisfiability problem for both classes is PSPACE-complete. Through unfolding these formulas by setting the universal variables to true and false, we get an existentially quantified Horn formula (2-CNF formula respectively). Since any true QCNF formula with maximal deficiency $k \geq 0$ has a model over at most $2^{4k/3}$ universal variables, the length of the unfolded formula can be bounded polynomially in the length of the initial formula. Since the satisfiability of Horn and 2-CNF formulas is decidable in polynomial time, we obtain the following result.

Lemma 14.6.4. *Let k be fixed.*

1. *The satisfiability problem for formulas in QEHORN and QE2-CNF with maximal deficiency k is solvable in polynomial time.*
2. *The minimal falsity problem for formulas in QEHORN and QE2-CNF with deficiency k can be decided in polynomial time.*

Formulas in MF(1) are closely related to formulas in MU(1). Every formula $F = Qf$ in MF(1) has a matrix $f_{|\exists} \in \text{MU}(1)$. But the other direction does not hold. A simple counterexample is as follows.

Example 14.6.1. Consider

$$F = \forall x \exists y (\neg x \vee y) \wedge (x \vee \neg y).$$

$((\neg x \vee y) \wedge (x \vee \neg y))|_{\exists} = (\neg x \wedge x) \in \text{MF}(1)$, but the formula F is satisfiable (by the model $y = x$).

Theorem 14.6.5. [KZ08a] *The minimal falsity problem $\text{MF}(1)$ is solvable in polynomial time.*

The polynomial-time algorithm is based on the following observations:

1. The satisfiability problem for QCNF formulas with maximal deficiency 1 is solvable in polynomial time.
2. For any true QCNF formula with $d^*(F) = 1$, there exists at most one universal variable y , such that there is a model in which the model functions are either the constants 0 or 1, or the formulas y or $\neg y$.
3. The clauses of a $\text{MF}(1)$ -formula must satisfy some properties on the connectivity of clauses.

14.7. Applications and Experimental Results

The core problems of relevant applications in this area is to extract minimal unsatisfiable sub-formulas (“MUS’s”) of a CNF-formula, where more precisely three levels can be distinguished:

1. finding some “small” unsatisfiable sub-formula;
2. finding some minimal unsatisfiable sub-formula (MUS);
3. finding a smallest minimal unsatisfiable sub-formula.

Additionally we are also interested in finding all MUS’s. Regarding finding “small” unsatisfiable sub-formulas, [BS01, Bru03] enhance and modify DPLL-solvers so that they target “hard clauses”, from which the unsatisfiable sub-formula is obtained. [ZM04] also only finds “small” unsatisfiable sub-formulas, but uses the resolution refutation found by conflict-driven SAT solvers. Regarding finding MUS’s, a natural and simple algorithm is given in [vW08], while learning of conflict-driven SAT solvers is exploited in [OMA⁺04], and [GMP06, GMP07a] use the information obtained by local search solvers on maximally satisfiable sub-formulas (see [GMP07b] for generalisations regarding constraint satisfaction problems). For finding smallest MUS’s, in [Bru05] ideas from linear programming are applied to special classes of CNF-formulas, while a general branch-and-bound algorithm is given in [MLA⁺05]. Regarding finding all MUS’s, [LS05] exploit the duality between MUS’s and maximally satisfiable sub-formulas (“MSS’s”; the generalisation for non-boolean variables and irredundant clause-sets is given in Lemma 6.11 in [Kul07a]). Finally, connecting MUS’s with “autarkies” (as a weaker form of redundancies), we mention [KLMS06, LS08].

14.8. Generalising satisfying assignments through “autarkies”

At several places did we already encounter the notion of an “autarky”. In the subsequent sections we give an overview on the emerging theory of autarkies.

14.8.1. Notions and notations

In the previous section the “logical aspect” of SAT has been emphasised, and thus the basic objects of study were called “formulas”. Autarky theory takes a more combinatorial turn and needs to take full account of “syntactical details”, and thus we will now speak of *clause-sets*, which are (here only finite) sets of *clauses*, where a clause is a finite and complement-free set of literals. Some useful notions:

- The *empty clause* is denoted by $\perp := \emptyset$, while the *empty clause-set* is denoted by $\top := \emptyset$.
- For a literal x we denote the underlying variable by $\text{var}(x)$, while for a clause C we define $\text{var}(C) := \{\text{var}(x) : x \in C\}$, and $\text{var}(F) := \bigcup_{C \in F} \text{var}(C)$ for a clause-set F .
- The number of clauses of a clause-set F is $c(F) := |F| \in \mathbb{N}_0$, while the number of variables is $n(F) := |\text{var}(F)| \in \mathbb{N}_0$.

An important step is to emancipate the notion of a *partial assignment*, which is a map $\varphi : V \rightarrow \{0, 1\}$ where V is some finite set of variables (possibly the empty set); we use $\text{var}(\varphi) := V$ to denote the domain of φ .² Using $\varphi(\bar{v}) = \varphi(v)$, partial assignments are extended to literals (over their domain). The application of a partial assignment φ to a clause-set F is denoted by $\varphi * F$, and is defined as the clause-set obtained from F by first removing all clauses satisfied by φ , and then removing from the remaining clauses all literal occurrences which are falsified by φ . Partial assignments φ, ψ can be combined by the operation $\varphi \circ \psi$ which is the partial assignment with domain the union of the domains of φ and ψ , while $(\varphi \circ \psi)(v)$ is defined as $\psi(v)$ if possible and otherwise $\varphi(v)$. Using $\langle \rangle$ for the empty partial assignment, we have the following fundamental laws:

$$\begin{aligned} (\varphi \circ \psi) \circ \theta &= \varphi \circ (\psi \circ \theta) \\ \varphi \circ \langle \rangle &= \langle \rangle \circ \varphi = \varphi \\ \varphi * (\psi * F) &= (\varphi \circ \psi) * F \\ \langle \rangle * F &= F \\ \varphi * \top &= \top \\ \varphi * (F_1 \cup F_2) &= \varphi * F_1 \cup \varphi * F_2 \\ \perp \in F &\Rightarrow \perp \in \varphi * F. \end{aligned}$$

A clause-set F is satisfiable if it has a satisfying assignment φ , that is, fulfilling $\varphi * F = \top$ (while a “falsifying assignment” fulfils $\perp \in \varphi * F$). We need some specific notions to fix the variables involved in satisfying assignments:

Definition 14.8.1. For a clause-set F and a set of variables V with $\text{var}(F) \subseteq V$ let $\text{mod}_V(F)$ be the set of satisfying assignments φ with domain exactly V , while we use $\text{mod}(F) := \text{mod}_{\text{var}(F)}(F)$.

Satisfying partial assignments in the sense of Definition 14.8.1, with a fixed domain including all variables in F , are called “total satisfying assignments”. We

²Often partial assignments are identified with clauses, interpreting them as setting their literals to 1 (for CNF); for a systematic treatment however this convenient “trick” is better avoided, and we put emphasis on the different roles played by clauses and partial assignments.

denote the restriction of a partial assignment φ to the domain $V \cap \text{var}(\varphi)$ by $\varphi|V$ for a set V of variables. Finally, for a partial assignment φ we denote by C_φ^ε for $\varepsilon \in \{0, 1\}$ the clause consisting of exactly the literals x with $\varphi(x) = \varepsilon$; thus C_φ^0 consists of the literals falsified by φ , the “CNF representation” of φ , while C_φ^1 consists of the literals satisfied by φ , the “DNF representation” of φ .

Partial assignments assign truth values 0, 1 to values, and their operation on clause-sets F by $\varphi * F$ handles literals accordingly; a simpler operation is that by a (finite) set V of variables, where now literals involving these variables are simply crossed out, and we write $V * F$ for this operation. While for partial assignments the above laws just reflect, that we have an operation of the monoid of partial assignments (see Subsection 14.9.1) on the (upper) semilattice of clause-sets, here now we have the operation of finite sets of variables as (upper) semilattice, with set-union as composition, on the (upper) semilattice of clause-sets, with the laws $V * (W * F) = (V \cup W) * F$, $\emptyset * F = F$, $V * \top = \top$, $V * (F_1 \cup F_2) = V * F_1 \cup V * F_2$, and also $\perp \in F \Rightarrow \perp \in V * F$.

In order to give some examples, we need some notation for specific partial assignments, and we use for example “ $\langle x \rightarrow 1, y \rightarrow 0 \rangle$ ” to denote the partial assignment which sets variable x to 1 (i.e., true) and y to 0 (i.e., false); instead of variables also literals can be used here.

Example 14.8.1. Using four (different) variables a, b, x, y and the clause-set $F := \{\{a, b\}, \{x, \bar{a}\}, \{y, a, b\}, \{\bar{x}, y, b\}\}$ we have $\langle x \rightarrow 1, y \rightarrow 0 \rangle * F = \{\{a, b\}, \{b\}\}$ and $\{a, x\} * F = \{\{b\}, \perp, \{y, b\}\}$.

Often we need to select clauses containing some variables from a given set of variables, and we do this by $F_V := \{C \in F : \text{var}(C) \cap V \neq \emptyset\}$ for clause-sets F and sets of variables V . Finally we need to *restrict* clause-sets F to some set V of variables, and, generalising a standard notion from hypergraph theory, we use $F[V]$ for this operation, defined by

$$F[V] := (\text{var}(F) \setminus V) * F_V.$$

Note that we have $F[V] = ((\text{var}(F) \setminus V) * F) \setminus \{\perp\}$. Finally we remark that for more combinatorially-oriented investigations often clauses need to occur several times, and thus (at least) *multi*-clause-sets are needed; the reader finds the generalisation of the considerations here to multi-clause-sets in [Kul07a], while in Subsection 14.11.3.2 we discuss the more general notion of “labelled clause-sets”.

14.8.2. Autarkies

Now we come to the fundamental notion of an “autarky”. The term was coined by [MS85] for a partial assignment whose application produces a sub-clause-set, while implicitly used in works like the similar [Luc84] or in the earlier [EIS76]. Since these works took a more “logical” point of view (they were just concerned with deciding satisfiability, not with more detailed structural investigations), the underlying notion of an “autarky” was ambiguous w.r.t. whether contractions of clauses after application of partial assignments was taken into account or not. This ambiguity is resolved by distinguishing between “weak autarkies” and “(normal) autarkies”:

Definition 14.8.2. A partial assignment φ is called a **weak autarky for F** if $\varphi * F \subseteq F$ holds, while φ is an **autarky for F** if φ is a weak autarky for all sub-clause-sets F' of F .

Every satisfying assignment for F is an autarky for F . Thus every partial assignment is an autarky for \top .

Example 14.8.2. The partial assignment $\langle b \rightarrow 0 \rangle$ is a weak autarky for $F := \{\{a\}, \{a, b\}\}$, but not an autarky for F . The partial assignment $\langle b \rightarrow 1 \rangle$ is an autarky for F .

The basic fact about (weak) autarkies is the observation:

*If φ is a weak autarky for F , then $\varphi * F$ is satisfiability equivalent to F .*

(For every partial assignment φ we have that from $\varphi * F$ being satisfiable follows F being satisfiable, while the other direction, that if F is satisfiable then $\varphi * F$ is satisfiable, follows from $\varphi * F \subseteq F$.) A well-known reduction for SAT-solving is the elimination of pure literals, and this is a special case of an “autarky reduction” (see Subsection 14.8.3 for the treatment of full autarky reduction).

Example 14.8.3. A *pure literal* (also called “monotone literal”) for a clause-set F is a literal x such that \bar{x} does not occur in F (i.e., $\bar{x} \notin \bigcup F$). Every pure literal x for F yields an autarky $\langle x \rightarrow 1 \rangle$ for F . In Example 14.8.2, literals a, b are pure literals for F . See Subsection 14.11.1 for more on “pure autarkies”.

Autarkies are easily characterised by

φ is an autarky for F if and only if for every clause $C \in F$
 either φ does not “touch” C , i.e., $\text{var}(\varphi) \cap \text{var}(C) = \emptyset$,
 or φ satisfies C , i.e., $\varphi * \{C\} = \top$.

Weak autarkies are allowed to touch clauses without satisfying them, if the resulting clause (after removal of falsified literals) was already present in the original clause-set. Since we regard it as essential that an autarky for a clause-set is also an autarky for every sub-clause-set, the fundamental notion is that of an “autarky”; see Subsection 14.8.4 for a discussion. The basic characterisations of autarkies in terms of satisfying assignments are given by the following equivalent statements (for arbitrary clause-sets F and partial assignments φ):

1. φ is an autarky for F
2. iff φ is a satisfying assignment for $F_{\text{var}(\varphi)}$
3. iff φ is a satisfying assignment for $F[\text{var}(\varphi)]$.

The following properties of autarkies are considered to be the most basic ones (leading to an “axiomatic” generalisation in Section 14.11), for arbitrary clause-sets F , partial assignments φ and sets V of variables:

1. $\langle \rangle$ is an autarky for F . In general, φ is an autarky for F iff the restriction $\varphi|_{\text{var}(F)}$ is an autarky for F , and φ is called a *trivial autarky* for F if $\text{var}(\varphi) \cap \text{var}(F) = \emptyset$ (i.e., iff $\varphi|_{\text{var}(F)} = \langle \rangle$).
2. If φ is an autarky for F , then φ is also an autarky for $F' \subseteq F$.

3. If φ, ψ are autarkies for F then also $\psi \circ \varphi$ is an autarky for F . More generally, if φ is an autarky for F and ψ is an autarky for $\varphi * F$, then $\psi \circ \varphi$ is an autarky for F .
4. If $\text{var}(\varphi) \cap V = \emptyset$, then φ is an autarky for $V * F$ iff φ is an autarky for F .
5. φ is an autarky for F iff φ is an autarky for $F \cup \{\perp\}$.
6. If φ is an autarky for F , and F' is isomorphic to F (by renaming variables and flipping polarities; compare Subsection 14.9.5), then applying the same renamings and flipping of polarities to φ we obtain an autarky φ' for F' .

An *autark subset* (or “autark sub-clause-set”) of F is some $F' \subseteq F$ which is (exactly) satisfied by some autarky φ for F , i.e., $F' = F \setminus (\varphi * F)$. \top is an autarky sub-clause-set of F , and if F_1, F_2 are autark sub-clause-sets of F , then so is $F_1 \cup F_2$. It follows that there is the *largest autark sub-clause-set* of F .

14.8.3. Autarky reduction and lean clause-sets

Given an autarky φ for clause-set F , we can reduce F satisfiability-equivalent to $\varphi * F$. A clause-set F is called *lean* if no autarky-reduction is possible, that is, if every autarky for F is trivial. This notion was introduced in [Kul00b], and further studied in [Kul03, Kul07a]. Examples for lean clause-sets are \top , all minimally unsatisfiable clause-sets, and clause-sets obtained from lean clause-sets by the extension rule of extended resolution (see Lemma 3.2 in [Kul00b]). Except of \top , every lean clause-set is unsatisfiable, and F is lean iff $F \cup \{\perp\}$ is lean. If F is lean, then so is $V * F$ and the restriction $F[V]$. The union of lean clause-sets is again lean, and thus, as with autark subsets, the lean sub-clause-sets of a clause-set form a set stable under union, with smallest element \top , while the largest element is called the **lean kernel** and denoted by $N_a(F)$.

Another possibility to define the lean kernel is by using that autarky reduction is confluent: By repeating autarky-reduction for a clause-set F as long as possible, i.e., until we arrive at a lean sub-clause-set $F' \subseteq F$, we obtain the lean kernel $N_a(F) = F'$ (here the letter “N” stands for “normal form”). The lean kernel can be characterised in many other ways:

1. $N_a(F)$ is the largest lean sub-clause-set of F .
2. $F \setminus N_a(F)$ is the largest autark subset of F .
3. The decomposition $F = N_a(F) \cup (F \setminus N_a(F))$ is characterised as the unique decomposition $F = F_1 \cup F_2$, $F_1 \cap F_2 = \emptyset$, such that
 - (a) F_1 is lean, and
 - (b) $\text{var}(F_1) * F_2$ is satisfiable.
4. So $N_a(F)$ is the unique $F' \subseteq F$ such that F' is lean and $\text{var}(F') * (F \setminus F')$ is satisfiable.

The operator N_a is a kernel operator, that is, we have $N_a(F) \subseteq F$, $F \subseteq G \Rightarrow N_a(F) \subseteq N_a(G)$, and $N_a(N_a(F)) = N_a(F)$; furthermore we have $N_a(F) = \top$ iff F is satisfiable, while $N_a(F) = F$ iff F is lean.

We now consider the fundamental *duality* between autarkies and resolution. A precursor of this duality in the context of tableaux calculi has been established in [Van99] (see especially Theorems 5.2, 5.3 there); in Subsection 14.10.2 we will

further discuss this work. We recall the resolution rule, which allows for “parent clauses” C, D which clash in exactly one literal x , i.e., $C \cap \overline{D} = \{x\}$, to derive the “resolvent” $R := (C \setminus \{x\}) \cup (D \setminus \{\overline{x}\})$. A resolution refutation for F is a (rooted) binary tree labelled with clauses, such that the leaves are labelled with clauses from F , every inner node is labelled by a resolvent of its two children, and the root is labelled with \perp . F is unsatisfiable iff it has a resolution refutation. We remark that such resolution refutations do not allow for “dead ends”, and that handling “full resolution”, i.e., resolution in dag-form, where clauses can be parent-clauses for several resolution steps, can be achieved in this framework by not counting nodes of the tree but only counting different clauses. A basic observation is that a clause $C \in F$ containing a pure literal cannot be used (i.e., label a leaf) in any resolution refutation, since we can never get rid off this pure literal. This can be generalised to the fact that if φ is an autarky for F satisfying some leaf clause of a resolution tree, then φ also satisfies every clause on the path from this leaf to the root (the autarky condition prevents the possibility that all satisfied literals vanish together). Thus a clause satisfied by some autarky cannot be part of any resolution refutation. In Section 3.3 in [Kul00b] it was shown that also the reverse direction holds.

Theorem 14.8.1. *For every clause-set F the lean kernel $N_a(F)$ consists of exactly the clauses from F which can be used in some (tree) resolution refutation of F (without dead-ends). In other words, there exists an autarky satisfying some clause $C \in F$ if and only if C cannot be used in any resolution refutation of F .*

Theorem 14.8.1 yields a method for computing the lean kernel, which will be discussed in Subsection 14.10.3.

14.8.4. Remarks on autarkies vs. weak autarkies

A weak autarky φ for a clause-set F is not an autarky for F iff there exists some $F' \subset F$ such that φ is not a weak autarky for F' ; e.g., in Example 14.8.2 $\langle b \rightarrow 0 \rangle$ is not a weak autarky for $\{\{a, b\}\} \subset F = \{\{a\}, \{a, b\}\}$. So the property of being a weak autarky is not inherited by sub-clause-sets, which makes weak autarkies a more fragile, “accidental” or “non-algebraic” concept. Nevertheless, weak autarkies share many properties with autarkies:

1. If φ is a weak autarky for F , and ψ a weak autarky for $\varphi * F$, then $\psi \circ \varphi$ is a weak autarky for F (this follows by definition).
2. Consider a weak autarky ψ for F ; as mentioned, if ψ is not an autarky for F then ψ is not a weak autarky for some sub-clause-set F' of F . However ψ is a weak autarky for each $F' \subseteq F$ such that there is a weak autarky φ for F with $F' = \varphi * F$ (since if ψ is not a weak autarky for F' anymore, then the “absorbing” clause $C \in F$ for some “new” clause $\psi * D = C$, $D \in F'$, created by ψ , must have vanished, which in this case means that $\varphi * \{C\} = \top$, implying $\varphi * \{D\} = \top$, and thus also D vanished).
3. It follows that the composition of weak autarkies is again a weak autarky. So the weak autarkies for a clause-set F form a sub-monoid of $(\text{PASS}, \circ, \langle \rangle)$, containing the autarky monoid $\text{Auk}(F)$ (see Section 14.9 for the autarky monoid).

4. Furthermore reduction by weak autarkies is confluent, yielding a (well-defined) sub-clause-set of $N_a(F)$.

14.9. The autarky monoid

We have already mentioned that the composition of autarkies yields again an autarky. This fundamental observation was made in [Oku00], and it initiated the study of the *autarky monoid* in [Kul00b], continued in [KMT08]. In this subsection we discuss the basic features of the autarky monoid. Some prerequisites from algebra are used, and the following literature might help to provide the missing (always elementary) definitions: [Lau06] in Chapters 1 - 4 provides basic material on algebraic structures and hull (“closure”) systems; [Bou89], Sections §I.1 - §I.5, presents the basics on monoids, groups and operations in a systematic way, while Chapter I in [Lan02] presents such material (including categories) in a somewhat more advanced fashion; regarding category theory an accessible introduction is given by the first two chapters of [Pie91].

14.9.1. The monoid of partial assignments

Since “autarky monoids” are sets of autarkies together with the composition of partial assignments, we need to take a closer look at the monoid \mathcal{PASS} of all partial assignments. Starting with an arbitrary set \mathcal{VA} of “variables”, we obtain the set \mathcal{LIT} of literals (uncomplemented and complemented variables), the set \mathcal{CL} of clauses (finite and clash-free sets of literals) and the set \mathcal{CLS} of clause-sets (finite sets of clauses), while \mathcal{PASS} is the set of maps $\varphi : V \rightarrow \{0, 1\}$ for some finite $V \subseteq \mathcal{VA}$.³ The monoid $(\mathcal{PASS}, \circ, \langle \rangle)$ of partial assignments (together with the composition of partial assignments, and the empty partial assignment as the neutral element) has the following properties:

1. \mathcal{PASS} is generated by the elementary partial assignments $\langle v \rightarrow \varepsilon \rangle$ for variables $v \in \mathcal{VA}$ and $\varepsilon \in \{0, 1\}$. The defining relations between elementary partial assignments (those relations which specify the composition of \mathcal{PASS}) are

- (a) $\langle v \rightarrow \varepsilon \rangle \circ \langle v \rightarrow \varepsilon' \rangle = \langle v \rightarrow \varepsilon' \rangle$;
- (b) $\langle v \rightarrow \varepsilon \rangle \circ \langle w \rightarrow \varepsilon' \rangle = \langle w \rightarrow \varepsilon' \rangle \circ \langle v \rightarrow \varepsilon \rangle$ for $v \neq w$.

For a partial assignment $\varphi \in \mathcal{PASS}$ we have the unique representation $\varphi = \circ_{v \in \text{var}(\varphi)} \langle v \rightarrow \varphi(v) \rangle$ (using the commutativity of elementary partial assignments for different variables).

³The set \mathcal{VA} may be some finite set; more useful would be the choice $\mathcal{VA} = \mathbb{N}$, while actually for a theoretical study the choice of \mathcal{VA} as a universe of set theory (a set stable under all set-theoretical operations) is most appropriate. Literals are best represented via $\mathcal{LIT} := \mathcal{VA} \times \{0, 1\}$, where 0 stands for “uncomplemented”. And a map f with domain X is a set $\{(x, f(x)) : x \in X\}$ of ordered pairs, so that a partial assignment is formally the same as a clause, namely a set of pairs (v, ε) , only that now the interpretation is the opposite: while a literal $(v, \varepsilon) \in C$ in a clause C means “ v shall not get value ε ”, an assignment $(v, \varepsilon) \in \varphi$ for a partial assignment φ means that v gets value ε ; this duality reflects that clauses are part of a CNF representation of the underlying boolean function, while (satisfying) partial assignments are part of a DNF representation.

2. The closure (hull) of a finite set $P \subseteq \mathcal{PASS}$ of partial assignments under composition (i.e., the generated monoid) is again finite (since every partial assignment involves only finitely many variables).
3. \mathcal{PASS} is idempotent, i.e., for all $\varphi \in \mathcal{PASS}$ we have $\varphi \circ \varphi = \varphi$.
4. The following assertions are equivalent for $\varphi, \psi \in \mathcal{PASS}$:

- (a) φ, ψ commute (i.e., $\varphi \circ \psi = \psi \circ \varphi$);
- (b) φ, ψ are compatible (i.e., $\forall v \in \text{var}(\varphi) \cap \text{var}(\psi) : \varphi(v) = \psi(v)$);
- (c) there exists a partial assignment $\theta \in \mathcal{PASS}$ with $\varphi \subseteq \theta$ and $\psi \subseteq \theta$.

For a partial assignment $\varphi \in \mathcal{PASS}$ the submonoid $\mathcal{PASS}(\varphi) := \{\psi \in \mathcal{PASS} : \psi \subseteq \varphi\}$ of partial assignments contained in φ is commutative, and for every finite commutative submonoid M of \mathcal{PASS} there exists a partial assignment φ with $M \subseteq \mathcal{PASS}(\varphi)$.

5. The partial order \subseteq between partial assignments⁴ has the following properties:

- (a) $\langle \rangle$ is the smallest element; there is no largest element iff \mathcal{VA} is not empty, and there are no maximal elements iff \mathcal{VA} is infinite.
- (b) The infimum of any set $\emptyset \neq P \subseteq \mathcal{PASS}$ of partial assignments is the intersection of the elements of P .
- (c) $P \subseteq \mathcal{PASS}$ has an upper bound iff P is finite and all elements of P are pairwise compatible, and in this case P has a supremum (namely the union).
- (d) The order is right-compatible with the composition, that is, for partial assignments $\varphi, \psi, \theta \in \mathcal{PASS}$ with $\varphi \subseteq \psi$ we have $\varphi \circ \theta \subseteq \psi \circ \theta$.

However, the order is not left-compatible with the composition, so for example we have $\langle v \rightarrow 0 \rangle \supset \langle \rangle$, but $\langle v \rightarrow 1 \rangle \circ \langle v \rightarrow 0 \rangle = \langle v \rightarrow 0 \rangle \not\subseteq \langle v \rightarrow 1 \rangle \circ \langle \rangle = \langle v \rightarrow 1 \rangle$.

- (e) The order is identical with the natural right-compatible order of the monoid \mathcal{PASS} , that is, $\varphi \subseteq \psi \Leftrightarrow \psi \circ \varphi = \psi$ (while $\text{var}(\varphi) \subseteq \text{var}(\psi) \Leftrightarrow \varphi \circ \psi = \psi$).
- (f) Since the smallest element is the neutral element, \mathcal{PASS} is “right non-negative”, and we always have $\varphi \subseteq \psi \circ \varphi$ (while we only have $\text{var}(\varphi) \subseteq \text{var}(\varphi \circ \psi)$).

6. The formation of the domain of partial assignments, i.e., the map var , is a (surjective) homomorphism from the monoid \mathcal{PASS} to the monoid of finite subsets of \mathcal{VA} together with union, that is, $\text{var}(\varphi \circ \psi) = \text{var}(\varphi) \cup \text{var}(\psi)$ and $\text{var}(\langle \rangle) = \emptyset$. Restricted to the commutative submonoid $\mathcal{PASS}(\varphi)$ for some $\varphi \in \mathcal{PASS}$, var is an isomorphism from $\mathcal{PASS}(\varphi)$ to $\mathbb{P}(\text{var}(\varphi))$ (the powerset of the domain of φ).

A natural representation of \mathcal{PASS} as a transformation monoid is obtained as follows: Assume $0, 1 \notin \mathcal{VA}$, let $\mathcal{VA}' := \mathcal{VA} \cup \{0, 1\}$, and define the operation $*$: $\mathcal{PASS} \times \mathcal{VA}' \rightarrow \mathcal{VA}'$ by $\varphi * v := \varphi(v)$ for $v \in \text{var}(\varphi)$, and $\varphi * x := x$ otherwise. Now we have $\langle \rangle * x = x$ and $(\varphi \circ \psi) * x = \varphi * (\psi * x)$ for $x \in \mathcal{VA}'$.

⁴ $\varphi \subseteq \psi$ holds iff $\text{var}(\varphi) \subseteq \text{var}(\psi)$ and $\forall v \in \text{var}(\varphi) : \varphi(v) = \psi(v)$; we have $\varphi \subseteq \psi$ iff $C_\varphi^0 \subseteq C_\psi^0$ iff $C_\varphi^1 \subseteq C_\psi^1$

Furthermore the operation is faithful, i.e., for $\varphi \neq \psi$ there is $x \in \mathcal{VA}'$ with $\varphi * x \neq \psi * x$. The corresponding injective monoid-morphism from \mathcal{PASS} into the set of transformations of \mathcal{VA}' represents partial assignments φ and their composition by transformations $(\varphi * x)_{x \in \mathcal{VA}'} : \mathcal{VA}' \rightarrow \mathcal{VA}'$ and their composition.

14.9.2. Autarky monoid and autarky semigroup

As already mentioned, the composition of autarkies is again an autarky, which can be easily seen as follows: Consider autarkies φ, ψ for F , that is, for all $F' \subseteq F$ we have $\varphi * F' \subseteq F'$ and $\psi * F' \subseteq F'$. Now we have $(\varphi \circ \psi) * F' = \varphi * (\psi * F') \subseteq \varphi * F'' \subseteq F''$ for $F'' := \psi * F' \subseteq F'$, and thus $(\varphi \circ \psi)$ is an autarky for F .

Definition 14.9.1. For a clause-set $F \in \mathcal{CLS}$ the **autarky monoid**, denoted by $\text{Auk}(F)$, is the sub-monoid of \mathcal{PASS} given by all autarkies for F , while the **autarky semigroup** is $\text{Auks}(F) := \text{Auk}(F) \setminus \{\langle \rangle\}$. For performing computations, the **restricted** versions $\text{Auk}^r(F) := \{\varphi \in \text{Auk}(F) : \text{var}(\varphi) \subseteq \text{var}(F)\}$ and $\text{Auks}^r(F) := \text{Auks}(F) \setminus \{\langle \rangle\}$ are preferable.

Remarks:

1. $\text{Auk}(F), \text{Auk}^r(F)$ are submonoids of \mathcal{PASS} , where $\text{Auk}^r(F)$ is always finite, while $\text{Auk}(F)$ is infinite iff \mathcal{VA} is infinite. $\text{Auks}(F), \text{Auks}^r(F)$ are subsemigroups of $\mathcal{PASS} \setminus \{\langle \rangle\}$.
2. $\text{Auk}(F)$ is obtained from the elements of $\text{Auk}^r(F)$ by extending them arbitrarily on variables not in $\text{var}(F)$.
3. For every set X the “right-null semigroup” is the semigroup $(X, *)$ with $x * y := y$. Now the set $\text{mod}(F)$ of total satisfying assignments for a clause-set F is a right-null sub-semigroup of $\text{Auks}^r(F)$, and if F is satisfiable, then this set equals the set of “maximal autarkies”, as discussed below.

Some simple examples, where we know the full autarky monoid:

1. F is lean iff $\text{Auk}^r(F) = \{\langle \rangle\}$ iff $\text{Auks}^r(F) = \emptyset$.
2. Consider the unique clause-set F with $\text{var}(F) = \{v_1, \dots, v_n\}$ ($n \geq 1$) which is equivalent (as CNF) to the condition $v_1 \oplus \dots \oplus v_n = \varepsilon \in \{0, 1\}$, where “ \oplus ” is exclusive-or (F consists of 2^{n-1} clauses, each involving all variables). Now every non-trivial autarky for F is a satisfying assignment, and every satisfying assignment involves all variables, and so the restricted autarky semigroup of F is the right-null semigroup on the set of the 2^{n-1} satisfying assignments.

Basic properties of the autarky monoid are as follows:

1. Let $\text{var}(\text{Auk}(F)) := \text{var}(\text{Auk}^r(F)) := \bigcup_{\varphi \in \text{Auk}^r(F)} \text{var}(\varphi)$. Then the largest autark subset of F is $F_{\text{var}(\text{Auk}(F))}$.
2. Since $\text{Auk}^r(F)$ is finite, $\text{Auk}^r(F)$ has maximal elements, called *maximal autarkies*, and for every maximal autarky φ we have $\text{var}(\varphi) = \text{var}(\text{Auk}(F))$, while $F \setminus (\varphi * F)$ is the largest autark subset of F . We denote the set of maximal autarkies of F by $\text{Auk}\uparrow(F)$. Note that F is lean iff $\text{Auk}\uparrow(F) = \{\langle \rangle\}$.
3. The maximal autarkies of F are exactly the total satisfying assignments for $F[\text{var}(\text{Auk}(F))]$. So $\text{Auk}\uparrow(F)$ is a right-null sub-semigroup of $\text{Auks}^r(F)$. If F is satisfiable, then $\text{Auk}\uparrow(F) = \text{mod}(F)$.

4. The minimal elements of the restricted autarky semigroup $\text{Auks}^r(F)$ are called *minimal autarkies*. F has a minimal autarky iff F is not lean, and the minimal autarkies are exactly the atoms of the partial order $\text{Auk}^r(F)$. (One could thus speak of “atomic autarkies”, but it seems that the slightly different contexts for “maximal” and “minimal” autarkies do not cause confusion.) We denote the set of minimal autarkies of F by $\text{Auk}\downarrow(F)$ (so F is lean iff $\text{Auk}\downarrow(F) = \emptyset$).

If only the autark *subsets* are of interest (not their certificates, i.e., their associated autarkies), then the (upper) semilattice (with zero)

$$\text{Auk}^s(F) := \{F' \subseteq F \mid \exists \varphi \in \text{Auk}(F) : \varphi * F = F \setminus F'\}$$

of autark subsets is to be studied (the operation is just set-union, the neutral element is \top). The canonical homomorphism $\Phi : \text{Auk}(F) \rightarrow \text{Auk}^s(F)$ given by $\varphi \mapsto F \setminus (\varphi * F)$ is surjective, and the inverse image of \top is the set of trivial autarkies. Also the restriction $\Phi : \text{Auk}^r(F) \rightarrow \text{Auk}^s(F)$ is surjective, and in general also the restriction is not injective.

14.9.3. Finding (semi-)maximal autarkies

Given any nontrivial autarky, we can efficiently find some (contained) minimal autarky by the observation made in [KMT08], that “within” a partial assignment autarky search is easy:

Definition 14.9.2. For any submonoid M resp. subsemigroup S of \mathcal{PASS} and for a partial assignment $\varphi \in \mathcal{PASS}$ we denote by $M(\varphi) := M \cap \mathcal{PASS}(\varphi)$ resp. $S(\varphi) := S \cap \mathcal{PASS}(\varphi)$ the submonoid resp. subsemigroup of M resp. S obtained by restriction to partial assignments contained in φ .

Lemma 14.9.1. Consider a clause-set $F \in \mathcal{CLS}$ and a partial assignment $\varphi \in \mathcal{PASS}$. Then $\text{Auk}(F)(\varphi)$ has a (unique) largest element φ_0 , which can be efficiently computed as follows:

1. Let $\varphi_0 := \varphi$.
2. If φ_0 is an autarky for F , then stop. Otherwise, choose $C \in F$ with $\text{var}(\varphi) \cap \text{var}(C) \neq \emptyset$ and $\varphi * \{C\} \neq \top$, choose $v \in \text{var}(\varphi) \cap \text{var}(C)$, let φ_0 be the restriction of φ_0 to $\text{var}(\varphi_0) \setminus \{v\}$, and repeat this step.

For a given clause-set F with $V := \text{var}(F)$, the map $\varphi \in \{\varphi \in \mathcal{PASS} : \text{var}(\varphi) \subseteq V\} \mapsto \varphi_0 \in \text{Auk}^r(F)$, which assigns to every partial assignment the contained largest autarky, is obviously surjective. Such autarkies φ_0 which are largest elements of some $\text{Auk}(F)(\varphi)$ for total assignments φ (i.e., $\text{var}(\varphi) = \text{var}(F)$) are called *semi-maximal autarkies*. In Subsection 14.10.1 some applications are discussed.

Corollary 14.9.2. Given a nontrivial autarky φ for a clause-set F , we can efficiently compute some minimal autarky $\varphi_0 \in \text{Auk}\downarrow(F)$ (with $\varphi_0 \subseteq \varphi$).

Proof. Try removing assignments from φ and obtaining a smaller nontrivial autarky by Lemma 14.9.1 until a minimal autarky is obtained. \square

14.9.4. Generating autarkies

Now we are considering generating sets of the autarky monoid, i.e., subsets E of $\text{Auk}^r(F)$ such that the generated submonoid is $\text{Auk}^r(F)$ itself. The autarky monoid has the potential to give a succinct representation of a large set of satisfying assignments: Though there are even more autarkies than satisfying assignments, a generating set might nevertheless be much smaller.

Example 14.9.1. For $n \geq 0$ we consider the (well-known) satisfiable clause-set $F := \{\{v_1, w_1\}, \dots, \{v_n, w_n\}\}$ with $2n$ variables (well-known for not having a short DNF-representation). The structure of $\text{Auk}^r(F)$ is as follows:

- There are $2n$ minimal autarkies $\langle v_i \rightarrow 1 \rangle, \langle w_i \rightarrow 1 \rangle$.
- $|\text{mod}(F)| = 3^n$, where the satisfying (total) assignments, which are also the maximal autarkies here, are all combinations of the three satisfying assignments for the clauses $\{v_i, w_i\}$.
- $|\text{Auk}^r(F)| = 6^n$, where the autarkies are all combinations of the six autarkies for the clauses $\{v_i, w_i\}$.
- Using $E_i := \{\langle v_i \rightarrow 1 \rangle, \langle w_i \rightarrow 1 \rangle, \langle v_i \rightarrow 1, w_i \rightarrow 0 \rangle, \langle w_i \rightarrow 1, v_i \rightarrow 0 \rangle\}$, the set $E := \bigcup_{i=1}^n E_i$ is a generating set for $\text{Auk}^r(F)$ of size $4n$.

So a basic question is to obtain interesting notions of generating sets for autarky monoids. Only at first glance it might appear that the minimal autarkies are sufficient to compute at least the lean kernel, but the following example shows that this is clearly not the case.

Example 14.9.2. Minimally unsatisfiable Horn clause-sets have deficiency 1; moreover, the Horn clause-sets with $n \geq 0$ variables, which are even saturated minimally unsatisfiable, are up to the names of the variables exactly the clause-sets $H_n := H'_n \cup \{\{\bar{v}_1, \dots, \bar{v}_n\}\}$, where

$$H'_n := \{\{v_1\}, \{\bar{v}_1, v_2\}, \{\bar{v}_1, \bar{v}_2, v_3\}, \dots, \{\bar{v}_1, \dots, \bar{v}_{n-1}, v_n\}\}.$$

For example $H_0 = \{\perp\}$, $H_1 = \{\{v_1\}, \{\bar{v}_1\}\}$ and $H_2 = \{\{v_1\}, \{\bar{v}_1, v_2\}, \{\bar{v}_1, \bar{v}_2\}\}$. It is not hard to see that

$$\text{Auk}^r(H'_n) = \{\langle \rangle, \langle v_n \rightarrow 1 \rangle, \langle v_{n-1}, v_n \rightarrow 1 \rangle, \dots, \langle v_1, \dots, v_n \rightarrow 1 \rangle\}.$$

So $\text{Auk}^r(H'_n)$ as a partial order is a linear chain with $n + 1$ elements, with $\langle \rangle$ as smallest element and with $\varphi_n := \langle v_1, \dots, v_n \rightarrow 1 \rangle$ as largest element; for example $\text{Auk}^r(H'_2) = \{\langle \rangle, \langle v_2 \rightarrow 1 \rangle, \langle v_1, v_2 \rightarrow 1 \rangle\}$. For $n \geq 1$ the only minimal autarky is $\langle v_n \rightarrow 1 \rangle$.

So what can we say about a generating set G of the (restricted) autarky semigroup $\text{Auks}^r(F)$? Clearly every minimal autarky for F must be element of G , and, more generally, every *directly indecomposable* autarky $\varphi \in \text{Auks}^r(F)$ must be in G , which are characterised by the condition that whenever $\varphi = \psi_1 \circ \psi_2$ for $\psi_1, \psi_2 \in \text{Auk}^r(F)$ holds, then $\psi_1 = \varphi$ or $\psi_2 = \varphi$ must be the case. The directly indecomposable autarkies for Example 14.9.1 are exactly the elements of the generating set E given there, but the following example shows that the directly indecomposable autarkies in general do not generate all autarkies.

Example 14.9.3. Let $F := \{\{v_1, v_2, v_3\}, \{v_1, \bar{v}_2, \bar{v}_3\}\}$. For a partial assignment φ and a set of variables V with $V \cap \text{var}(\varphi) = \emptyset$ let us denote by $[\varphi]_V$ the set of all partial assignments ψ with $\varphi \subseteq \psi$ and $\text{var}(\psi) \subseteq \text{var}(\varphi) \cup V$. Using $\varphi_1 := \langle v_1 \rightarrow 1 \rangle$, $\varphi_2 := \langle v_2 \rightarrow 1, v_3 \rightarrow 0 \rangle$ and $\varphi_3 := \langle v_2 \rightarrow 0, v_3 \rightarrow 1 \rangle$ we have $\text{Auks}^r(F) = [\varphi_1]_{\{v_2, v_3\}} \cup [\varphi_2]_{\{v_3\}} \cup [\varphi_3]_{\{v_3\}}$, whence $|\text{Auks}^r(F)| = 3^2 + 3 + 3 - 1 - 1 = 13$. There are three minimal autarkies, namely $\varphi_1, \varphi_2, \varphi_3$, and four further directly indecomposable autarkies, namely $\langle v_1 \rightarrow 1, v_2 \rightarrow \varepsilon \rangle$ and $\langle v_1 \rightarrow 1, v_3 \rightarrow \varepsilon \rangle$ for $\varepsilon \in \{0, 1\}$. These seven elements generate eleven of the thirteen (non-trivial) autarkies, leaving out $\varphi_2 \circ \langle v_1 \rightarrow 0 \rangle$ and $\varphi_3 \circ \langle v_1 \rightarrow 0 \rangle$.

Given a set $E \subseteq \text{Auk}^r(F)$ of autarkies, instead of allowing all compositions of elements of E it makes sense to only allow “commutative compositions”, that is we only consider subsets $E' \subseteq E$ of pairwise commuting (pairwise compatible) partial assignments and their composition $\circ_{\varphi \in E'} \varphi$; note that due to the imposed commutativity here we do not need to take care of the order, and due to idempotency also no exponents need to be considered. We call E a *commutatively generating set* for $\text{Auks}^r(F)$ if the set of commutative compositions of E is $\text{Auks}^r(F)$, while we speak of a *commutatively semi-generating set*, if the commutative compositions of E at least yield all semi-maximal autarkies (different from $\langle \rangle$; recall Subsection 14.9.3).⁵ The generating set E in Example 14.9.1 is also a commutatively generating set; Example 14.9.1 is just a combination of variable-disjoint clauses, and we conclude this subsection by discussing the autarky-monoid and its generation for singleton clause-sets (the smallest non-trivial examples).

Example 14.9.4. Consider a clause C , and let $F := \{C\}$ and $n := n(F) = |C|$.

- There are n minimal autarkies (i.e., $|\text{Auk}\downarrow(F)| = n$).
- $|\text{Auk}^r(F)| = 3^n - (2^n - 1)$ (the non-autarkies are all partial assignments using only value 0, except of the empty partial assignment).
- For $n \geq 1$ there are $2^n - 1$ maximal autarkies (i.e., $|\text{Auk}\uparrow(F)| = 2^n - 1$), which are also the satisfying assignments, while if $n = 0$, then F is unsatisfiable and lean.
- Every semi-maximal autarky is also a maximal autarky.
- There are $n + n(n - 1)$ directly indecomposable autarkies, namely the minimal autarkies plus the partial assignments $\langle x \rightarrow 1, y \rightarrow 0 \rangle$ for $x \in C$ and $y \in C \setminus \{x\}$.
- The set I of directly indecomposable autarkies is a (smallest) generating set, and it is also a commutatively generating set.
- If we replace the n minimal autarkies in I by the single autarky $\langle x \rightarrow 1 : x \in C \rangle$, obtaining I' , then I' is a commutatively semi-generating set (of size $n(n - 1) + 1$).

14.9.5. The autarky monoid as a functor

In [Sze03] the basic form of categories of clause-sets has been introduced (recall Section 14.3), called \mathcal{CLS} here, and which is defined as follows:

⁵We could also speak of “compatibly generating”. Using “sign vectors” instead of partial assignments, according to Definition 5.31 in [BK92] we could also speak of “conformally generating”.

1. The set of objects of \mathfrak{CLS} is \mathcal{CLS} .
2. For a clause-set F let $\text{lit}(F) := \text{var}(F) \cup \overline{\text{var}(F)}$ be the set of literals over F (which occur in at least one polarity; for a set L of literals we use $\overline{L} := \{\bar{x} : x \in L\}$).
3. Now a morphism $f : F \rightarrow G$ from clause-set F to clause-set G is a map $f : \text{lit}(F) \rightarrow \text{lit}(G)$ with the following two properties:
 - (a) f preserves complements, i.e., for $x \in \text{lit}(F)$ we have $f(\bar{x}) = \overline{f(x)}$.
 - (b) f preserves clauses, i.e., for $C \in F$ we have $f(C) \in G$, where $f(C) := \{f(x) : x \in C\}$.

The isomorphisms in \mathfrak{CLS} are the standard isomorphisms between clause-sets, allowing the renaming of variables accompanied with flipping polarities. Extending [Sze03] (Section 3) we can now recognise $F \in \mathcal{CLS} \mapsto \text{Auk}(F)$ as a contravariant functor from \mathfrak{CLS} to the category \mathfrak{MON} of monoids (objects are monoids, morphisms are homomorphisms of monoids):

Lemma 14.9.3. *The formation of the autarky monoid is a contravariant functor $\text{Auk} : \mathfrak{CLS} \rightarrow \mathfrak{MON}$, where for a morphism $f : F \rightarrow G$ between clause-sets the homomorphism $\text{Auk}(f) : \text{Auk}(G) \rightarrow \text{Auk}(F)$ assigns to the autarky $\varphi \in \text{Auk}(G)$ the partial assignment $\text{Auk}(f)(\varphi)$ given as follows:*

1. the domain of $\text{Auk}(f)(\varphi)$ is the set of variables $v \in \text{var}(F)$ such that $\text{var}(f(v)) \in \text{var}(\varphi)$;
2. for $v \in \text{var}(\text{Auk}(f)(\varphi))$ we set $\text{Auk}(f)(\varphi)(v) := \varphi(f(v))$.

Proof. First for $\varphi \in \text{Auk}(G)$ and $\psi := \text{Auk}(f)(\varphi)$ we need to show $\psi \in \text{Auk}(F)$. So consider a clause $C \in F$ touched by ψ . Thus there is $x \in C$ such that $\varphi(f(x))$ is defined. Now φ touches $f(C)$, so there is $x' \in C$ with $\varphi(f(x')) = 1$, i.e., $\psi(x') = 1$. To see that Auk preserves identities we just note that $\text{id}_F = \text{id}_{\text{lit}(F)}$, and then $\text{Auk}(\text{id}_F) = \text{id}_{\text{Auk}(F)}$. Finally consider morphisms $f : F \rightarrow G$ and $g : G \rightarrow H$ in \mathfrak{CLS} ; we have to show $\text{Auk}(g \circ f) = \text{Auk}(f) \circ \text{Auk}(g)$, and this follows directly from the definitions. \square

Also Auk^f yields a functor. We remark that the coproduct in \mathfrak{CLS} is the variable-disjoin sum, and the functor Auk^f anti-preserved coproducts, i.e., maps the variable-disjoin sum of clause-sets to the product of their autarky-monoids.

14.9.6. Galois correspondences

Finally we consider the Galois correspondence given by the autarky notion. Consider the set \mathcal{CL} of clauses and the set \mathcal{PASS} of partial assignments. We have two fundamental relations between clauses and partial assignments:

1. S_0 is the set of pairs $(C, \varphi) \in \mathcal{CL} \times \mathcal{PASS}$ such that φ is a satisfying assignment for $\{C\}$, that is, $\varphi * \{C\} = \top$.
2. S_1 is the set of pairs $(C, \varphi) \in \mathcal{CL} \times \mathcal{PASS}$ such that φ is an autarky for $\{C\}$, that is, $\varphi * \{C\} \in \{\top, \{C\}\}$.

If we use the alternative representation $\mathcal{PASS}' := \mathcal{CL}$ of partial assignments by clauses containing the literals satisfied by the partial assignment, i.e., a partial

assignment φ corresponds to the clause C_φ^1 , then we obtain the corresponding relations $S'_0 = \{(C, D) \in \mathcal{CL} \times \mathcal{PASS}' : C \cap D \neq \emptyset\}$ and $S'_1 = \{(C, D) \in \mathcal{CL} \times \mathcal{PASS}' : C \cap \overline{D} \neq \emptyset \Rightarrow C \cap D \neq \emptyset\}$.

Given the “polarities” S_0, S_1 , we obtain (as usual) Galois correspondences (X_0, Y_0) resp. (X_1, Y_1) between the partial orders $(\mathbb{P}(\mathcal{CL}), \subseteq)$ and $(\mathbb{P}(\mathcal{PASS}), \subseteq)$, given as $X_i : \mathbb{P}(\mathcal{CL}) \rightarrow \mathbb{P}(\mathcal{PASS})$ and $Y_i : \mathbb{P}(\mathcal{PASS}) \rightarrow \mathbb{P}(\mathcal{CL})$ defined by

$$\begin{aligned} X_i(F) &:= \{\varphi \in \mathcal{PASS} \mid \forall C \in F : S_i(C, \varphi)\} \\ Y_i(P) &:= \{C \in \mathcal{CL} \mid \forall \varphi \in P : S_i(C, \varphi)\}. \end{aligned}$$

for $F \subseteq \mathcal{CL}$ and $P \subseteq \mathcal{PASS}$. Using $\text{mod}^*(F) := \{\varphi \in \mathcal{PASS} : \varphi * F = \top\}$ for the set of all satisfying partial assignments for F , we see that

$$X_0(F) = \text{mod}^*(F), \quad X_1(F) = \text{Auk}(F)$$

for sets of clauses F .⁶ As it is well known, $Z_i := Y_i \circ X_i$ for $i \in \{0, 1\}$ yields a closure operator on $\mathbb{P}(\mathcal{CL})$ (i.e., $Z_i(F) \supseteq F$, $Z_i(Z_i(F)) = Z_i(F)$ and $F \subseteq G \Rightarrow Z_i(F) \subseteq Z_i(G)$). It is a well-known generalisation of the fundamental duality-law for the formation of the transversal hypergraph, that $Z_0(F)$ is just the set of all clauses C which follow logically from F , i.e., $Z_0(F) = \{C \in \mathcal{CL} : F \models C\}$. Using \mathcal{PASS}' instead of \mathcal{PASS} , we have $Y_i = X_i$ for $i \in \{0, 1\}$, and thus the semantical closure $Z_0(F)$ can be understood as $Z_0(F) = \text{mod}^*(\text{mod}^*(F)) =: \text{mod}^{**}(F)$. And analogously we can understand the *autarky closure* $Z_1(F)$, the largest set of clauses with the same autarky monoid as F , as $Z_1(F) = \text{Auk}(\text{Auk}(F))$; thus we write the autarky closure as $\text{Auk}^2(F) := Z_1(F)$. Some simple properties of the autarky closure are (for all $F \subseteq \mathcal{CL}$):

1. $\text{Auk}^2(\top) = \top$ (also $\text{mod}^{**}(\top) = \top$).
2. $\perp \in \text{Auk}^2(F)$, and thus $\text{Auk}^2(F) \supseteq F \cup \{\perp\}$ (while $\perp \in \text{mod}^{**}(F)$ iff F is unsatisfiable).
3. We have $\text{var}(\text{Auk}^2(F)) = \text{var}(F)$. This is quite different from mod^{**} , where for $F \neq \top$ we have $\text{var}(\text{mod}^{**}(F)) = \mathcal{VA}$, since $\text{mod}^{**}(F)$ is stable under addition of super-clauses.
4. A clause-set F is lean iff $\text{Auk}^2(F) = \{C \in \mathcal{CL} : \text{var}(C) \subseteq \text{var}(F)\}$, that is, iff $\text{Auk}^2(F)$ contains all possible clauses over $\text{var}(F)$ (in other words, iff $\text{Auk}^2(F)$ is as large as possible).
5. $\text{Auk}^2(F)$ is stable under resolution, that is, if $C, D \in F$ with $C \cap \overline{D} = \{x\}$, then $R \in \text{Auk}^2(F)$ for the resolvent $R := (C \setminus \{x\}) \cup (D \setminus \{\overline{x}\})$.
6. $\text{Auk}^2(F)$ is stable under the composition of partial assignments considered as clauses, that is, if $C, D \in \text{Auk}^2(F)$ then also $(C \setminus \overline{D}) \cup D \in \text{Auk}^2(F)$.

14.10. Finding and using autarkies

In this section we discuss the methods which have been applied to find autarkies, and what use has been made of those autarkies. First some remarks on the complexity of the most basic algorithmic problems. The class of lean clause-sets

⁶This includes, of course, clause-sets, which we defined as *finite* sets of clauses.

has been shown in [Kul03] to be coNP-complete, and thus finding a non-trivial autarky is NP-complete. By Corollary 14.9.2 also finding a minimal autarky is NP-complete, while by contrast deciding whether for a given clause-set F and partial assignment φ it is φ a maximal autarky for F is coNP-complete (if φ is an autarky for F , then φ is a maximal autarky iff $F \setminus (\varphi * F)$ is lean). As shown in [KMT08], the “autarky existence problem” is self-reducible, that is, given an oracle for deciding whether a clause-set is lean, one can efficiently find a maximal autarky. Lemma 8.6 in [Kul03] shows how (just) to compute the lean kernel given such an oracle. In [KMT08] one finds complexity characterisations of other basic tasks related to autarkies. In Subsection 14.11.6 we will discuss a refined list of the basic algorithmic problems of autarky theory.

14.10.1. Direct approaches

At first sight it might appear that time $\tilde{O}(3^{n(F)})$ is needed to exhaustively search for a non-trivial autarky in a clause-set F , since there are $3^{n(F)}$ partial assignments. However, we can find all semi-maximal autarkies (recall Subsection 14.9.3) in time $\tilde{O}(2^{n(F)})$ by running through all total assignments φ and determining the maximal autarky $\varphi_0 \subseteq \varphi$ for F (this was first observed in [KMT08]). Thus the lean kernel can be computed in time $\tilde{O}(2^{n(F)})$ (for arbitrary clause-sets, using linear space). See Subsection 14.10.8 for applications of this method in local search solvers (while in Corollary 14.10.2 the bound $\tilde{O}(2^{n(F)})$ is improved for restricted clause-length).

The direct backtracking approach searching for an autarky is closely related to the tableau calculus, when focusing on a specific clause to be satisfied by some autarky, and we further comment on this subject in Subsection 14.10.2. From a somewhat more general perspective, searching for an autarky can be considered as a constraint satisfaction problems where variables have 3-valued domains; yet there are no experiences with this approach, but in Subsection 14.10.4 we discuss the reduction of the autarky search problem to SAT.

14.10.2. Autarkies and the tableau-calculus

A (standard) tableau-based SAT solver starts with a “top” clause $C \in F$, chooses a literal $x \in C$, and tries recursively to refute that $\langle x \rightarrow 1 \rangle$ could be extended to a satisfying assignment for F (this is then repeated for all literals in C , with the goal to conclude unsatisfiability of F at the end). It has been observed in [Van99] that this process should better be considered as the natural form of searching for an autarky for F satisfying C , since in case the solver gets stuck, that is, cannot finish the unsatisfiability-proof based on x (and thus cannot proceed to the other literals in C), we actually found an autarky $\langle x \rightarrow 1 \rangle \subseteq \varphi$ for F , so that we can repeat the whole process with $\varphi * F \subset F$, and either finally find F unsatisfiable (that is, find some subset $F' \subseteq F$ unsatisfiable with $N_a(F) \subseteq F'$), or can compose the various autarkies φ found in the repetitions of this process to a (global) satisfying assignment. This view of the (standard, propositional) tableau calculus yields an explanation why SAT solvers are usually faster: Exhaustively searching for an autarky is a somewhat harder task than just (exhaustively) searching for a satisfying assignment (especially to determine that there is none), and so for the

clause-based branching performed by a tableau-solver the top clause C is split into $|C|$ branches $\langle x \rightarrow 1 \rangle$ for $x \in C$, while a SAT solver can use some order $C = \{x_1, \dots, x_k\}$ and set in branch i additionally to $x_i \rightarrow 1$ also $x_j \rightarrow 0$ for $j < i$ (where for the autarky search the x_j stay unassigned). Roughly spoken, SAT only needs to search through 2^n (total) assignments, while tableau search somehow needs to search through 3^n partial assignments. However for instances having “nice” autarkies (not too small, not too big), the autarky approach should have merits. The approach from [Van99] has been extended by parallel processing in [Oku00], exploiting that the composition of autarkies again is an autarky (and so we can combine autarkies found in parallel), while applications are discussed in [VO99].

14.10.3. Computing the lean kernel by the autarky-resolution duality

Based on the duality between autarkies and resolution (recall Theorem 14.8.1), the following meta-theorem has been given (in variations) in [Kul01, Kul07a] for computing the lean kernel:

Theorem 14.10.1. *Consider a class $\mathcal{C} \subseteq \text{CLS}$ of clause-sets, an “upper bound” function $f : \mathcal{C} \rightarrow \mathbb{R}_{\geq 0}$ and an algorithm \mathfrak{A} defined on inputs $F \in \mathcal{C}$ with the following properties:*

1. \mathcal{C} is stable under restriction, that is, for all (finite) $V \subseteq \mathcal{VA}$ and all $F \in \mathcal{C}$ we have $F[V] \in \mathcal{C}$.
2. The running time of \mathfrak{A} on input $F \in \mathcal{C}$ is $\tilde{O}(f(F))$.
3. f is monotone w.r.t. restriction, that is, for $V \subseteq \mathcal{VA}$ and $F \in \mathcal{C}$ we have $f(F[V]) \leq f(F)$.
4. \mathfrak{A} for input F either returns a satisfying partial assignment φ_F for F or a non-empty set of variables $\emptyset \neq V_F$ used in some resolution refutation F .

Then for input $F_0 \in \mathcal{C}$ we can compute the lean kernel as well as an autarky realising the lean kernel (a “quasi-maximal autarky”) in time $\tilde{O}(f(F_0))$ as follows:

- Let $F := F_0$.
- Run \mathfrak{A} on F . If the output is a satisfying assignment φ , then return (F, φ) , while if the output is a set V of variables then let $F := F[V]$ and repeat.

For the pair (F, φ) computed we have $F = N_a(F_0)$, $\varphi \in \text{Auk}(F_0)$ and $\varphi * F_0 = F$.

Given a quasi-maximal autarky, we can determine the variables which are in the lean kernel but not in the largest autark subset, and then by arbitrary extension we can also compute a maximal autarky. It is not too complicated to provide a backtracking SAT solver (look-ahead or conflict-driven) without much space- or time-overhead with the ability to output in case of unsatisfiability the set of variables involved in the resolution refutation found; note that we do not need the resolution refutation itself, which can require exponential space, but only the set of variables involved, computed recursively bottom-up from the leaves, cutting off branches if the branching variable is not used as resolution variable.⁷

⁷This realises “intelligent backtracking” also for conflict-driven solvers, and is implemented in the `OKsolver-2002`.

For example, we can use $\mathcal{C} = \mathcal{CLS}$, $f = b^{n(F)}$ where b depends on the maximal clause-length of F , and for \mathfrak{A} the classical CNF algorithm from [MS85, Luc84] (branching on a shortest clauses, and using the autarky found when no clause is shortened; see Subsection 14.10.5), and we obtain:

Corollary 14.10.2. *For a clause-set $F \in \mathcal{CLS}$ let $\text{rk}(F) \in \mathbb{N}_0$ denote the maximal clause-length. Then a maximal autarky for input $F \in \mathcal{CLS}$ can be computed in time $\tilde{O}(\tau_{\text{rk}(F)-1}^{n(F)})$, where $\tau_{\text{rk}(F)-1} = \tau(1, \dots, \text{rk}(F) - 1)$ is the solution $x > 1$ of $\sum_{i=1}^{\text{rk}(F)-1} x^{-i} = 1$ (see Subsection 8.3.2 in Chapter 8 on branching heuristics). For inputs restricted to 3-CNF we have $\text{rk}(F) \leq 3$, where $\tau(1, 2) = 1.618\dots$, that is, a maximal autarky for inputs F in 3-CNF can be computed in time $O(1.619^{n(F)})$.*

It is not known to what extent the improved k -CNF bounds can be applied: Closest is [Kul99b], but as shown in [Kul99c], the use of blocked clauses cannot be simulated by resolution, so the meta-theorem is not applicable (at least *prima facie*). All other algorithms are based on some form of probabilistic reasoning, and thus in case of unsatisfiability do not yield (in some form) resolution refutations, so also here the meta-theorem (Theorem 14.10.1) is not applicable.

An application of the computation of the lean kernel to the problem of finding “unsatisfiable cores” in clause-sets is discussed in [KLMS06] (concentrating especially on the different roles of clauses, like “necessary”, “potentially necessary”, “usable” or “unusable” clauses).

14.10.4. Reduction to SAT

A translation of the autarky search problem to SAT has been introduced in [LS08], considering applications similar to those mentioned in [KLMS06]; the basic method used for the translation is the use of “clause indicator variables” for clauses satisfied by the autarky, and using also “variable indicator variables” to indicate whether an original variable is used by the autarky. The experimental results suggest that this works complementary to the method used in [KLMS06] (see the previous Subsection 14.10.3): Computation of the lean kernel via the autarky-resolution duality, based on a conflict-driven solver here, tends to use many iterations, while the algorithm of [LS08] searches directly for the largest autark subset (to express this, the clause-indicator variables are used, together with “AtMost”-constraints).

There are many variations possible for such translations, but the basic translation, encoding autarkies for clause-set F exactly as satisfying assignments of $A(F)$, is simple: For every variable $v \in \text{var}(F)$ introduce three variables $a_{v,\varepsilon}$ for $\varepsilon \in \{0, 1, *\}$, where “*” stands for “unassigned”, and $a_{v,\varepsilon}$ means that v shall get “value” ε ; so we have $n(A(F)) = 3n(F)$. A literal x over $\text{var}(F)$ is interpreted by the positive literal $a(x)$ over $\text{var}(A(F))$, where for positive literals v we set $a(v) := a_{v,1}$, while for negative literals \bar{v} we set $a(\bar{v}) := a_{v,0}$. Now a clause $C \in F$ yields $|C|$ many clauses of length $|C|$, namely for each $x \in C$ the “autarky clause” $C_x := \{\bar{a}(\bar{x})\} \cup \{a(y) : y \in C \setminus \{x\}\}$ (which requires that if one literal x is set to false, then some other literal y must be set to true). Then $A(F)$ consists of the clauses C_x for $C \in F$ and $x \in C$ together with the ALO-clauses, that is, for every

variable $v \in \text{var}(F)$ the (positive, ternary) clause $\{a_{v,0}, a_{v,1}, a_{v,*}\}$, and together with the AMO-clauses, that is for each $v \in \text{var}(F)$ and $\varepsilon, \varepsilon' \in \{0, 1, *\}$, $\varepsilon \neq \varepsilon'$ the (negative, binary) clause $\{\overline{a_{v,\varepsilon}}, \overline{a_{v,\varepsilon'}}\}$. Obviously we have a natural bijection from $\text{mod}(A(F))$ to $\text{Auk}^r(F)$ (note that every satisfying (partial) assignment for $A(F)$ must actually be total). A problem now is that to express non-triviality of the autarky, we need the long clause $\{\overline{a_{v,*}} : v \in \text{var}(F)\}$ (containing *all* variables); to avoid this clause of maximal length, and to obtain more control over the autarky obtained, [LS08] uses the above mentioned indicator variables.

14.10.5. Autarkies for worst-case upper bounds

Apparently the first application of “autarkies” (without the name, which was invented 10 years later) can be found in [EIS76], where they are used to show that 2-SAT is decidable in polynomial time. This very simple method works as follows for a clause-set F with maximal clause-length $\text{rk}(F) \leq 2$: Consider any literal x in F , and let the partial assignment φ_x be obtained from $\langle x \rightarrow 1 \rangle$ by adding all inferred unit-clause propagations for F . If $\perp \in \varphi_x * F$, then F is satisfiability-equivalent to $\langle x \rightarrow 0 \rangle * F$ and we eliminated one variable. Otherwise we know that all clauses in $\varphi_x * F$ must have length at least 2, and thus, due to $\text{rk}(F) \leq 2$, φ_x is an autarky for F — so in this case F is satisfiability equivalent to $\varphi_x * F$, and again at least one variable has been eliminated.

If F has unrestricted clause-length, then in case of $\perp \notin \varphi_x * F$ and where furthermore φ_x is not an autarky for F (which can be easily checked), we know that F must contain a clause C of length $2 \leq |C| \leq \text{rk}(F) - 1$ (note that this generalises the above argument). Applying this argument to both branches $\varphi_x, \varphi_{\bar{x}}$ has been exploited in [MS85] for improved k -SAT upper bounds (and in this article also the notion of an “autark assignment” has been introduced). Basically the same argument, but in a different form, has been used in [Luc84]; see [KL97, KL98] for discussions (the point is while [MS85] checks whether $\varphi_x, \varphi_{\bar{x}}$ are autarkies for the current “residual” clause-set (at each node of the search tree), [Luc84] only checks the special cases which are actually needed to prove the bound).

These ideas have been systematically extended in [Kul99b], on the one hand generalising autarkies to “Br-autarkies”, allowing for the application of an arbitrary reduction and the possible elimination of blocked clauses afterwards. And on the other hand, the notion of a *weak k -autarky* is introduced (where “weak” is added now according to the general distinction between “weak autarkies” and “autarkies”) for $k \geq 0$, which is a partial assignment φ such that $|(\varphi * F) \setminus F| \leq k$; note that weak 0-autarkies are exactly the weak autarkies. For $k \geq 1$ in general $\varphi * F$ is no longer satisfiability-equivalent to F , however the point is that, using $N := (\varphi * F) \setminus F$ for the set of new clauses created by φ , for every partial assignment ψ with $\text{var}(\psi) \subseteq \text{var}(N)$ (thus $\text{var}(\psi) \cap \text{var}(\varphi) = \emptyset$) and $\psi * N = \top$ (i.e., ψ satisfies N) the partial assignment φ is a weak autarky for $\psi * F$.⁸ In [Kul99b] this k -autarky principle has been applied by considering a complete branching (ψ_1, \dots, ψ_m) for N (i.e., covering all total assignments), where then those branches ψ_i satisfying N can be augmented by φ . In Subsection 14.13.2

⁸The proof is: $(\varphi * (\psi * F)) \setminus (\psi * F) = ((\varphi \circ \psi) * F) \setminus (\psi * F) = ((\psi \circ \varphi) * F) \setminus (\psi * F) = (\psi * (\varphi * F)) \setminus (\psi * F) \subseteq (\psi * (N \cup F)) \setminus (\psi * F) = ((\psi * N) \cup (\psi * F)) \setminus (\psi * F) = \top$.

we discuss another possibility to exploit this situation, by adding “look-ahead autarky clauses”.

Finally we mention the “black and white literals principle” ([Hir00]), which generalises the “generalised sign principle” from [KL97], and which reformulates the “autarky principle” (that applying an autarky yields a satisfiability-equivalent clause-set) in such a way that it becomes easily applicable as a source for reductions in worst-case upper-bound proofs (see [KL98] for a discussion).

14.10.6. Incomplete autarky search in complete SAT solvers

The basic idea from [MS85], as explained in Subsection 14.10.5, is to check the assignments φ_x (obtained by adding all inferred unit-clause propagation to a test-assignment $x \rightarrow 1$) for being an autarky (in which case there is no need to branch). This has been implemented in the `OKsolver-2002` (see [Kul98, Kul02])⁹, incorporating the ideas from [Kul99b]:

- Now arbitrary binary splitting are considered (and not clause-branching as in [MS85]).
- The assignments φ_x occur naturally when performing “failed-literal reduction”.
- The branching heuristics is based on counting new clauses, and the autarky-test is actually necessary to avoid branches without “progress” (i.e., with zero new clauses).

See Subsection 8.7.4.1 in Chapter 8 on the general theory of branching heuristics for more information. This type of “ad-hoc” and “enforced” autarky search has also been applied (with variations) in the `march` solvers.

14.10.7. Employing autarkies in generalised unit-clause-propagation

Unit-clause propagation can be strengthened to failed-literal reduction, and further to arbitrary levels (corresponding to levels of generalised Horn formulas); see [Kul99a] for a thorough treatment and an overview on the literature. There, through the use of oracles, special poly-time procedures for finding autarkies (e.g., finding “linear autarkies”; see Subsection 14.10.9) are employed, enhancing the hierarchies by adding more satisfiable instances to each level.

This approach only uses autarkies at the leaves (to ensure confluence); in a more ad-hoc manner in [DE92] the assignments found when searching for enforced assignments at the various levels of the hierarchy (generalising the approach from Subsection 14.10.6 in a certain way) are directly checked for the autarky property.

14.10.8. Local search

Local search solvers search through total assignments, and each such total assignment can be inspected for being an autarky, according to Lemma 14.9.1. A first implementation one finds in `UnitMarch` (enhancing the local search solver `UnitWalk`; see [Hv08]). Combinations with other local search solvers might become

⁹this “historic” solver is now part of the `OKlibrary` (<http://www.ok-sat-library.org>)

interesting in the future (especially when adapting the heuristics to the new goal of finding autarkies). Direct local search through partial assignments should also be interesting, but has not been tried yet.

14.10.9. Polynomial-time cases

Most classes of clause-sets, where basic tasks like autarky finding or computation of the lean kernel can be performed in polynomial time, are handled by special types of autarkies, which is the subject of the following Section 14.11. Here we only comment on the most prominent cases, and especially how they can be handled by the techniques discussed in the current section (considering general autarkies); see [KMT08] for a more elaborated study.

We already mentioned in Subsection 14.10.5 that the consideration of clause-sets F in 2-CNF (every clause contains at most two literals) was at the beginning of “autarky theory”. And it is easy to see that actually if F is not lean then there must be some literal x such that φ_x (which was the extension of $\langle x \rightarrow 1 \rangle$ by unit-clause propagations) is an autarky (see [KMT08] for more details). So the autarky-existence problem is in P for 2-CNF, and (since 2-CNF is stable under the application of partial assignments) also the lean kernel is computable in polynomial time. This method for finding autarkies is covered by the method discussed in Subsection 14.10.6 for finding “ad-hoc enforced autarkies”, and thus is actually implemented in look-ahead solvers like the `OKsolver-2002` or the `march-solvers` (see Subsection 14.10.6). Another way to handle 2-CNF is by Theorem 14.10.1, where for finding a resolution-refutation one could also apply the stability of 2-CNF under the resolution rule (though finding a resolution refutation by a backtracking solver is more efficient). Finally every autarky for F in 2-CNF is a special case of a “linear autarky”, as discussed in Subsection 14.11.3, and thus can be handled also by the special methods there.

In a certain sense “dual” to 2-CNF is the class of clause-sets F such that every variable occurs at most once positively and at most once negatively. Minimally unsatisfiable such F are exactly the marginal minimally unsatisfiable clause-sets of deficiency 1. It is well known (and trivial) that by DP-resolution (un)satisfiability for this class is decidable in polynomial time, so we can find easily a resolution refutation, while by using self-reduction we can also find a satisfying assignment; so again by Theorem 14.10.1 we obtain that the computation of the lean kernel (and the computation of a maximal autarky) can be done in polynomial time. Another approach is given by the observation that every autarky for such F must be a “matching autarky”, as discussed in Subsection 14.11.2, and thus we can use the (poly-time) methods from there. Finally, minimal autarkies of F correspond to the cycles in the conflict multigraph of F (compare [Kul04a] for the notion of the conflict (multi-)graph), and thus we can find them by finding cycles.

Finally we mention that also for Horn clause-sets we can compute the lean kernel in polynomial time by Theorem 14.10.1. Again this can be handled also by linear autarkies (see Subsection 14.11.3).

14.10.10. Final remarks on the use of autarkies for SAT solving

Until now, the applications of autarky search to practical SAT solving have been rather restricted, mostly focusing on searching autarkies directly in the input, while autarky search at each node of the search tree, as discussed in Subsection 14.10.6, just checks whether “by chance” the partial assignments at hand are actually autarkies. Now in special cases autarky search as preprocessing will help, but stronger results can only be expected when *systematically* searching for autarkies at *each* node of the search tree. We close this section by showing (by example) that under “normal circumstances” relevant autarkies are created deeper in the search tree. Consider an input clause-set F , and we ask how many autarkies we obtain after application of a partial assignment φ . To simplify the discussion, we assume that F is unsatisfiable (these are also the relevant hard cases created at least during search). The basic intuition is that we obtain the more autarkies the more “redundancies” are contained in F . By definition an unsatisfiable clause-set is “irredundant” iff it is minimally unsatisfiable, and minimally unsatisfiable clause-sets are lean. Now there are stronger “degrees k of irredundancy”, achieved by requiring that for every partial assignment φ with $n(\varphi) \leq k$ for some given k we have that $\varphi * F$ is minimally unsatisfiable. Minimally unsatisfiable F are characterised by $k = 0$, saturated minimally unsatisfiable F by $k = 1$, and unsatisfiable hitting clause-sets F by $k = \infty$; see Chapter 6 in [Kul07a] for investigations of these issues. So from the autarky-perspective unsatisfiable hitting clause-sets are the most intractable cases — whatever partial assignment is applied, never any autarky arises. On the other end of the spectrum we have marginal minimally unsatisfiable clause-sets F of deficiency 1 — here already for $n(\varphi) = 1$ the clause-set $\varphi * F$ decomposes in variable-disjoint components, one of them minimally unsatisfiable (again marginal minimally unsatisfiable of deficiency 1), while all other components are satisfiable (and actually “matching-satisfiable”; see Subsection 14.11.2), and so we have (easy, relevant) autarkies. For practical applications, instances will not even be minimally unsatisfiable, and typically also are assembled from several parts, and thus the appearance of relevant autarkies not too deep down the search tree is to be expected.

14.11. Autarky systems: Using weaker forms of autarkies

In this section we consider restricted notions of autarkies, which allow to find such restricted autarkies in polynomial time, while still sharing many of the properties with general autarkies. The first example for a special form of autarkies, “linear autarkies”, was introduced in [Kul00b], and the general properties of the formation $F \mapsto \text{Auk}(F)$ of the (full) autarky monoid have been paralleled with the properties of the sub-monoid $F \mapsto \text{LAuk}(F) \leq \text{Auk}(F)$ of linear autarkies. Based on these investigations, in [Kul03] various forms of “autarky systems” have been introduced, axiomatising the basic properties. Some preliminary study on further generalisations can be found in [Kul01], while the notions have been revised and adapted to clause-sets with non-boolean variables in [Kul07a].

In the light of Lemma 14.9.3, an appropriate definition of an “autarky system” would be that of a contravariant functor $\mathcal{A} : \mathcal{CLS} \rightarrow \mathfrak{MN}$ such that the

canonical inclusion (of sub-monoids) is a natural transformation $\mathcal{A} \rightarrow \text{Auk}$. But since the study of such categorical notions in the context of SAT has not really started yet, we refrain here from such functorial formulations, and call an **autarky system** a map \mathcal{A} defined on all clause-sets such that $\mathcal{A}(F)$ is a sub-monoid of $\text{Auk}(F)$ for all $F \in \mathcal{CLS}$, and such that for $F_1 \subseteq F_2$ we have $\mathcal{A}(F_2) \subseteq \mathcal{A}(F_1)$. The most basic examples of autarky systems are $\mathcal{A} = \text{Auk}$, the full autarky system, and $\mathcal{A} = (\{\langle \rangle\})_{F \in \mathcal{CLS}}$, the trivial autarky system. From an autarky system \mathcal{A} we obtain the *restricted system* $\mathcal{A}^r(F) := \mathcal{A}(F) \cap \text{Auk}^r(F)$, which is again an autarky system if \mathcal{A} is “standardised” (that is, variables not in F do not matter; see below for the definition). The restricted version is especially important for practical considerations, however for theoretical investigations mostly the “full” versions (also using variables not in F) are more convenient. As before, we call the minimal elements of $\mathcal{A}^r(F) \setminus \{\perp\}$ *minimal \mathcal{A} -autarkies*, and the maximal elements of $\mathcal{A}^r(F)$ *maximal \mathcal{A} -autarkies*. If \mathcal{A}^r is an autarky system, then all maximal autarkies have the same domain (use the same variables).

A clause-set F is called *\mathcal{A} -lean* if $\mathcal{A}(F)$ contains only trivial autarkies. Using \mathcal{A} -autarky reduction instead of autarky reduction, i.e., reduction $F \rightsquigarrow \varphi * F$ for $\varphi \in \mathcal{A}(F)$, generalising Subsection 14.8.3 we obtain the *\mathcal{A} -lean kernel* $N_{\mathcal{A}}(F) \subseteq F$, the largest \mathcal{A} -lean sub-clause-set of F ; note that due to the anti-monotonicity condition for an autarky system, \mathcal{A} -autarky reduction still is confluent. Again we have that $N_{\mathcal{A}}(F) = F$ holds iff F is \mathcal{A} -lean, while in case of $N_{\mathcal{A}}(F) = \top$ we call F *\mathcal{A} -satisfiable*. The lean kernel formation $F \mapsto N_{\mathcal{A}}(F)$ is again a kernel operator. The union of \mathcal{A} -lean clause-sets is \mathcal{A} -lean, and $N_{\mathcal{A}}(F)$ is the union of all \mathcal{A} -lean sub-clause-sets of F .

If there exists $\varphi \in \mathcal{A}(F)$ with $\varphi * F = \top$, then F is \mathcal{A} -satisfiable, but the reverse direction does not hold in general. In other words, using *\mathcal{A} -autark subsets* of F as sub-clause-sets satisfied by some \mathcal{A} -autarky for F , we again have that the union of \mathcal{A} -autark subsets is again an \mathcal{A} -autark subsets, and thus there is a largest \mathcal{A} -autark subsets, where the largest \mathcal{A} -autark subset is disjoint with the largest lean subset $N_{\mathcal{A}}(F)$ — however we do not obtain a partition of F in this way, and additional properties of autarky systems are needed. We do not want to discuss various forms of strengthened autarky systems, but we only consider the strongest form, called a **normal autarky system**, which comprises the six basic properties of autarkies listed in Subsection 14.8.2. More precisely, we require the following five additional properties (for all partial assignments φ, ψ , all clause-sets F and all finite sets V of variables):

standardised $\varphi \in \mathcal{A}(F) \Leftrightarrow \varphi|_{\text{var}(F)} \in \mathcal{A}(F)$;

iterative if $\varphi \in \mathcal{A}(F)$ and $\psi \in \mathcal{A}(\varphi * F)$, then $\psi \circ \varphi \in \mathcal{A}(F)$;

invariant under variable elimination if $\text{var}(\varphi) \cap V = \emptyset$, then $\varphi \in \mathcal{A}(F) \Leftrightarrow \varphi \in \mathcal{A}(V * F)$;

\perp -invariant $\mathcal{A}(F) = \mathcal{A}(F \cup \{\perp\})$;

invariant under renaming if F' is isomorphic to F , then the same isomorphism turns $\text{Auk}(F)$ into $\text{Auk}(F')$.

(Note that for the functorial definition of an autarky system mentioned above, the property of invariance under renaming is automatically fulfilled.) If \mathcal{A} is a normal autarky system, then the restricted system \mathcal{A}^r is an autarky system which fulfils

all additional properties except of being standardised (that is, \mathcal{A}^F is iterative, invariant under variable elimination, \perp -invariant and invariant under renaming). If $\mathcal{A}_1, \mathcal{A}_2$ are (normal) autarky systems, then also $F \mapsto \mathcal{A}_1(F) \cap \mathcal{A}_2(F)$ is a (normal) autarky system.¹⁰

We assume from now on that \mathcal{A} is a normal autarky system, which can be justified by the fact that every autarky system has a unique strengthening which is a normal autarky system (just by adding the “missing” autarkies). Now for all clause-sets F there is an \mathcal{A} -maximal autarky φ with $\varphi * F = N_{\mathcal{A}}(F)$, especially F is \mathcal{A} -satisfiable iff there is $\varphi \in \mathcal{A}(F)$ with $\varphi * F = \top$. Regarding the full autarky system, from an autarky φ with $\varphi * F = N_{\mathcal{A}}(F)$ we can easily obtain a maximal autarky φ' , by adding arbitrary assignments for variables in $\text{var}(F \setminus \varphi * F)$ which do not already have a value (and also variables not in F need to be removed). However for arbitrary (normal) autarky systems this might not be possible, and so we call \mathcal{A} -autarkies φ with $\varphi * F = N_{\mathcal{A}}(F)$ *quasi-maximal*. Every \mathcal{A} -maximal autarky is \mathcal{A} -quasi-maximal.

If F is \mathcal{A} -lean, then also $V * F$ and $F[V]$ are \mathcal{A} -lean for (finite) sets V of variables, and every clause-set $F' \supseteq F$ with $\text{var}(F') = \text{var}(F)$ is \mathcal{A} -lean as well.¹¹ The \mathcal{A} -autark subsets of F , i.e., the subsets $F_{\text{var}(\varphi)}$ for $\varphi \in \mathcal{A}(F)$, can be characterised as the \mathcal{A} -satisfiable subsets F_V for $V \subseteq \text{var}(F)$, where furthermore F_V is \mathcal{A} -satisfiable iff $F[V]$ is \mathcal{A} -satisfiable. The set of \mathcal{A} -autark subsets of F is closed under union, with smallest element \top and largest element $F \setminus N_{\mathcal{A}}(F)$. The partition of F into $N_{\mathcal{A}}(F)$ and $F \setminus N_{\mathcal{A}}(F)$ (where some part can be empty) has, as before, several characterisations; it is the partition of F into the largest \mathcal{A} -lean and the largest \mathcal{A} -autark subset, or, equivalently, if $F = F_1 \cup F_2$, where F_1 is \mathcal{A} -lean and $\text{var}(F_1) * F_2$ is \mathcal{A} -satisfiable, then $F_1 = N_{\mathcal{A}}(F)$ and $F_2 = F \setminus N_{\mathcal{A}}(F)$ (and also the other way around; note that disjointness of F_1, F_2 actually follows from $\text{var}(F_1) * F_2$ being satisfiable). \mathcal{A} -satisfiability is “self-reducible” in the sense that (in the same way as for the full autarky system) from an oracle deciding \mathcal{A} -leanness we obtain efficiently a way for computing the lean kernel (see Lemma 8.6 in [Kul03]); however for also computing an \mathcal{A} -quasi-maximal autarky (as in [KMT08]) additional conditions on the autarky system \mathcal{A} are needed.

14.11.1. Pure autarkies

In Example 14.8.3 we have already seen that every pure literal x for a clause-set F induces an autarky $\langle x \rightarrow 1 \rangle \in \text{Auk}(F)$. This is not yet an autarky system, since we do not have closure under composition. So we call a partial assignment φ a *simple pure autarky* for F if for all literals x with $\varphi(x) = 1$ we have $\bar{x} \notin \bigcup F$; the set of all simple pure autarkies is denoted by $\text{PAut}_0(F)$. In this way we obtain an autarky system $F \mapsto \text{PAut}_0(F)$, which also is standardised, invariant

¹⁰More generally, arbitrary intersections of (normal) autarky systems are again (normal) autarky systems, and we obtain the complete lattice of autarky systems and the complete lattice of normal autarky systems, and the corresponding closures (hulls; as always in algebra).

¹¹We remark here that for *formal clause-sets*, which correspond to the notion of a hypergraph and are pairs (V, F) for sets V of variables and clause-sets over V (so that now “formal variables” are allowed, i.e., elements of $V \setminus \text{var}(F)$), \mathcal{A} -leanness of (V, F) implies $V = \text{var}(F)$, since otherwise a non-trivial autarky would exist.

under variable elimination, \perp -invariant, and invariant under renaming, however not iterative (applying a simple pure autarky can create new pure literals).

Example 14.11.1. For $F := \{\{a, b\}, \{\bar{b}\}\}$ we have $\text{PAut}_0(F) = \{\langle \rangle, \langle a \rightarrow 1 \rangle\}$, and so the unique PAut_0 -maximal autarky is $\langle a \rightarrow 1 \rangle$. However this is not a satisfying assignment for F , despite the fact that F is PAut_0 -satisfiable.

To obtain a normal autarky system, according to the general theory we consider $\text{PAut}(F)$, which is the closure of $\text{PAut}_0(F)$ under “iteration” of autarkies. So the elements of $\text{PAut}(F)$ are the partial assignments $\varphi_m \circ \dots \circ \varphi_1$, where φ_i is a simple pure autarky for F_{i-1} , where $F_0 := F$ and $F_{i+1} := \varphi_{i+1} * F_i$. The elements of $\text{PAut}(F)$ are called *pure autarkies*.

Given any autarky system \mathcal{A} , it is natural to study which random clause-sets (say, in the constant-density model, fixing a clause-length $k \geq 2$, and considering all k -uniform clause-lists of length c over n given variables as equally likely) are \mathcal{A} -satisfiable. Experimental evidence seems to suggest that at least the “natural” autarky systems considered here all show a threshold behaviour (below a certain threshold density every clause-list is almost surely \mathcal{A} -satisfiable, above that density almost surely none). Only for pure autarkies this has been finally rigorously established in [Mol05], proving that for all $k \geq 2$ a threshold exists, at the density $\frac{c}{n} = 1$ for $k = 2$ and at $\frac{c}{n} = 1.636\dots$ for $k = 3$.

14.11.2. Matching autarkies

The notion of “matching autarkies” is based on the work in [FV03], which introduced “matched clause-sets”, that is, clause-sets F with $d^*(F) = 0$ (recall Definition 14.2.1¹²), which are the *matching satisfiable clause-sets* using our systematic terminology for autarky systems (that is, clause-sets satisfiable by matching autarkies). Perhaps the earliest work where matching autarkies are implicitly used is [AL86]. Matching satisfiable sub-clause-sets of a clause-set F as the independent sets of a transversal matroid have been used in [Kul00a] to show that SAT for clause-sets with bounded maximal deficiency can be decided in polynomial time. The first thorough study of matching lean clause-sets (clause-sets without non-trivial matching autarkies) one finds in [Kul03], completed (and extended to clause-sets with non-boolean variables) in [Kul07a]. As shown there, the basic tasks like finding a maximal matching autarkies can be performed in polynomial time. The structure of the matching autarky monoid has not been investigated yet.

As introduced in [Kul03], “matching autarkies” are partial assignments which satisfy in every clause they touch a literal with underlying *unique* variable.

Definition 14.11.1. A partial assignment φ is called a *matching autarky* for a clause-set F if there is an injection $v : F_{\text{var}(\varphi)} \rightarrow \text{var}(\varphi)$ such that for all clauses $C \in F_{\text{var}(\varphi)}$ there is a literal $x \in C$ with $v(C) = \text{var}(x)$ and $\varphi(x) = 1$.

Clearly every matching autarky is in fact an autarky. The set of matching autarkies is denoted by $\text{MAuk}(F)$ resp. $\text{MAuk}^r(F)$ (considering only matching autarkies with variables in F).

¹²we remark that also the notion of “deficiency” was introduced in [FV03]

Example 14.11.2. If every literal occurs only once, then every autarky is a matching autarky; see for example Example 14.9.1. As the simplest example where some autarkies are left out consider $F := \{\{v_1\}, \{v_1, v_2\}\}$; we have $\text{MAuk}^r(F) = \{\langle \rangle, \langle v_2 \rightarrow 1 \rangle, \langle v_1 \rightarrow 1, v_2 \rightarrow 1 \rangle\}$ (note that $\langle v_1 \rightarrow 1 \rangle$ is an autarky for F but not a matching autarky). While F is still matching satisfiable, the clause-set $\{\{v_1, v_2\}, \{v_1, \bar{v}_2\}, \{\bar{v}_1, v_2\}\}$ is satisfiable but matching lean.

Using *multi*-clause-sets F instead of clause-sets, a partial assignment φ is a matching autarky for F iff $F[\text{var}(\varphi)]$ is matching satisfiable (we have to use multi-clause-sets in order to avoid the contraction of clauses).

Example 14.11.3. $\langle v \rightarrow 1 \rangle$ is *not* a matching autarky for $F := \{\{v\}, \{w\}, \{v, w\}\}$, and accordingly as multi-clause-set $F[\text{var}(\varphi)]$ consists of two occurrences of the clause $\{v\}$, and thus is not matching satisfiable. But as a clause-set we would obtain $F[\text{var}(\varphi)] = \{\{v\}\}$ which is matching satisfiable.

The operator $F \mapsto \text{MAuk}(F)$ yields a normal autarky system, but only for multi-clause-sets; for clause-sets we have an autarky system which fulfils all properties of normal autarky systems except of being invariant under variable elimination. The matching satisfiable clause-sets are exactly the clause-sets with $d^*(F) = 0$, while the matching lean clause-sets are exactly the clause-sets F with $\forall F' \subset F : d(F') < d(F)$ (thus $d^*(F) = d(F)$, and if $F \neq \top$, the $d(F) \geq 1$). This generalises the fact from [AL86] that minimally unsatisfiable clause-sets have deficiency at least 1. More on matching autarkies one finds in Section 7 of [Kul03], and in Section 4 of [Kul07a].

14.11.3. Linear autarkies

The notion of a “linear autarky”, introduced in [Kul00b], was motivated by the applications of linear programming to SAT solving in [vW00] (see Theorem 2 there). The basic notion is that of “simple linear autarkies”, yielding an autarky system which fulfils all conditions of a normal autarky system except of being iterative, which then is repaired by the notion of a “linear autarky”. Let a *variable weighting* be a map $w : \mathcal{VA} \rightarrow \mathbb{Q}_{>0}$, that is, every variable gets assigned a positive rational number (real numbers could also be used). We extend the weighting to literals and clauses, relative to a partial assignment φ , as follows (using an arithmetisation of “false” by -1 and “true” by $+1$):

- For a literal x let $\text{sgn}_\varphi(x) := 0$ if $\text{var}(x) \notin \text{var}(\varphi)$, otherwise $\text{sgn}_\varphi(x) := +1$ if $\varphi(x) = 1$, while $\text{sgn}_\varphi(x) := -1$ if $\varphi(x) = 0$.
- Now for a literal x let $w_\varphi(x) := \text{sgn}_\varphi(x) \cdot w(\text{var}(x))$.
- And for a clause C we define $w_\varphi(C) := \sum_{x \in C} w_\varphi(x)$,

Note that for clauses C we have $w_\varphi(\bar{C}) = -w_\varphi(C)$. Now we can state the definition of “simple linear autarkies” (as introduced in [Kul00b]):

Definition 14.11.2. A partial assignment φ is a *simple linear autarky* for a clause-set F if there exists a weighting $w : \mathcal{VA} \rightarrow \mathbb{Q}_{>0}$ such that for all $C \in F$ we have $w_\varphi(C) \geq 0$.

Clearly a simple linear autarky is an autarky, and also clearly we only need to consider the variables actually occurring in F . Defining *linear autarkies* as the closure of simple linear autarkies under iteration we obtain a normal autarky system.

14.11.3.1. Comparison to pure and matching autarkies

Example 14.11.4. Every pure literal x for a clause-set F yields a simple linear autarky $\langle x \rightarrow 1 \rangle$, certified by any constant weighting. The partial assignment $\langle v_1 \rightarrow 1, v_2 \rightarrow 2 \rangle$ is a (satisfying) simple linear autarky for the matching lean clause-set $\{\{v_1, v_2\}, \{v_1, \bar{v}_2\}, \{\bar{v}_1, v_2\}\}$ from Example 14.11.2, again certified by any constant weighting. The partial assignment $\varphi := \langle v_1, v_2, v_3 \rightarrow 1 \rangle$ is not a simple linear autarky for $F := \{\{v_1, \bar{v}_2, \bar{v}_3\}, \{\bar{v}_1, v_2\}, \{v_3\}\}$, since if it had a certificate w , then $w(\bar{v}_3) < 0$ in the first clause, so from $0 \leq w(\{v_1, \bar{v}_2, \bar{v}_3\}) = w(\{v_1, \bar{v}_2\}) + w(\bar{v}_3)$ we obtain $w(\{v_1, \bar{v}_2\}) \geq -w(\bar{v}_3) > 0$, but $w(\{\bar{v}_1, v_2\}) = -w(\{v_1, \bar{v}_2\})$, and thus the second clause gets a negative weight. On the other hand, φ is a matching autarky for F .

So it might seem that simple linear autarkies and matching autarkies are incomparable in strength, however this is misleading: every clause-set which has a non-trivial matching autarky also has a non-trivial simple linear autarky, as shown in [Kul00b] (by basic linear algebra one shows that a matching satisfiable clause-set $F \neq \top$ must have a non-trivial simple linear autarky, and thus F must be linearly satisfiable (by iteration); using invariance under variable elimination this is lifted to arbitrary non-matching-lean F). So the linearly-lean kernel of a clause-set is always contained in the matching-lean kernel. In Example 14.11.4 the clause-set F has the simple linear autarky $\langle v_1 \rightarrow 1, v_2 \rightarrow 1 \rangle$, and while the partial assignment φ is not a simple linear autarky, it is actually a linear autarky.

Example 14.11.5. Consider $F := \{\{v_1, \bar{v}_2, \bar{v}_3\}, \{\bar{v}_1, v_2, \bar{v}_3\}, \{\bar{v}_1, \bar{v}_2, v_3\}\}$. The partial assignment $\varphi := \langle v_1, v_2, v_3 \rightarrow 1 \rangle$ is a matching autarky for F but not a simple linear autarky; furthermore φ is a minimal autarky for F and thus φ is also not a linear autarky. So we see that, although the reduction power of linear autarkies is as least as big as the reduction power of matching autarkies (in this example, $\langle v_1, v_2 \rightarrow 0 \rangle$ is a simple linear autarky for F), there are matching autarkies which do not contain any non-trivial linear autarkies.

14.11.3.2. Matrix representations of clause-sets

Now we turn to the question of finding linear autarkies in polynomial time. This is best done by translating the problem into the language of linear programming. For a clause-set F consider the clause-variables matrix $M(F)$ of size $c(F) \times n(F)$. Let us emphasise that this is different to the use of matrices in Example 14.2.1, where matrices only are used for an economic representation, while here now “mathematical” matrices are used, with entries from $\{-1, 0, +1\} \subset \mathbb{Z}$, where the rows correspond to the clauses of F (in some order), and the columns correspond to the variables of F (in some order). Now F is linearly lean if and only if $M(F) \cdot \vec{x} \geq 0$ has the only solution $\vec{x} = 0$, and furthermore every solution \vec{x} corresponds to a simple linear autarky by the same arithmetisation as used before,

i.e., 0 corresponds to “not assigned”, +1 corresponds to “true” and -1 corresponds to “false”. Thus by linear programming we can find a non-trivial linear autarky (if one exists).

Via linear autarkies, several basic cases of poly-time SAT decision are covered. Using a constant weighting, we see that every autarky for a clause-set F in 2-CNF (every clause has length at most 2) is a simple linear autarky, and thus every satisfiable 2-CNF is linearly satisfiable. [van00] applies linear autarkies to q -Horn formulas, while in [Kul99a] it is shown how satisfiable generalised Horn clause-sets (in a natural hierarchy of generalised Horn clause-sets, covering all clause-sets) can be captured by linearly satisfiable clause-sets (used as an oracle to amplify the general hierarchy studied in [Kul99a]). For more on linear autarkies see [Kul00b, Kul03], while [Kul06] contains more on “balanced” linear autarkies (see Subsection 14.11.4). In general the field of linear autarkies appears still largely unexplored; for example there seems to be a threshold for linear satisfiability of random 3-CNF at around density 2 (i.e., having twice as many clauses as variables).

Since matrix representations of satisfiability problems are at least of great theoretical value, we conclude this subsection on linear autarkies by some general comments on technical problems arising in this context. First, what is a “matrix”?! The appropriate definition of the notion of a (general) matrix is given in [Bou89], where a *matrix over a set V* is defined as a triple (R, C, f) , where R, C are arbitrary sets (the “row indices” and the “column indices”), and $f : R \times C \rightarrow V$ gives the entries of the matrix. It is important to note that for row and column indices arbitrary objects can be used, and that no order is stipulated on them. In this context it is appropriate to introduce *labelled clause-sets* (corresponding to general hypergraphs) as triples (V, F_0, F) , where V, F_0 are arbitrary sets (the “variables” and the “clause-labels”), while $F : F_0 \rightarrow \mathcal{CLS}(V)$ maps every clause-label to a clause over V . Note that labelled clause-sets can have *formal variables*, i.e., variables $v \in V$ not occurring in the underlying clause-set ($v \notin \text{var}(F(F_0))$), and that clauses can occur multiple times (furthermore clauses have “names”). Now we have a perfect correspondence between finite matrices over $\{-1, 0, +1\}$ and finite labelled clause-sets, more precisely we have two ways to establish this correspondence, either using the *clause-variable matrix*, which assigns to (V, F_0, F) the matrix (F_0, V, F') (where $F'(C, v)$ is ± 1 or 0, depending on whether v occurs in $F(C)$ positively, negatively or not at all), or using the *variable-clause matrix* (V, F_0, F'') (with $F''(v, C) := F'(C, v)$). *Standardised matrices* use row-sets $R = \{1, \dots, n\}$ and column-sets $C = \{1, \dots, m\}$ for $n, m \in \mathbb{N}_0$, and in this way also “automatically” an order on the rows and columns is established (so that standardised matrices can be identified with “rectangular schemes of values”). Ironically this less appropriate notion of a matrix (with its ambiguous treatment of order) is common in the field of combinatorics, so that, in the spirit of [BR91], in this context we call the above matrices “combinatorial matrices”. In the context of the autarky part of this chapter, clause-variable matrices (as well as its transposed, variable-clause-matrices) are combinatorial matrices, so that we save us the ordeal of having to determine somehow an order on variables and clauses.¹³

¹³In Subsection 14.12.2 we will consider the determinant of (square) clause-variable matrices,

Clause-sets do not allow formal variables nor multiple clauses, and thus their clause-variable matrices don't have zero columns nor identical rows. Thus when we speak of a matrix corresponding to a clause-set, then by default we consider clause-variable matrices, and the matrices don't contain zero columns or identical rows (while when considering labelled clause-sets no such restrictions are applied).

14.11.4. Balanced autarkies

We now consider the important (normal) autarky system of “balanced autarkies” which, unlike pure, matching and linear autarkies, has an NP-complete search problem (as the full autarky system): the main motivation behind balanced autarkies perhaps can be understood as providing a bridge from hypergraph theory to satisfiability theory.

Definition 14.11.3. A partial assignment φ is a *balanced autarky* for a clause-set F if φ an autarky for F as well as for $\overline{F} = \{\overline{C} : C \in F\}$, or, in other words, if in every clause $C \in F$ touched by φ there are satisfied literals as well as falsified literals.

Some basic facts about balanced autarkies are as follows:

1. Balanced autarkies yield a normal autarky system.
2. Balanced-satisfiable clause-sets, i.e., clause-sets satisfiable by balanced autarkies, are exactly the instances of NAESAT (“not-all-equal-sat”), that is, clause-sets which have a satisfying assignment which in every clause also falsifies some literals.
3. φ is a balanced autarky for F iff φ is an autarky for $F \cup \overline{F}$.
4. For *complement-invariant* clause-sets, i.e., where $F = \overline{F}$ holds, the balanced autarkies are exactly the autarkies. Especially, the satisfying partial assignments of complement-invariant clause-sets are exactly the balanced-satisfying assignments.
5. A complement-invariant clause-set F is satisfiable iff the underlying variable-hypergraph $\mathfrak{H}(F) = (\text{var}(F), \{\text{var}(C) : C \in F\})$ is 2-colourable.¹⁴

An example for a class of balanced lean clause-sets (having no non-trivial balanced autarky) is the class of clause-sets $F \setminus \{C\}$ for $F \in \text{MU}(1)$ and $C \in F$ (note that every such $F \setminus \{C\}$ is matching satisfiable).¹⁵

and the determinant of a combinatorial matrix is only determined up to its sign — fortunately actually only the absolute value of the determinant is needed there!

¹⁴A *hypergraph* is a pair (V, E) , where V is the set of “vertices”, while E , the set of “hyperedges”, is a set of subsets of V . A 2-colouring of a hypergraph (V, E) is a map $f : V \rightarrow \{0, 1\}$ such that no hyperedge is “monochromatic”, i.e., the 2-colourings of F correspond exactly to the satisfying assignments for the (complement-invariant) clause-set $F_2((V, E)) := E \cup \overline{E}$ (using the vertices as variables).

¹⁵That every such $F \setminus \{C\}$ is balanced lean can be shown by induction on $n(F)$. The assertion is trivial for $n(F) = 0$, so assume $n(F) > 0$. F must contain a variable v occurring positively and negatively only once. If $v \notin \text{var}(C)$, then we can apply the induction hypothesis to F' obtained from F by (singular) DP-resolution on v . If on the other hand there is no such v , then F is renamable to a Horn clause-set, so, since F is unsatisfiable, F must contain a unit-clause $\{x\} \in F$, and we can apply the induction hypothesis to F'' obtained from F by (singular) DP-resolution on $\text{var}(x)$.

Regarding the intersection of the autarky system of balanced autarkies with the autarky systems presented until now, *balanced linear autarkies* seem most important (that is, linear autarkies which are also balanced, constituting a strong autarky system).

Example 14.11.6. The clause-set $F = \{\{v_1, \bar{v}_2, \bar{v}_3\}, \{\bar{v}_1, v_2, \bar{v}_3\}, \{\bar{v}_1, \bar{v}_2, v_3\}\}$ from Example 14.11.5 is balanced satisfiable (for example by setting all variables to 1 or setting all variables to 0), while F is balanced linearly lean (has no non-trivial balanced lean autarky).

Balanced linear autarkies for a clause-set F can be found easier than general linear autarkies, by just solving a system of linear equations (not linear inequalities), namely they correspond to the solution of $M(F) \cdot x = 0$ (recall Subsection 14.11.3). As already alluded to in Subsection 14.4.5, they have been implicitly used in [Sey74]: While matching autarkies are used to show that minimally unsatisfiable clause-sets have a deficiency at least 1, balanced linear autarkies are used to show that minimally non-2-colourable hypergraphs have deficiency at least 0 (where we define the deficiency of a hypergraph (V, E) as $|E| - |V|$, the difference of the number of hyperedges and the number of vertices). Slightly more general, any clause-set F which is balanced linearly lean has $d(F) \geq 0$, which follows directly from the matrix characterisation of balanced linear autarkies; actually for such F we have the stronger property $d^*(F) = d(F)$ (Lemma 7.2 in [Kul06]). For more on the relation of balanced autarkies to combinatorics see Subsections 14.12.1, 14.12.2.

14.11.5. Generalising minimally unsatisfiable clause-sets

In [Kul07b] the notion of **minimally \mathcal{A} -unsatisfiable** clause-sets F has been introduced for arbitrary (normal) autarky systems \mathcal{A} , which are clause-sets F which are \mathcal{A} -unsatisfiable but where every strict sub-clause-set is \mathcal{A} -satisfiable. The motivation is as follows: The hypergraph 2-colouring problem for a hypergraph $G = (V, E)$ (where V is a finite set of vertices, and E is a set of subsets of V) can be naturally expressed as the satisfiability problem for the clause-set $F_2(G)$ (as already mentioned in Subsections 14.4.5 14.11.4), using the elements of V as variables, while the clauses are the hyperedges $H \in E$ itself (which become now “positive clauses”) together with the complements \bar{H} (which become “negative clauses”). The notion of *minimally non-2-colourable hypergraphs* (or *critically 3-colourable hypergraphs*) has been studied intensively in the literature (see for example Chapter 15 in [JT95]). It is easy to see that G is minimally non-2-colourable if and only if $F_2(G)$ is minimally unsatisfiable. Analogously to clause-sets, for hypergraphs G we can consider the *deficiency* $d(G) := |E(G)| - |V(G)|$. It has been shown in [Sey74] that $d(G) \geq 0$ holds for minimally non-2-colourable hypergraphs. The situation is very similar to $d(F) \geq 1$ for minimally unsatisfiable clause-sets, and indeed, while the proof of this property for clause-sets relies on matching autarkies, for hypergraphs we use balanced linear autarkies instead (thus replacing matching theory by linear algebra; see [Kul06] for some initial investigations on this subject). Deciding the class MU(1) in polynomial time has been discussed in Subsection 14.2.2, while the analogous problem for

hypergraphs, deciding whether a *square hypergraph* (of deficiency 0) is minimally 2-colourable, is actually a much more difficult problem, which was finally resolved in [RST99, McC04] (see Subsection 14.12.2). Now satisfiability of the elements of $\text{MU}(1)$ after removal of a clause is of a very special kind, namely they are *matching satisfiable*, and analogously satisfiability of square minimally non-2-colourable hypergraphs after removal of a hyperedge is covered by *balanced linear satisfiability* (regarding the translation $F_2(G)$). So we have several natural and important cases of a restricted kind of minimal unsatisfiability, namely where satisfiability after removal of a clause yields an \mathcal{A} -satisfiable clause-set for some (feasible) autarky system \mathcal{A} . And instead of requiring that the whole clause-set must be unsatisfiable, we only need it to be \mathcal{A} -unsatisfiable; thus minimal \mathcal{A} -unsatisfiability at the same time strengthens and weakens the notion of minimal unsatisfiability.

Regarding the full autarky system Auk , minimal Auk -unsatisfiability is just minimal unsatisfiability. And every minimally unsatisfiable clause-set is minimally \mathcal{A} -unsatisfiable for every autarky system \mathcal{A} . The minimally matching unsatisfiable (i.e., minimally MAuk -unsatisfiable) clause-sets F are exactly the matching lean clause-sets of deficiency 1, which includes $\text{MU}(1)$, while all other such F are satisfiable.

We have already seen another generalisation of (ordinary) minimal unsatisfiability, namely the notion of \mathcal{A} -lean clause-sets. Now minimal unsatisfiable clause-sets F are not just lean, but they are “minimally lean” in the sense that every strict sub-clause-set except of \top is not lean, so one could introduce the notion of “minimally \mathcal{A} -lean clause-sets” — however the reader can easily convince himself that a clause-set F is “minimally \mathcal{A} -lean” iff F is minimally \mathcal{A} -unsatisfiable. So to arrive at a new notion, we have to be more careful, and instead of demanding that every strict sub-clause-set of F except of \top is not \mathcal{A} -lean, we require that after removal of any *single* clause we obtain a non- \mathcal{A} -lean clause-set. We have arrived at the notion of a **barely \mathcal{A} -lean** clause-set, which generalises the notion of a “barely L -matrix” in [BS95] (see Subsection 14.12.1 below).

Generalising the notion of an “ L -indecomposable matrix” in [BS95] (again, compare Subsection 14.12.1), in [Kul07b] the notion of an **\mathcal{A} -indecomposable clause-set** has been introduced. This notion applies to \mathcal{A} -lean clause-sets, where an \mathcal{A} -lean clause-set F by definition is \mathcal{A} -decomposable if the clause-variable matrix $M(F)$ can be written as $\begin{pmatrix} A & 0 \\ * & B \end{pmatrix}$ for non-empty matrices A, B (having at least one row and one column) corresponding to clause-sets F_1, F_2 which are \mathcal{A} -lean (then the pair (F_1, F_2) yields an \mathcal{A} -decomposition of F). Note that since we are dealing here with clause-sets, B may not contain repeated rows (as in Definition 4 of [Kul07b]), which is justified when only Theorem 14.11.1 is considered, since if F is barely \mathcal{A} -lean, then no contraction can occur in an \mathcal{A} -decomposition.

Example 14.11.7. Consider two (different) variables a, b and the clause-set $F := F_1 \cup F_2'$, where $F_1 := \{\{a\}, \{\bar{a}\}\}$ and $F_2' := \{\{a, b\}, \{\bar{a}, \bar{b}\}\}$. We consider the full autarky system. Now F is barely lean, but not minimally unsatisfiable, and an autarky-decomposition of F is given by F_1, F_2 for $F_2 := F[\{b\}] = \{\{b\}, \{\bar{b}\}\}$. The clause-set $F' := F_1 \cup F_2''$ for $F_2'' := F_2' \cup \{\{a, \bar{b}\}\}$ has no autarky-decomposition as a clause-set (but see below), and it is lean but not barely lean.

The basic theorem now is ([Kul07b]):

Theorem 14.11.1. *Consider a normal autarky system \mathcal{A} . Then a clause-set F with at least two clauses is minimally \mathcal{A} -unsatisfiable if and only if F is barely \mathcal{A} -lean and \mathcal{A} -indecomposable.*

If the autarky system \mathcal{A} is sensitive to repetition of clauses (as are matching autarkies; recall Example 14.11.3), then multi-clause-sets or even labelled clause-sets (which additionally allow for formal variables and for clause-labels; recall Subsection 14.11.3.2) are needed. For the above definition of \mathcal{A} -(in)decomposability then labelled clause-sets are used instead of clause-sets, and so the submatrices A, B may contain zero columns and repeated rows (but note that if A or B contains a zero column then the corresponding labelled clause-set cannot be \mathcal{A} -lean).

Example 14.11.8. Considering $F' = \{\{a\}, \{\bar{a}\}, \{a, b\}, \{\bar{a}, \bar{b}\}, \{a, \bar{b}\}\}$ from Example 14.11.7 as a multi-clause-set, it has now the autarky-decomposition consisting of $\{a\} + \{\bar{a}\}$ and $\{b\} + 2 \cdot \{\bar{b}\}$. And the clause-set $\{\{a\}, \{\bar{a}\}, \{a, b\}, \{\bar{a}, \bar{b}\}\}$ is matching lean (but not barely matching lean), and as a clause-set it has no matching-autarky-decomposition, while as a multi-clause-set it has the matching autarky decomposition consisting of $\{a\} + \{\bar{a}\}$ and $2 \cdot \{b\}$.

An \mathcal{A} -lean labelled clause-set $F = (V, F_0, F^*)$ has an \mathcal{A} -autarky decomposition if and only if there exists $\emptyset \subset V' \subset V$ such that the clause-label-set $F'_0 := \{C \in F_0 : \text{var}(F^*(C)) \subseteq V'\}$ is not empty and the labelled clause-set $F_1 := (V', F'_0, F^*|_{F'_0})$ is \mathcal{A} -lean (this corresponds to the matrix A in the above definition, while $F_2 = F[V \setminus V']$; note that leanness of F_2 is implied by leanness of F , and that in general zero rows in B can be moved to A).

14.11.6. The basic algorithmic problems

To conclude this section on autarky systems, we collect now the basic algorithmic problems concerning autarkies. First we need notations for the various classes of clause-sets involved; consider a class $\mathbb{C} \subseteq \mathcal{CLS}$ of clause-sets and a normal autarky system \mathcal{A} . By \mathcal{A} -SAT(\mathbb{C}) resp. \mathcal{A} -UNSAT(\mathbb{C}) we denote the \mathcal{A} -satisfiable resp. \mathcal{A} -unsatisfiable clause-sets in \mathbb{C} , by \mathcal{A} -LEAN(\mathbb{C}) the \mathcal{A} -lean clause-sets in \mathbb{C} , by \mathcal{A} -MU(\mathbb{C}) the minimally \mathcal{A} -unsatisfiable clause-sets in \mathbb{C} , and finally by \mathcal{A} -BRLEAN(\mathbb{C}) resp. \mathcal{A} -INDEC(\mathbb{C}) the barely \mathcal{A} -lean clause-sets resp. the \mathcal{A} -indecomposable clause-sets in \mathbb{C} . If \mathcal{A} is not mentioned, then the default is the full autarky system, and if \mathbb{C} is not mentioned, then the default is the class \mathcal{CLS} of all clause-sets. Thus $\text{MU}(k) = \text{MU}(\{F \in \mathcal{CLS} : d(F) = k\})$, while LEAN is the set of all lean clause-sets.

The basic *decision problems* are now as follows, as “promise problems”, that is, where $F \in \mathbb{C}$ is already given:

1. The AUTARKY EXISTENCE PROBLEM for \mathcal{A} and \mathbb{C} is to decide whether $F \in \mathcal{CLS} \setminus \mathcal{A}$ -LEAN(\mathbb{C}) holds, while its negation, the LEANNESS PROBLEM, is to decide $F \in \mathcal{A}$ -LEAN(\mathbb{C}).
2. The SATISFIABILITY PROBLEM for \mathcal{A} and \mathbb{C} is to decide whether $F \in \mathcal{A}$ -SAT(\mathbb{C}) holds, while its negation, the UNSATISFIABILITY PROBLEM, is to decide $F \in \mathcal{A}$ -UNSAT(\mathbb{C}).
3. The MINIMAL UNSATISFIABILITY PROBLEM for \mathcal{A} and \mathbb{C} is to decide whether $F \in \mathcal{A}$ -MU(\mathbb{C}) holds.

4. The BARELY LEANNESS PROBLEM is to decide $F \in \mathcal{A}\text{-BRLEAN}(\mathbb{C})$.
5. The INDECOMPOSABILITY PROBLEM is to decide $F \in \mathcal{A}\text{-INDEC}(\mathbb{C})$.

If we can solve the satisfiability problem “efficiently”, and \mathbb{C} is stable under formation of sub-clause-sets (i.e., if $F \in \mathbb{C}$ and $F' \subseteq F$, then also $F' \in \mathbb{C}$), then by definition we can solve “efficiently” the minimal unsatisfiability problem. If we can solve “efficiently” the autarky existence problem, and \mathbb{C} is stable under formation of sub-clause-sets, then by definition the barely leanness problem can also be solved “efficiently”.

The most basic *functional problems* are as follows (again for input $F \in \mathbb{C}$):

1. The LEAN KERNEL PROBLEM for \mathcal{A} and \mathbb{C} is the problem of computing the lean kernel $N_{\mathcal{A}}(F)$.
2. The NON-TRIVIAL AUTARKY PROBLEM for \mathcal{A} and \mathbb{C} is the autarky existence problem together with the computation of some non-trivial autarky in case it exists.
3. The QUASI-MAXIMAL AUTARKY PROBLEM for \mathcal{A} and \mathbb{C} is the problem of computing some quasi-maximal autarky.

If we can solve the non-trivial autarky problem “efficiently”, and \mathbb{C} is stable under formation of sub-clause-sets, then by iteration we can solve “efficiently” the quasi-maximal autarky problem. Obviously solving the quasi-maximal autarky problem implies solving the non-trivial autarky problem and the lean kernel problem, and solving the lean kernel problem implies solving the satisfiability problem and the autarky existence problem. Call \mathbb{C} *stable* if \mathbb{C} is stable under formation of sub-clause-sets and under crossing out variables (that is, if $F \in \mathbb{C}$, then for any set V of variables we have $V * F \in \mathbb{C}$); stability implies stability under application of partial assignments and under restrictions.¹⁶ Now the proof of Lemma 8.6 in [Kul03] yields an algorithm, which for stable classes allows to derive from an “efficient” solution of the autarky existence problem an “efficient” solution of the lean kernel problem; however, as already mentioned at the end of the introduction to Section 14.11, in order to solve also the non-trivial autarky problem further conditions on \mathcal{A} are needed.

Theorem 14.10.1 yields a method for computing maximal (general) autarkies for classes \mathbb{C} which are stable under restriction and for which we can solve the satisfiability problem and the unsatisfiability problem in a functional sense. It is not known whether Theorem 14.10.1 can be generalised to more general autarky systems. Regarding the full problems (unrestricted autarkies and unrestricted clause-sets), as already remarked in the introduction to Section 14.10, the autarky existence problem is NP-complete and the leanness problem is coNP-complete. Of course, the (full) satisfiability problem is NP-complete, the (full) unsatisfiability problem coNP-complete, and the full minimal unsatisfiability problem is D^P -complete. Finally, (full) barely leanness decision is D^P -complete ([KMT08]), while for the (full) indecomposability problem it is only known that it is in Π_2 (the second level of the polynomial hierarchy).

¹⁶Expressed in terms of clause-variable matrices, stability of \mathbb{C} corresponds to the property of a class of $\{-1, 0, +1\}$ -matrices to be stable under formation of submatrices (i.e., under elimination of rows and columns). So “stability” is (the in our opinion essential) half of the conditions on a *semicentral* class of clause-sets in the sense of [Tru98] (Section 5.2).

Considering the classes $\mathcal{CLS}(k) := \{F \in \mathcal{CLS} : d^*(F) = k\}$ (and still unrestricted autarkies; note that these classes are stable under sub-clause-formation), the satisfiability problem is not only polynomial-time solvable for fixed k (recall Section 14.2), but it is also fixed-parameter tractable in k ([Sze04]), and furthermore also finding a satisfying assignment resp. a tree resolution refutation is fixed-parameter tractable. On the other hand, the lean kernel problem is known to be decidable in polynomial time for fixed k (Theorem 4.2 in [Kul00a]), but it is not known whether this problem is also fixed-parameter tractable. Whether solving the non-trivial autarky problem is decidable in polynomial time is not known (only for $k = 1$ we know how to compute a quasi-maximal autarky, by first computing a quasi-maximal matching autarky, and then using that a matching-lean clause-set of deficiency 1 is minimally unsatisfiable iff it is unsatisfiable). The basic problem with the classes $\mathcal{CLS}(k)$ is that they are not stable under crossing out variables. Nothing is known here about the indecomposability problem.

Further complexity results regarding (the autarky system of) balanced autarkies (and unrestricted clause-sets) one finds in Subsection 14.12.2.

14.12. Connections to combinatorics

We need some good notions for some important properties of clause-sets in relation to standard notions from combinatorics: The *degree of a literal* l in a clause-set F is the number of clauses $C \in F$ with $l \in C$, while the *degree of a variable* v in a clause-set F is the sum of the degrees of the literals v and \bar{v} . Note that these degrees are the degrees of literals and variables in the *bipartite literal-clause graph* resp. the *bipartite variable-clause graph*, while the length of a clause is its degree in any of these two most basic graphs related to clause-sets. Regarding a whole clause-set, one needs to distinguish between *minimal literal-degree* and *maximal literal-degree* and between *minimal variable-degree* and *maximal variable-degree*. A clause-set F is called *literal-regular* if every literal in $\text{var}(F) \cup \text{var}(\bar{F})$ has the same (literal-)degree, while F is called *variable-regular* if every variable in $\text{var}(F)$ has the same (variable-)degree. Finally F is called *uniform* if all clauses of F have the same length.

A well-known field of activity relating SAT and combinatorics concerns the question how low the maximal variable-degree can be pushed in a k -uniform minimally unsatisfiable clause-set. These investigations started with [Tov84], with the most recent results in [HS05, HS06]. A related extremal problem is considered in [SZ08], where instead of the maximal variable-degree the number of edges in the *conflict graph* of a k -uniform minimally unsatisfiable clause-set is minimised, where the conflict graph of a clause-set F has the clauses of F as vertices, with an edge joining two vertices iff they have at least one conflict.¹⁷

Further differentiations are relevant here: Instead of considering arbitrary minimally unsatisfiable clause-sets, on the one hand we can restrict attention to hitting clause-sets (i.e., the conflict graph is a complete graph), and on the other hand we can require variable-regularity or, stronger, literal-regularity. Another

¹⁷Note that we take the notion of a “graph” in the strict sense, namely where an edge is a 2-subset of the vertex set, and thus loops or parallel edges are not possible.

regularity condition is *conflict-regularity*, where the conflict-multigraph (now allowing parallel edges) is required to be regular. First investigations regarding hitting clause-sets are found in [SS00, SST07], continued in [HK08]. Here we cannot go further into this interesting field, but we will only consider relations to combinatorics which are related to the notion of *deficiency*.

Especially for hitting clause-sets (and generalisations) the field concerning biclique partitioning (and the hermitian rank) is of interest, relating the notion of deficiency to eigenvalues of graphs and quadratic forms; for first explorations of the connections to SAT see [Kul04a, GK05] (further extended in [Kul07a, HK08]). Again due to space constraints we cannot go further in this direction, but we will restrict our attention to relations which directly concern autarkies.

14.12.1. Autarkies and qualitative matrix analysis

“Qualitative matrix analysis” (“QMA”; see [BS95] for a textbook) is concerned with matrices over the real numbers, where matrices A, B are considered equivalent if they have the same sign matrices, i.e., $\text{sgn}(A) = \text{sgn}(B)$ (these are $\{-1, 0, +1\}$ -matrices), and where questions from matrix analysis (starting with solvability of systems of linear equations) are considered “modulo” this equivalence relation.

As an example consider the notion of a non-singular (square) matrix A (over \mathbb{R}): A is non-singular iff $\det(A) \neq 0$, while A is *sign-non-singular* (short: an *SNS-matrix*) iff every matrix B with $\text{sgn}(B) = \text{sgn}(A)$ is non-singular (for example, $\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$ is an SNS-matrix, while $\begin{pmatrix} 1 & 2 \\ 1 & 1 \end{pmatrix}$ is not). We remark that from $\det(A) = \det(A^t)$ it follows that A is sign-non-singular iff its transposition A^t is sign-non-singular. In the subsequent Subsection 14.12.2 we will discuss the connections between SNS-matrices and SAT in more detail.

Motivated by [DD92], in [Kul03] the basic translations between SAT and QMA have been outlined; it seems justified to call QMA “SAT in disguise”, but with a rather different point of view. Recall from Subsections 14.11.3, 14.11.4, that linear autarkies resp. balanced linear autarkies of a clause-set F correspond to the solutions of $M(F) \cdot \vec{x} \geq 0$ resp. $M(F) \cdot \vec{x} = 0$. Taking these systems of (in)equalities only “qualitatively”, that is, the entries of $M(F)$ can be changed when only their signs are preserved, we arrive at exactly all autarkies resp. all balanced autarkies for F (restricted to $\text{var}(F)$). This is the basic connection between SAT and QMA; more precisely, the details are as follows.

The class of all real matrices B with $\text{sgn}(B) = \text{sgn}(A)$ is denoted by $\mathfrak{Q}(A)$ (the “qualitative class of A ”). Recall from Subsection 14.11.3 that linear autarkies φ for clause-sets F correspond to solutions of $M(F) \cdot \vec{x} \geq 0$, where $M(F)$ is the clause-variable matrix, via the association $\vec{x} \mapsto \varphi_{\vec{x}}$ for partial assignments with $\text{var}(\varphi_{\vec{x}}) \subseteq \text{var}(F)$ given by $\text{sgn}_{\varphi_{\vec{x}}}(l) = \text{sgn}(\vec{x}_{\text{var}(l)})$ for literals l over F (that is, $l \in \text{var}(F) \cup \overline{\text{var}(F)}$). By the same translation from real vectors to partial assignments, (arbitrary) autarkies of F correspond to the solutions of $A \cdot \vec{x} \geq 0$ for $A \in \mathfrak{Q}(M(F))$ (all together), while balanced autarkies of F correspond to the solutions of $A \cdot \vec{x} = 0$ for $A \in \mathfrak{Q}(M(F))$. Furthermore, satisfying (partial) assignments for F correspond to the solutions of $A \cdot \vec{x} > 0$ for $A \in \mathfrak{Q}(M(F))$.¹⁸

¹⁸Where “ $a > b$ ” for vectors a, b (of the same length) means that $a_i > b_i$ for all indices i .

Now the basic dictionary between SAT and QMA is as follows, where, corresponding to the convention in [BS95], clause-sets are represented by their variable-clause-matrix, the transposition of the clause-variable matrix (often characterisations in QMA are based on the characterisations of the above qualitative systems $A \cdot \vec{x} \geq 0$, $A \cdot \vec{x} = 0$ and $A \cdot \vec{x} > 0$ via Gordan's transposition theorem (and its variations)):

- Balanced lean clause-sets correspond to *L-matrices* (matrices A such that all $B \in \Omega(A)$ have linearly independent rows, that is, from $\vec{y}^t \cdot B = 0$ follows $\vec{y} = 0$).
- Lean clause-sets correspond to *L⁺-matrices* (matrices A such that for all $B \in \Omega(A)$ from $\vec{y}^t \cdot B \geq 0$ follows $\vec{y} = 0$).
- Unsatisfiable clause-sets correspond to *sign-central matrices* (matrices A such that for all $B \in \Omega(A)$ there is $\vec{x} \geq 0$, $\vec{x} \neq 0$ with $B \cdot x = 0$)¹⁹, while minimally unsatisfiable clause-sets correspond to *minimal sign-central matrices* (sign-central matrices, where elimination of any column destroys sign-centrality).
- Minimally unsatisfiable clause-sets of deficiency 1 (i.e., the elements of MU(1)) correspond to *S-matrices* (matrices A with exactly one column more than rows, which are *L-matrices*, stay *L-matrices* after elimination of any column, and where there exists $\vec{x} > 0$ with $A \cdot \vec{x} = 0$). The saturated elements of MU(1) correspond to *maximal S-matrices* (where changing any 0 to ± 1 renders the matrix a non-*S*-matrix).
- Thus SNS-matrices are exactly the square *L-matrices*. And, as already mentioned in Subsection 14.11.4, from every $F \in \text{MU}(1)$ we obtain an SNS-matrix by choosing $C \in F$ and considering the variable-clause matrix (or the clause-variable matrix) of $F \setminus \{C\}$.

For some more details on these correspondences see [Kul03]. The exploration of the connections between SAT and QMA has only been started yet, and interesting collaborations are to be expected in this direction.

14.12.2. Autarkies and the even cycle problem

Consider the following decision problems:

- Is a square hypergraph minimally non-2-colourable? (the “square critical hypergraph decision problem”)
- Is a square matrix an SNS-matrix? (the “SNS-matrix decision problem”)
- By multiplying some entries of a square matrix A by -1 , can one reduce the computation of the permanent of A to the computation of the determinant of A ? (“Polya's permanent problem”)
- Does a directed graph contain a directed cycle of even length? (the “even-cycle decision problem”)

All these problems are closely linked by direct translations (see [McC04] for a systematic account, containing many more equivalent problems²⁰). Whether any

¹⁹the equivalence to unsatisfiability follows directly from Gordan's transposition theorem

²⁰regarding the traditional combinatorial point of view, which unfortunately excludes SAT

(thus all) of these problems is solvable in polynomial time was a long-standing open problem, finally (positively) solved in [RST99, McC04]. Now by putting SAT in the centre, the equivalence of these problems becomes very instructive.

14.12.2.1. The equivalence of the basic problems

We already mentioned hypergraph colouring in Subsections 14.4.5 and 14.11.5, introducing the deficiency $d(G)$ of a hypergraph and the *reduced deficiency* $d_r(F)$ of a complement-invariant clause-set (as $d_r(F) := d(\mathfrak{V}(F))$, where $\mathfrak{V}(F)$ is the variable-hypergraph of F). So every minimally unsatisfiable complement-invariant clause-set F has $d_r(F) \geq 0$, and the square critical hypergraph decision problem is up to a different encoding the same as the problem of deciding whether a complement-invariant clause-set F with $d_r(F) = 0$ is minimally unsatisfiable, but where F is a “PN-clause-set”, that is, every clause is either positive or negative. Now the standard reduction of arbitrary clause-sets F to PN-clause-sets (introducing a new variable and a new binary clause for each “mixed” literal-occurrence), symmetrised by using the same variable for a clause C and its complement \bar{C} , translates complement-invariant clause-sets into complement-invariant PN-clause-sets while maintaining the reduced deficiency, and thus we see that by this simple transformation the square critical hypergraph decision problem is the same problem as to decide whether an (arbitrary) complement-invariant clause-sets of reduced deficiency 0 is minimally unsatisfiable.

By the results of Subsection 14.12.1, the SNS-matrix decision problem is (nearly) the same problem as to decide whether a clause-set F with $d(F) = 0$ is balanced lean²¹, which is the same problem as to decide whether a complement-invariant clause-set F with $d_r(F) = 0$ is lean. So we need to find out for complement-invariant clause-set F with $d_r(F) = 0$, what the precise relationship is between the problem of deciding leanness and deciding minimal unsatisfiability. Since a clause-set F is minimally balanced unsatisfiable iff $F \cup \bar{F}$ is minimally unsatisfiable, this is the same as the relationship between the problem of deciding balanced leanness and deciding minimal balanced unsatisfiability for clause-sets F_0 with $d(F_0) = 0$,

For clause-sets F with deficiency $d(F) = 1$, minimal unsatisfiability is equivalent to (that is, is implied by) being lean. Analogously one could expect for complement-invariant clause-sets F with $d_r(F) = 0$, that leanness implies minimal unsatisfiability, or equivalently, that balanced leanness for F_0 with $d(F_0) = 0$ implies minimal balanced unsatisfiability — however this is not the case, as the trivial examples $F = \{\{a\}, \{\bar{a}\}, \{b\}, \{\bar{b}\}\}$ resp. $F_0 = \{\{a\}, \{b\}\}$ shows (the reason is roughly that $1+1 = 2$ while $0+0 = 0$, and so a balanced lean F_0 with deficiency zero can contain a non-empty balanced lean strict sub-clause-set with deficiency zero). The first key here is Theorem 14.11.1, which yields that a clause-set F_0 is minimally balanced unsatisfiable iff F is barely balanced lean and balanced indecomposable. The second key is that for balanced lean F_0 with $d(F_0) = 0$ the autarky decompositions (F_1, F_2) w.r.t. balanced autarkies are exactly the \mathcal{A}_0 -autarky decompositions (F_1, F_2) with $d(F_1) = d(F_2) = 0$ of F_0 w.r.t. the smallest normal autarky system \mathcal{A}_0 (note that every clause-set is \mathcal{A}_0 -lean; see Theorem

²¹there are trivial differences due to clause-sets not having multiple clause-occurrences

13, Part 3 in [Kul07b]). Now these \mathcal{A}_0 -decompositions are the decompositions associated to the notion of a “partly decomposable matrix” (see Theorem 13, Part 4 in [Kul07b], and Subsection 4.2 in [BR91]), and thus can be found in polynomial time. So we can conclude now: Given on the one hand an algorithm for deciding whether F_0 with $d(F_0) = 0$ is balanced lean, to decide whether F_0 with $d(F_0) = 0$ is minimally balanced unsatisfiable, we first check whether F_0 is balanced lean, and if this is the case then we check whether $M(F_0)$ is not partly decomposable (that is, whether $M(F_0)$ is “fully indecomposable”) — F_0 is minimally balanced unsatisfiable iff both tests are passed. On the other hand, assume now that an algorithm is given for deciding whether F_0 with $d(F_0) = 0$ is minimally balanced unsatisfiable. Here one needs to add the observation that if (F_1, F_2) is an \mathcal{A}_0 -autarky decomposition of F , then F is \mathcal{A} -lean iff both F_1, F_2 are \mathcal{A} -lean (for any normal autarky system \mathcal{A}). So for given F_0 first we check whether F_0 is minimally balanced unsatisfiable — if this is the case then F_0 is balanced lean. Otherwise we search for an \mathcal{A}_0 -decomposition (A_1, A_2) with $d(A_1) = d(A_2) = 0$ — if no such decomposition exists then F_0 is not balanced lean while otherwise F_0 is balanced lean iff both F_1, F_2 are balanced lean (applying the whole procedure recursively).

Considering the determinant computation via the Leibniz expansion, it is quite straightforward to show that a square matrix A is an SNS-matrix iff $\det(A) \neq 0$ and $\text{per}(|A|) = |\det(A)|$ holds, where $|A|$ is obtained from A by taking absolute values entrywise, and $\text{per}(A) = \sum_{\pi \in S_n} \prod_{i=1}^n A_{i,\pi(i)}$. This establishes the basic connection to Polya’s permanent problem. We remark that for a clause-set F with $d(F) = 0$ the number of matching satisfying assignments for F is $\text{per}(|M(F)|)$. Finally, by considering the decomposition of permutations into cycles, it is also straightforward to show that a reflexive digraph G (every vertex has a loop) has no even (directed) cycle iff its adjacency matrix (a square $\{0, 1\}$ -matrix, with all entries on the main diagonal equal to 1 due to reflexivity of G) is an SNS-matrix.²²

14.12.2.2. Generalisations and strengthenings

Let us now recapitulate the poly-time decision results in the light of the general algorithmic problems from Subsection 14.11.6. We introduced already the convention that for a class $\mathcal{C} \subseteq \mathcal{CLS}$ of clause-sets, $\mathcal{C}(k)$ is the class of $F \in \mathcal{C}$ with $d^*(F) = k$ (note that for $F \in \text{MU}$ we have $d^*(F) = d(F)$). In general, for some function $f : \mathcal{C} \rightarrow \mathbb{R}$ we write $\mathcal{C}_{f=k} := \{F \in \mathcal{C} : f(F) = k\}$, and similarly $\mathcal{C}_{f \leq k}$ and so on; so $\text{MU}(k) = \text{MU}_{d=k}$. The class of complement-invariant clause-sets is denoted by $\text{CI} := \{F \in \mathcal{CLS} : F = \overline{F}\}$, while the autarky system of balanced autarkies is denoted by the prefix “B”.

Let us denote by $\text{MUCI} := \text{MU}(\text{CI})$ the class of all complement-invariant minimally unsatisfiable clause-sets F , and so by $\text{MUCI}_{d_r=k}$ for $k \in \mathbb{N}_0$ the subclass of clause-sets of reduced deficiency k is denoted. We know

$$\text{MUCI} = \bigcup_{k \in \mathbb{N}_0} \text{MUCI}_{d_r=k},$$

²²If we have given an arbitrary $\{0, 1\}$ -matrix A (possibly with zeros on the diagonal), and we want to reduce the SNS-decision problem for A to the even-cycle problem, then we use that if $\det(A) \neq 0$ then by row-permutation of A we can transform A into a matrix with 1-constant main diagonal (while this transformation does not alter the SNS-property).

where $\text{MUCI}_{d_r=0}$ is decidable in polynomial time (as discussed in Subsection 14.12.2.1). Furthermore we denote by $\text{BMU} := \text{B-MU}$ the class of minimally balanced unsatisfiable clause-sets F , and thus by $\text{BMU}(k)$ for $k \in \mathbb{N}_0$ the subclass given by $d(F) = k$ is denoted. So

$$\text{BMU} = \bigcup_{k \in \mathbb{N}_0} \text{BMU}(k),$$

where $\text{BMU}(0)$ is decidable in polynomial time (again, as discussed in Subsection 14.12.2.1). Note that BMU can be phrased as the class of “minimally not-all-equal-unsatisfiable clause-sets”. And note that, as with $\text{MU}(k)$, for $F \in \text{BMU}$ we have $d^*(F) = d(F)$. Analogously to the $\text{MU}(k)$ -hierarchy, the following conjecture seems natural:

Conjecture 14.12.1. The MINIMAL UNSATISFIABILITY PROBLEM for classes of complement-invariant clause-sets with bounded reduced deficiency is solvable in polynomial time. That is, for every $k \in \mathbb{N}_0$ the class $\text{MUCI}_{d_r=k}$ is decidable in polynomial time. Equivalently, all $\text{BMU}(k)$ for $k \in \mathbb{N}_0$ are decidable in polynomial time. Another equivalent formulation is that for all fixed $k \in \mathbb{N}_0$ the problem whether a hypergraph with deficiency k is minimally non-2-colourable is decidable in polynomial time.

Similarly we define $\text{LEANCI} := \text{LEAN}(\text{CI})$ as the class of complement-invariant lean clause-sets, while $\text{BLEAN} := \text{B-LEAN}$ denotes the class of balanced lean clause-sets (recall that for $F \in \text{BLEAN}$ we have $d^*(F) = d(F)$). So $\text{LEANCI} = \bigcup_{k \in \mathbb{N}_0} \text{LEANCI}_{d_r=k}$ and $\text{BLEAN} = \bigcup_{k \in \mathbb{N}_0} \text{BLEAN}(k)$. As discussed in Subsection 14.12.2.1, for $k = 0$ in both cases we have poly-time decision.

Conjecture 14.12.2. The AUTARKY EXISTENCE PROBLEM for classes of complement-invariant clause-sets with bounded reduced deficiency is solvable in polynomial time. That is, for every $k \in \mathbb{N}_0$ the class $\text{LEANCI}_{d_r=k}$ is decidable in polynomial time. Equivalently, all $\text{BLEAN}(k)$ for $k \in \mathbb{N}_0$ are decidable in polynomial time. Another equivalent formulation is that for all fixed $k \in \mathbb{N}_0$ the problem whether a matrix over $\{-1, 0, +1\}$ (or, equivalently, over $\{0, 1\}$) with exactly k more columns than rows is an L -matrix.

It needs to be investigated whether the reductions from Subsection 14.12.2.1 can be generalised, so that we obtain analogously the equivalence of Conjecture 14.12.2 to Conjecture 14.12.1. Finally we note that for $\text{MU}(k)$ we actually have fixed-parameter tractability, and so we also conjecture the strengthening:

Conjecture 14.12.3. The decision problems in Conjecture 14.12.1 are not just poly-time decidable for each (fixed) $k \in \mathbb{N}_0$, but they are also fixed-parameter tractable in this parameter, i.e., there exists a time bound $f(\ell, k)$ for decision of MUCI depending on k and the number ℓ of literal occurrences in the input, which is of the form $f(\ell, k) = \alpha(k) \cdot \ell^\beta$ for some function α and some constant β .

The analogous problem to Conjecture 14.12.2, namely to decide $\text{LEAN}(k)$, is not known to be fixed-parameter tractable, and so we refrain from conjecturing that also for the problems in Conjecture 14.12.2 we have fixed-parameter tractability.

14.12.2.3. Solving SAT problems by autarky reduction

While in the previous Subsection 14.12.2.2 we considered the basic decision problems as outlined in Subsection 14.11.6, we now turn to the functional problems as discussed there. Recall that for the classes $\mathcal{CLS}(k)$ we do not just have minimally unsatisfiability decision, but stronger satisfiability decision in polynomial time (even fixed-parameter tractability), and furthermore we can solve the lean-kernel problem in polynomial time (but currently it is not known whether the non-trivial autarky problem, or, here equivalent, the quasi-maximal autarky problem, can be solved in polynomial time). Different from the approaches used for $\mathcal{CLS}(k)$, which were satisfiability- or unsatisfiability-based, here now our approach is autarky-based, fundamentally relying on the following “self-reducibility conjecture”.

Conjecture 14.12.4. Given a square non-SNS matrix A over $\{-1, 0, +1\}$, one can find in polynomial time a “witness” matrix $B \in \mathfrak{Q}(A)$ over \mathbb{Z} (with the same sign pattern as A) which is singular.

There are two avenues for proving Conjecture 14.12.4: “constructivising” the proofs in [RST99, McC04], or refining the method from [KMT08] for finding an autarky when only given a decision procedure for leanness (the problem here is, similar to the classes $\mathcal{CLS}(k)$, that we do not have stability under crossing out variables nor under addition of unit-clauses). A witness according to Conjecture 14.12.4 yields a non-trivial balanced autarky for the clause-set corresponding to A . In order to make use of this, analogously to d^* we need to introduce the *maximal reduced deficiency* $d_r^*(F)$ for a complement-invariant clause-set F , defined as the maximum of $d_r(F')$ for complement-invariant $F' \subseteq F$; by definition we have $d_r^*(F) \geq 0$. Now [Kul07b] shows the following, using $\text{SATCI} := \text{SAT}(\text{CI})$ for the satisfiable complement-invariant clause-sets and $\text{BSAT} := \text{B-SAT}$ for the balanced satisfiable clause-sets (i.e., not-all-equal satisfiable clause-sets).

Theorem 14.12.1. *Given Conjecture 14.12.4, we obtain poly-time decision of $\text{SATCI}_{d_r^*=0}$, that is, SAT decision for complement-invariant clause-sets with maximal reduced deficiency 0. Equivalently, we obtain poly-time decision of $\text{BSAT}(0)$, that is, NAESAT decision in poly-time for clause-sets F with $d^*(F) = 0$.*

Stronger, we can compute a quasi-maximal autarky for complement-invariant clause-sets F with $d_r^(F) = 0$. And, equivalently, we can compute a quasi-maximal balanced autarky for clause-sets F with $d^*(F) = 0$.*

Given the positive solution of Polya’s problem, Theorem 14.12.1 (that is, the possibility of computing a quasi-maximal autarky) actually is equivalent to Conjecture 14.12.4. The natural generalisation of Conjecture 14.12.4 thus is as follows.

Conjecture 14.12.5. The QUASI-MAXIMAL AUTARKY PROBLEM for classes of complement-invariant clause-sets with bounded maximal reduced deficiency is solvable in polynomial time, that is, for every $k \in \mathbb{N}_0$ there exists a poly-time procedure for computing for complement-invariant clause-sets F with $d_r^*(F) = k$ a quasi-maximal autarky. Equivalently, quasi-maximal balanced autarkies can be computed in poly-time for $d^*(F) = k$. Or, equivalently, there exists a polynomial-time procedure for deciding whether a matrix A over $\{-1, 0, +1\}$ with (exactly)

k more columns than rows is an L -matrix, and computing in the negative case a singular matrix $B \in \mathfrak{Q}(A)$ over \mathbb{Z} .

As discussed in general in Subsection 14.11.6, on the one hand Conjecture 14.12.5 implies poly-time decision for all $\text{SATCI}_{d_r^*=k}$, and, equivalently, poly-time decision of all $\text{BSAT}(k)$ (that is, NAESAT decision for clause-sets with maximal deficiency k), and thus implies Conjecture 14.12.1. And on the other hand Conjecture 14.12.5 implies also Conjecture 14.12.2.

Finally we remark that by the process of “PN-separation”, as discussed at the beginning of Subsection 14.12.2.1, every complement-invariant clause-set F can be transformed into a complement-invariant PN-clause-set F' (i.e., a hypergraph 2-colouring problem) such that F' is equivalent to F w.r.t. the properties of being satisfiable, minimally unsatisfiable and lean, and where $d_r(F') = d_r(F)$ and $d_r^*(F') = d_r^*(F)$. Actually it is easier to perform this transformation on one “core half” of F , a clause-set F_0 with $F = F_0 \cup \overline{F_0}$: then the properties being preserved by $F_0 \rightsquigarrow F'_0$ are balanced satisfiability, minimal balanced unsatisfiability and balanced leanness, and we have $d_r(F'_0) = d_r(F_0)$ and $d_r^*(F'_0) = d_r^*(F_0)$. Thus the various problems discussed in this subsection can be phrased as hypergraph-2-colouring problems, and the matrices occurring can be restricted to $\{0, 1\}$ -matrices.

14.13. Generalisations and extensions of autarkies

In Subsection 14.8.4 we have already commented on the (slight) generalisation given by the notion of a “weak autarky” (compared to (ordinary) autarkies). In this final section we will discuss more substantial generalisations, either concerning the autarky notion itself (in Subsections 14.13.1, 14.13.2), or concerning more general frameworks (in Subsections 14.13.3, 14.13.4).

14.13.1. Safe partial assignments

The most general case of “safe assignments” are *satisfiability-preserving partial assignments* φ , i.e., where $\varphi * F$ is satisfiability equivalent to F . This poses very mild restrictions on φ : if F is unsatisfiable, then every φ is satisfiability-preserving, while φ is satisfiability-preserving for satisfiable F iff there exists a satisfying (total) assignment extending φ . If φ is satisfiability-preserving for F , then also every $\varphi' \subseteq \varphi$ is satisfiability-preserving for F , and for satisfiable F the satisfiability-preserving partial assignments are exactly the $\varphi' \subseteq \varphi$ for the total satisfying assignments φ .

A satisfiability-preserving partial assignment amounts to specifying certain additional constraints which do not destroy satisfiability. The analogous notion of a *satisfiability-preserving clause* for a clause-set F is a clause C such that $F \cup \{C\}$ is satisfiability-equivalent to F . Examples for satisfiability-preserving clauses for F are clauses which follow logically from F . If C is satisfiability-preserving for F , then also every super-clause of C is satisfiability-preserving for F . Any C is a satisfiability-preserving clause for any unsatisfiable F , while C is satisfiability-preserving for a satisfiable F if and only if there exists $x \in C$ such that $\langle x \rightarrow 1 \rangle$

is satisfiability-preserving for F . So for a literal x the clause $\{x\}$ is satisfiability-preserving for F iff the partial assignment $\langle x \rightarrow 1 \rangle$ is satisfiability-preserving for F , and satisfiability-preservation of clauses in general weakens these cases, while satisfiability-preservation of partial assignments strengthens them.

Lemma 14.13.1. *Consider a clause-set F and compatible partial assignments φ, ψ such that φ is satisfiability-preserving for $\psi * F$. Then for every literal $x \in C_\varphi^1$ the clause $C_\psi^0 \cup \{x\}$ is satisfiability-preserving for F .*

Proof. If $\psi * F$ is unsatisfiable, then C_ψ^0 follows from F , and thus C_ψ^0 is satisfiability-preserving for F . If $\psi * F$ is satisfiable, then also $(\varphi \circ \psi) * F$ is satisfiable, thus $\varphi \circ \psi = \psi \circ \varphi$ is satisfiability-preserving for F , and so is $\langle x \rightarrow 1 \rangle$. \square

The composition of satisfiability-preserving partial assignments in general is not again satisfiability-preserving. The notion of a *safe partial assignment* provides a restriction having this property, where φ is safe for a clause-set F if for every partial assignment ψ with $\psi * F = \top$ we have $\psi * (\varphi * F) = \top$ as well (i.e., if ψ is a satisfying assignment, then so is $\psi \circ \varphi$). Every weak autarky is safe, for unsatisfiable clause-sets again every partial assignment is safe, and more generally every enforced partial assignment φ (i.e., every satisfying total assignment for F is an extension of φ) is safe. Every safe partial assignment is satisfiability-preserving. The safe partial assignments for F yield a monoid (with $\text{Auk}(F)$ as sub-monoid), as is easily checked (using just the fundamental properties of the operation of \mathcal{PASS} on \mathcal{CLS}).

14.13.2. Look-ahead autarky clauses, and blocked clauses

Recall the notion of a weak k -autarky φ for F from Subsection 14.10.5, defined by the condition that for the set $N(\varphi, F) := (\varphi * F) \setminus F$ of new clauses created by the application of φ to F we have $|N(\varphi, F)| \leq k$. For any partial assignment ψ with $\psi * N = \top$ and $\text{var}(\psi) \subseteq \text{var}(N)$ and for every $x' \in C_\varphi^1$ then by Lemma 14.13.1 the *look-ahead autarky clause* $C_\psi^0 \cup \{x'\}$ is satisfiability-preserving for F . In the special case of $\varphi = \varphi_x$, as discussed in Subsection 14.10.5, the choice $x' = x$ is appropriate. For a look-ahead autarky clause we actually can allow a slightly more general case, just given arbitrary partial assignments ψ, φ with $\text{var}(\varphi) \cap \text{var}(\psi) = \emptyset$ such that φ is a weak autarky for $\psi * F$: In this case ψ must satisfy all clauses of $N(\varphi, F)$ except of those which after application of ψ are already contained in $\psi * F$.

Recall the notion of a *blocked clause* for clause-set F w.r.t. $x \in C$ (introduced in [Kul99b], and further studied in [Kul99c]), that is, for every clause D in F with $\bar{x} \in D$ there is $y_D \in C \setminus \{x\}$ with $\overline{y_D} \in D$. Let $C_0 := C \setminus \{x\}$, and consider the partial assignment $\varphi_{C_0} := \langle y \rightarrow 0 : y \in C_0 \rangle$. Now the blocking-condition is equivalent to the literal x being pure for $\varphi_{C_0} * F$, and thus C is a look-ahead autarky clause for F . So look-ahead autarky clauses generalise blocked clauses, where for the latter it is shown in [Kul99c] that their addition to clause-sets cannot be simulated by (full) resolution (even if we only use C without new variables).

Thus addition of look-ahead autarky clauses by a SAT solver could be an interesting feature; though one would expect that the full power of extended

resolution is only unleashed by allowing blocked clauses with new variables, nevertheless the special case of look-ahead autarky clauses considered above, given by some partial assignment φ_x we naturally have “at hand” in a SAT solver, could become interesting in the future. In the `OKsolver-2002` the special case of a weak 1-autarky has been implemented as an experimental feature: if $C = \{a_1, \dots, a_k\}$ ($k \geq 2$) is the (single) new clause, then for $1 \leq i \leq k$ the k binary clauses $\{\overline{a_i}, x\}$ can be added.

Finally we should remark that addition of look-ahead autarky clauses is a form of “local learning”, that is, the added clauses are valid only at the current (“residual”) node in the backtracking tree, and need to be removed when backtracking.

14.13.3. Beyond clause-sets

Autarkies for generalised clause-sets, using non-boolean variables v and literals “ $v \neq \varepsilon$ ” for (single) values ε in the domain of v , are studied in [Kul07a], and some first applications to hypergraph colouring one finds in [Kul06]. As we have seen in Section 14.12.2, the hypergraph 2-colouring problem is captured by considering complement-invariant clause-sets, which can be reduced to their core halves, that is, to the underlying hypergraphs, by considering balanced autarkies. Now for k -colouring, variables with uniform domain $\mathbb{Z}_k = \{0, \dots, k-1\}$ are considered, and *weak hypergraph-colouring* (no hyperedge is monochromatic) is captured by *weakly-balanced autarkies*, which are autarkies where every touched clause contains at least two different assigned values, while *strong hypergraph-colouring* (every hyperedge contains all colours) is captured by *strongly-balanced autarkies*, autarkies where every touched clause contains all possible k assigned values.

Another route of generalisation is to consider boolean functions (in some representation, for example BDD’s as in [FKS⁺04]) instead of clauses, and, more generally, arbitrary sets of constraints. Just replacing “clause” by “constraint” in the basic condition “every touched clause is satisfied”, and allowing partial assignments for constraints (satisfying the constraint iff all total extensions satisfy it), we obtain a straight-forward generalisation.

Regarding QBF, a powerful framework is here to consider QCNF-problems as satisfiability problems, that is the universal variables are “eliminated” while we seek substitutions for the existential variables by boolean functions in the preceding universal variables such that a tautology is created (that is, every clause becomes a tautology). Now an autarky in this setting is a partial substitution of existential variables by boolean functions (depending on the universal variables on which the existential variable depends) such that the substitution either does not touch a clause or makes it a tautology. The simplest case is to consider only constant functions, that is we search for standard CNF-autarkies of the matrix where all universal variables are crossed out.

14.13.4. An axiomatic theory

A first approach towards an “axiomatic theory”, extending [Kul04b], is given in [Kul01], (in principle) comprising all extensions mentioned in Subsections 14.13.1

and 14.13.3. The basic idea is to consider the operation $*$ of a monoid (\mathcal{I}, \circ, e) of “instantiators” (like partial assignments) on a lower semilattice $(\mathcal{P}, \wedge, \top)$ of “problem instances” (like clause-sets with union). We obtain the induced partial order $P_1 \leq P_2$ for problem instances given by $P_1 \leq P_2 :\Leftrightarrow P_1 \wedge P_2 = P_1$. Now *weak autarkies* for problem instances $P \in \mathcal{P}$ are instantiators $\varphi \in \mathcal{I}$ with $\varphi * P \leq P$, while *autarkies* fulfil the condition $\varphi * P' \leq P'$ for all $P' \leq P$. Given the multitude of notions of autarkies, such a general theory should become indispensable at some time in the future.

14.14. Conclusion

An important structural parameter for satisfiability problems about clause-sets (CNF-formulas) and QBF-formulas is the (maximal) deficiency. Various hierarchies based on the notion of (maximal) deficiency emerged, with some poly-time results established, and most open:

1. For deciding minimally unsatisfiability see Section 14.2, while more generally in Subsection 14.11.6 satisfiability decision (and more) is discussed, and a general framework is given (with still open problems in this context).
2. Deciding the tautology/falsity property for quantified boolean formulas is discussed in Section 14.6.
3. “Not-all-equal satisfiability” (with the normal deficiency), or, equivalently, complement-invariant clause-sets with the reduced deficiency, is considered in Section 14.12.2 (see especially Subsection 14.12.2.3 for open problems and conjectures).

Chapter 15

Proofs of Unsatisfiability

Marijn J.H. Heule

15.1. Introduction

Satisfiability (SAT) solvers have become powerful tools to solve a broad spectrum of applications. Since the SAT problem is NP-complete, it is easy to validate a satisfiability claim using a certificate in the form of a variable assignment. However, if a solver reports that a formula has *no* solutions, the validation of that claim requires a proof of unsatisfiability. The correctness of SAT solving results is important for applications ranging from hardware verification to proving mathematical theorems. Proof checking is significantly less complex compared to the implementations of state-of-the-art SAT solvers, allowing efficient validation even by formally verified checkers [CFHH⁺17, Lam20]. Proofs of unsatisfiability are useful in several applications, including interpolation [VRN13], extraction of minimal unsatisfiable sets (MUSes) [Nad10], and several areas that rely on SAT solvers, such as theorem proving [AFG⁺11, Web06, WA09, WHH13]. This chapter covers the practical aspects of proofs of unsatisfiability, while Chapter 7 on proof complexity discusses the theoretical aspects in more detail.

Many proof formats have been proposed [ZM03, ES03, Bie08, Van08, WHH14, CFHH⁺17, Lam20, HKB19], and even though they might seem very different, they actually have a lot in common. Essentially all well-known proofs of unsatisfiability are so-called *clausal proofs*: sequences of clauses that are claimed to be redundant with respect to a given formula, where *redundant* means that the addition of a clause preserves the satisfiability status of the formula. The valid addition of the (trivially unsatisfiable) empty clause, usually in the final proof step, shows that the formula is unsatisfiable. In addition, the validity of each step should be efficiently checkable. The main difference between existing proof formats is whether so-called *hints* are included. A hint is information that a checker can use to validate the correctness of a clause-addition step more efficiently. Another difference is whether or not the formula is included in a proof.

The generation of unsatisfiability proofs in practical SAT solving dates back to 2003, when Zhang and Malik integrated logging of resolution steps with hints in the SAT solver **zChaff** [ZM03], while Goldberg and Novikov enhanced the solver **Berkmin** [GN03] with logging of proofs without hints. For clausal proofs based on

the resolution proof system, the hints refer to the antecedents of the resolution rule. Without the antecedents, a checker needs to search for clauses that can be resolved together to justify a clause addition step. Although the antecedents can be determined in polynomial time, this can be expensive in practice. On the other hand, including hints in proofs can make them much larger and render the proof production more complicated and expensive.

In recent years, clausal proofs have also been used to validate results of strong proof systems that go beyond resolution. An example of such a proof system is extended resolution [Tse83], which allows the addition of definitions to a formula. Such definitions consist of multiple clauses. In a clausal proof, these clauses are listed in an arbitrary order and validity is checked per clause. Some strong proof systems allow the addition of clauses for which checking the validity is NP-complete [HKB19] if no hint—usually called *witness* in that context—is provided. As a consequence, witnesses are mandatory whereas hints are not.

Whether or not to include hints in proofs typically depends on the usage of the proofs. For various applications that require resolution proofs, such as interpolation [McM03] or MUS extraction [NRS13], it is common to produce proofs with hints. Proofs without hints are more popular in the context of validating SAT solving results. For example, to check the results of the SAT Competitions or the proofs of mathematical theorems, such as the Erdős Discrepancy Theorem [KL14], the Pythagorean Triples Problem [HKM16], and Keller’s Conjecture [BHMN20]. There are exceptions: proofs without hints have also been studied for interpolation [GV14] and MUS extraction [BHMS14].

Support for proof logging started to become widespread in state-of-the-art solvers such as *Lingeling* [Bie13], *Glucose* [AS13], and *CryptoMiniSAT* [Soo13], in 2013, when the SAT Competition made unsatisfiability proofs mandatory for solvers participating in the unsatisfiability tracks. Practically all sequential solvers that participated in recent SAT Competitions, including the strongest solvers around (such as the three solvers mentioned above) emit proofs *without* hints, and only very few solvers support emitting proofs *with* hints.

The lack of support for proofs with hints is due to the overhead (both in CPU and memory) and the difficulty to represent some techniques used in contemporary SAT solvers in terms of resolution. One such technique is conflict clause minimization [SB09], which requires additional bookkeeping to produce a resolution proof [Van09]. Computing the resolution steps increases the runtime on both satisfiable and unsatisfiable formulas. In contrast, emitting a proof without hints incurs only a negligible overhead and requires just modest modifications for most solvers.¹ Proof validation is only required if the solver claims unsatisfiability.

Support for proof logging has become mainstream in recent years and it is now common practice to produce and validate a proof when using SAT technology to solve hard problems, such as the mathematical problems we mentioned earlier. The development of formally-verified proof checkers further increases the confidence in the correctness of results. The high level of trust in the results is important as SAT solvers are increasingly often used to check the correctness of hardware and software, and such claims should not be based on bugs.

¹A patch to add logging of proofs without hints to *MiniSAT* and *Glucose* is available at <https://github.com/marijnheule/drup-patch>.

15.2. Proof Systems

A proof of unsatisfiability is a sequence of clauses that are *redundant* with respect to a given formula. The most general notion of redundancy is satisfiability preservation, which requires that the addition of a clause to a formula does not affect satisfiability. Under this notion of redundancy, every clause is trivially redundant with respect to every unsatisfiable formula. However, unless $P = NP$, there exists no polynomial-time algorithm that can check the validity of clause-addition steps under this general notion of redundancy. Because of this, several proof systems have been invented that rely on simpler syntactic criteria that guarantee redundancy while still being efficiently checkable. In this section, we discuss several such proof systems that allow the addition of clauses that are learned by practical SAT solvers or generated by typical preprocessing and inprocessing techniques.

15.2.1. Preliminaries and Notation

We consider propositional formulas in *conjunctive normal form* (CNF), which are defined as follows. A *literal* is either a variable x (a *positive literal*) or the negation \bar{x} of a variable x (a *negative literal*). The *complement* \bar{l} of a literal l is defined as $\bar{l} = \bar{x}$ if $l = x$ and $\bar{l} = x$ if $l = \bar{x}$. For a literal l , we denote the variable of l by $\text{var}(l)$. A *clause* is a finite disjunction of the form $(l_1 \vee \cdots \vee l_k)$, where l_1, \dots, l_k are literals. If not stated otherwise, we assume that clauses do not contain *complementary literals*, i.e., a literal and its complement. A *formula* is a finite conjunction $C_1 \wedge \cdots \wedge C_n$, where C_1, \dots, C_n are clauses. Clauses can be viewed as sets of literals and formulas as sets of clauses.

An *assignment* is a function from a set of variables to the truth values 1 (*true*) and 0 (*false*). An assignment is *total* with respect to a formula if it assigns a truth value to all variables occurring in the formula, otherwise it is *partial*. We often denote assignments by the sequences of literals they satisfy. For instance, $x\bar{y}$ denotes the assignment that makes x true and y false. We denote the domain of an assignment α by $\text{var}(\alpha)$. A literal l is *satisfied* by an assignment α if l is positive and $\alpha(\text{var}(l)) = 1$ or if it is negative and $\alpha(\text{var}(l)) = 0$. A literal is *falsified* by an assignment if its complement is satisfied by the assignment. A clause is satisfied by an assignment α if it contains a literal that is satisfied by α . Finally, a formula is satisfied by an assignment α if all its clauses are satisfied by α . A formula is *satisfiable* if there exists an assignment that satisfies it, and *unsatisfiable* otherwise.

We denote the empty clause by \perp and the satisfied clause by \top . Given an assignment α and a clause C , we define $C|_\alpha = \top$ if α satisfies C , otherwise $C|_\alpha$ denotes the result of removing from C all the literals falsified by α . Moreover, for a formula F , we define $F|_\alpha = \{C|_\alpha \mid C \in F \text{ and } C|_\alpha \neq \top\}$. We say that a clause C *blocks* an assignment α if $C = \{x \mid \alpha(x) = 0\} \cup \{\bar{x} \mid \alpha(x) = 1\}$.

A *unit clause* is a clause that contains only one literal. The result of applying the *unit-clause rule* to a formula F is the formula $F|_\alpha$ with α being an assignment that satisfies a unit clause in F . The iterated application of the unit-clause rule to a formula, until no unit clauses are left, is called *unit propagation*. If unit propagation on a formula F yields the empty clause \perp , we say that it derived a

conflict on F . For example, unit propagation derives a conflict on $F = (\bar{x} \vee y) \wedge (\bar{y}) \wedge (x)$ since $F|x = (y) \wedge (\bar{y})$ and $F|xy = \perp$.

Two formulas are *logically equivalent* if they are satisfied by the same total assignments. Two formulas F and F' are *equisatisfiable* if both F and F' are satisfiable or if both F and F' are unsatisfiable. By $F \models F'$, we denote that F implies F' , i.e., every assignment that satisfies F and assigns all variables in $\text{var}(F')$ also satisfies F' . Furthermore, by $F \vdash F'$ we denote that for every clause $(l_1 \vee \dots \vee l_k) \in F'$, unit propagation derives a conflict on $F \wedge (\bar{l}_1) \wedge \dots \wedge (\bar{l}_k)$. If $F \vdash F'$, we say that F *implies F' via unit propagation*. As an example, $(x) \wedge (y) \vdash (x \vee z) \wedge (y)$, since unit propagation derives a conflict on both $(x) \wedge (y) \wedge (\bar{x}) \wedge (\bar{z})$ and $(x) \wedge (y) \wedge (\bar{y})$.

Throughout this chapter we will use the following formula E as an example to explain various concepts:

$$E := (\bar{b} \vee c) \wedge (a \vee c) \wedge (\bar{a} \vee b) \wedge (\bar{a} \vee \bar{b}) \wedge (a \vee \bar{b}) \wedge (b \vee \bar{c})$$

15.2.2. Resolution

The resolution rule [Rob65] states that, given two clauses $C_1 = (x \vee a_1 \vee \dots \vee a_n)$ and $C_2 = (\bar{x} \vee b_1 \vee \dots \vee b_m)$ with a complementary pair of literals (in this case x and \bar{x}), the clause $C = (a_1 \vee \dots \vee a_n \vee b_1 \vee \dots \vee b_m)$ can be inferred by resolving on variable x . We say C is the *resolvent* of C_1 and C_2 and write $C = C_1 \diamond C_2$. C_1 and C_2 are called the *antecedents* of C . C is logically implied by any formula containing C_1 and C_2 . The resolution proof system (RES) infers new clauses using the resolution rule. Chapter 7 covers the resolution proof system in more detail.

A *resolution chain* is a sequence of resolution operations such that the result of each operation is an antecedent of the next operation. Resolution chains are computed from left to right. Notice that the resolution operation is not associative. For example, we have $((a \vee c) \diamond (\bar{a} \vee b)) \diamond (\bar{a} \vee \bar{b}) = (\bar{a} \vee c)$, while $(a \vee c) \diamond ((\bar{a} \vee b) \diamond (\bar{a} \vee \bar{b})) = (c)$.

Let $C := (l_1 \vee l_2 \vee \dots \vee l_k)$ be a clause. We denote by \bar{C} the conjunction $(\bar{l}_1) \wedge (\bar{l}_2) \wedge \dots \wedge (\bar{l}_k)$ of unit clauses. C is called a *reverse unit propagation* (RUP) clause with respect to F , if F implies C via unit propagation [Van08]. Remember that F implies C via unit propagation, denoted by $F \vdash C$, if unit propagation derives a conflict on $F \wedge \bar{C}$. The prototypical RUP clauses are the learned clauses in conflict-driven-clause-learning (CDCL) solvers, which are the most common solvers (see Chapter 4 and Sect. 15.3). The conventional procedure for showing that these learned clauses are implied by the formula applies unit propagations in reverse of the order in which they were derived by the CDCL solver, which explains the name *reverse* unit propagation.

Clearly, if C is a RUP clause with respect to a formula F , then F implies C . This is an easy consequence of the fact that F implies C via unit propagation. In fact, it can be shown that one can construct a resolution chain for C using at most $|\text{var}(F)|$ resolutions. For example, $E \wedge (\bar{c}) \vdash (\bar{b}) \vdash (a) \vdash \perp$ uses the clauses $(\bar{b} \vee c)$, $(a \vee c)$, and $(\bar{a} \vee b)$. We can convert this into a resolution chain $(c) := (\bar{a} \vee b) \diamond (a \vee c) \diamond (\bar{b} \vee c)$.

Figure 15.1. A resolution derivation (left) and a resolution graph (right) for the example CNF formula E .

The notion of RUP clauses gives rise to the RUP *proof system*, which consists of a single rule that allows the addition of RUP clauses. More specifically, a RUP proof of a clause C_m from a formula F is a sequence C_1, \dots, C_m of clauses such that $F \wedge C_1 \wedge \dots \wedge C_{i-1} \vdash C_i$ for each $i \in 1, \dots, m$.

15.2.3. Extended resolution and its Generalizations

Extended resolution is a simple but powerful generalization of the ordinary resolution proof system, obtained by adding the so-called *extension rule* [Tse83]. Given a CNF formula F , the extension rule allows one to iteratively add definitions of the form $x \leftrightarrow a \wedge b$ by adding the *definition clauses* $(\bar{x} \vee a) \wedge (\bar{x} \vee b) \wedge (x \vee \bar{a} \vee \bar{b})$ to F , where x is a fresh variable (i.e., a variable that does not occur in the formula or in the previous part of the proof), and a and b are existing literals in the current formula or proof. The proof system of extended resolution (ER) [Tse83] consists of two rules: the resolution rule and the extension rule.

It can be easily seen that the extension rule is sound in the sense that it preserves satisfiability: Every satisfying assignment of a formula *before* addition of the definition clauses can be extended to a satisfying assignment of the formula *after* the addition of the definition clauses by setting the truth value of the fresh variable x to the truth value of $a \wedge b$.

Generalizations of extended resolution, which we discuss later, have a similar property: A satisfying assignment of the formula before addition of a redundant clause can be transformed into a satisfying assignment of the formula after addition of the clause. However, in these more general proof systems it is often not enough to simply extend the existing assignment—sometimes, the truth values of some literals need to be made true. This set of literals is often required as a *witness* (as mentioned earlier) to allow the validation of proofs in polynomial time.

The extended resolution proof system can polynomially simulate extended Frege systems [CR79], which is considered to be one of the most powerful proof systems. Extended resolution proofs can be exponentially smaller compared to resolution proofs. For example, Cook constructed short (polynomial-length) ER proofs for the pigeon hole formulas [Coo76], while Haken proved that resolution proofs of the pigeonhole principle must at least be exponential in size of the

formula [Hak85]. However, searching for ER proofs is challenging as it is difficult to come up with effective applications of the extension rule.

This difficulty of finding useful applications of the extension rule is also a reason why several generalizations of extended resolution have been proposed, in part to make it easier to find short proofs without the need to introduce new variables. The first of these generalizations is the *blocked clause (BC) proof system* [Kul99]. The concept of blocked clauses can be generalized to conditional autarky clauses [HKS17], which give rise to two other proof systems.

15.2.3.1. Blocked Clauses

Given a CNF formula F , a clause C , and a literal $l \in C$, the literal l *blocks* C with respect to F if (i) for each clause $D \in F$ with $\bar{l} \in D$, $C \diamond_l D$ is a tautology, or (ii) $\bar{l} \in C$, i.e., C is itself a tautology. Given a CNF formula F , a clause C is *blocked* with respect to F if there is a literal that blocks C with respect to F . Addition and removal of blocked clauses preserves satisfiability of formulas [Kul99].

Example 15.1. Recall the example formula E . Clause $(\bar{b} \vee c)$ is blocked on c with respect to E , because applying the resolution rule on the only clause containing \bar{c} results in a tautology, i.e., $(\bar{b} \vee c) \diamond (b \vee \bar{c}) = (\bar{b} \vee b)$. Since we know that E is unsatisfiable, $E \setminus \{(\bar{b} \vee c)\}$ must be unsatisfiable.

To see that blocked clause addition is a generalization of extended resolution, consider a formula without variable x , but that contains variables a and b . The three definition clauses from the extension rule, i.e., $(\bar{x} \vee a)$, $(\bar{x} \vee b)$, and $(x \vee \bar{a} \vee \bar{b})$ are all blocked on x or \bar{x} , regardless of the order in which they are added. This is an easy consequence of the fact that x is fresh and that the only resolvents upon x or \bar{x} are obtained by resolving the definition clauses with each other. Hence, blocked clause addition can add these three clauses while preserving satisfiability.

In contrast to extended resolution, blocked clause addition can extend the formula with clauses that are not logically implied by the formula *and* that do not contain a fresh variable. For example, consider the formula $F := (a \vee b)$. The clause $(\bar{a} \vee \bar{b})$ is blocked on \bar{a} (and \bar{b}) with respect to F and can thus be added using blocked clause addition.

15.2.3.2. Conditional Autarkies

An *autarky* is a partial assignment that satisfies all clauses it touches, i.e., all clauses for which the assignment assigns a truth value to at least one literal. Simple examples of autarkies are pure literals and satisfying assignments of a whole formula. Chapter 14 discusses autarkies in detail. A *conditional autarky* [HKS17] is a partial assignment that consists of a so-called *conditional part* and an *autarky part*, where the autarky part is an autarky for the formula restricted under the conditional part.

Example 15.2. Consider the formula $F = (x \vee y) \wedge (\bar{x} \vee z) \wedge (\bar{y} \vee \bar{z})$. The assignment $\omega = \bar{y}z$ is a conditional autarky with conditional part $\omega_{\text{con}} = \bar{y}$: By applying ω_{con} to F , we obtain the formula $F|_{\bar{y}} = (x) \wedge (\bar{x} \vee z)$. The only clause of $F|_{\bar{y}}$ that is touched by ω is the clause $(\bar{x} \vee z)$, which is satisfied by ω . The literal z is a conditional pure literal with respect to ω_{con} .

Conditional autarkies give rise to redundant clauses [KHB19]: If the assignment $c_1 \dots c_m a_1 \dots a_n$ is a conditional autarky (with conditional part $c_1 \dots c_m$) for a formula F , then F and $F \cup \{(c_1 \vee \dots \vee c_m \vee a_i) \mid 1 \leq i \leq n\}$ are equisatisfiable. We refer to the redundant clauses that can be added using this reasoning as conditional autarky clauses. It turns out that blocked clauses are conditional autarky clauses [HKSB17] with the blocking literal being the autarky part, while the other literals form the conditional part of the conditional autarky.

By allowing the autarky part to consist of multiple literals, the notion of blocked clauses can be generalized to *set-blocked clauses* [KSTB16] and *globally-blocked clauses* [KHB19]. Set-blocked clauses are conditional autarky clauses for which all literals in the autarky part are included in the clause. Globally-blocked clauses are conditional autarky clauses for which at least one literal in the autarky part is present in the clause. An example of these clauses is described below.

Example 15.3. Consider again the formula $F = (x \vee y) \wedge (\bar{x} \vee z) \wedge (\bar{y} \vee \bar{z})$. The clause $(x \vee \bar{y} \vee z)$ is a set-blocked clause with respect to F with witness $\omega = x \bar{y} z$. The clause (x) is a globally-blocked clause with respect to F with witness $\omega = x \bar{y} z$. Notice that ω is even an autarky for F .

Deciding if a clause is set-blocked or globally-blocked with respect to a formula is an NP-complete problem [KSTB16]. To efficiently validate the set-blockedness or globally-blockedness property, a witnessing assignment (or witness in short) is required. The witness is the autarky part of corresponding conditional autarky.

The set-blocked clause (SBC) proof system combines the resolution rule with the addition of set-blocked clauses, while the globally-blocked clause (GBC) proof system combines the resolution rule with the addition of globally-blocked clauses.

15.2.4. Strong Proof Systems

In the last decade, several strong proof systems have been proposed that combine the strengths of RUP (easy to emit and compact) with the generalizations of ER (expressive). These proof systems allow for short proofs for hard problems and can compactly express all techniques used in top-tier SAT solvers. The first proof system in this direction is RAT [JHB12]. Two recent generalizations are PR [HKB19] and SR [BT19].

15.2.4.1. Resolution Asymmetric Tautologies

resolution asymmetric tautologies (or RAT clauses) [JHB12] are a generalization of both RUP clauses and blocked clauses. Remember that a blocked clause is a clause that contains a literal such that all resolvents upon this literal are tautologies. If we do not require the resolvents to be tautologies, but instead allow them to be RUP clauses (remember that every tautology is a RUP clause), we obtain the notion of a RAT clause: A clause C is a RAT on a literal l (called the witness or pivot literal) with respect to a formula F if for all $D \in F$ with $\bar{l} \in D$, it holds that $F \vdash C \diamond D$.

It can be shown that the addition and removal of RAT clauses does not affect the satisfiability (or unsatisfiability) of a formula [JHB12]. More specifically, given a formula F and a clause C that is a RAT on $l \in C$ with respect to F , let α be an

assignment that satisfies F and falsifies C . The assignment ω , which is a copy of α with the exception that $\omega(l) = 1$, satisfies $F \wedge C$. While this is not supposed to be obvious, the proof of this observation is quite simple. The observation can be used to reconstruct a satisfying assignment for the original formula in case it is satisfiable. Details about solution reconstruction are described in Section 9.5 in Chapter 9.

We have already discussed why RAT clauses are a generalization of blocked clauses in the sense that every blocked clause is also a RAT clause. It can also be shown that RAT clauses generalize RUP clauses, based on the observation that whenever a clause C is a RUP clause with respect to a formula F , then C is a RAT on each of its literals. Note that this assumes that the considered clause is non-empty. As the empty clause does not contain any literals that could ensure the RAT property, it is often still considered a RAT clause “by definition”.

The RAT proof system consists of a single clause addition rule: the addition of RAT clauses. This proof system extends the RUP proof system by allowing to compactly express techniques that go beyond resolution, including bounded variable addition [MHB12] and symmetry breaking [HHJW15].

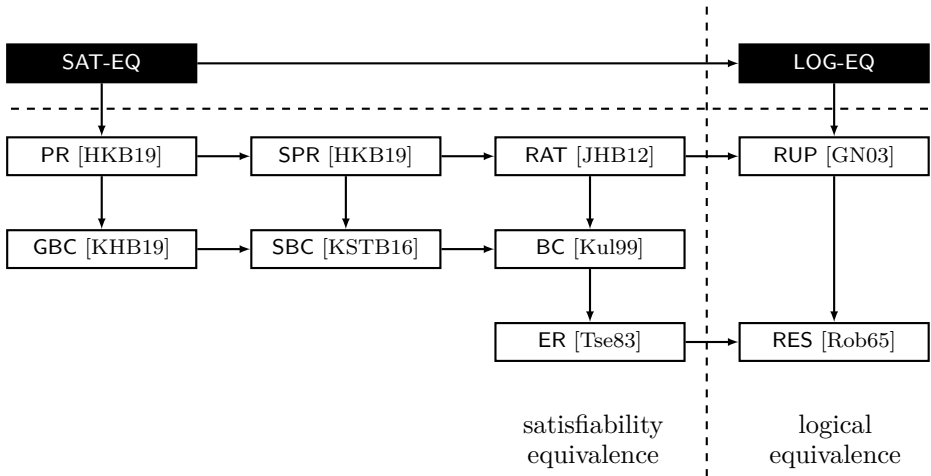

Figure 15.2. Relations between proofs systems for propositional logic. An arrow pointing from proof system A to proof system B means that A is a generalization of B . The black boxes on the top are not actual proof systems, but refer to abstract systems that would allow any clause-addition step that preserves satisfiability (SAT-EQ) or logical equivalence (LOG-EQ).

15.2.4.2. Propagation Redundancy

Another way to express the RAT property is as follows: Given a clause C and a formula F , let α denote the smallest assignment that falsifies C . Now, C is a RAT clause on literal l with respect to F if and only if $F|_{\alpha} \vdash F|_l$ [HKB19]. This notion can be generalized by using a set of literals instead of the single literal l .

A clause C has the *set-propagation redundancy* (SPR) property with respect to a formula F if and only if $F|_{\alpha} \vdash F|_L$, with α denoting the smallest assignment

that falsifies C , and L denoting a set of literals that all occur in C [HKB19]. The set L is the witness of the SPR property of C . SPR clauses generalize both set-blocked clauses and RUP clauses in a similar way that RAT clauses generalize blocked clauses and RUP clauses. The SPR proof system uses a single rule: the addition of SPR clauses. The SPR proof system is surprisingly powerful even when it is restricted such that no new variables are allowed to be introduced, known as SPR^- . For example, there exist short SPR^- proofs for many formulas that are hard for resolution, including the pigeonhole principle, parity principle, Tseitin tautologies, and clique-coloring tautologies [HKB19, BT19].

Finally, the *propagation redundancy* (PR) property generalizes the redundant clauses discussed in this section. A clause C has the PR property with respect to a formula F if and only if $F|\alpha \vdash F|\omega$, with α denoting the smallest assignment that falsifies C , and ω being an arbitrary witness assignment that satisfies C [HKB19]. The PR proof system allows the addition of PR clauses. Figure 15.2 shows a hierarchy of proof systems with PR being the most general one. There exists a polynomial simulation between all proof systems that go beyond logical equivalence, from ER to PR [KRPH18, HB18]. That does not mean that they are similar in practice. A polynomial blowup from PR to ER could mean an enormous increase in validation costs. Also, it is easier to search for proofs in the more general systems as they admit short proofs *without new variables* for some hard problems [HKB19].

15.2.5. Clause Deletion

All the proof systems considered so far in this section add clauses to a given formula. SAT solvers, however, combine both the addition and the deletion of clauses. Most of the discussed proof systems thus have corresponding systems that extend them by allowing the deletion of clauses. The most popular one of these proof systems is probably DRAT, which allows the addition of RAT clauses as well as the deletion of arbitrary clauses. It is important to support the deletion of clauses in proofs without hints for two reasons.

First, it is practically impossible to efficiently validate a proof without hints if no clauses are removed: Due to the lack of hints, the checker needs to find the antecedents, which becomes increasingly expensive as clauses are added to the formula. Even with clause deletion it is generally more expensive to validate the proof compared to its construction. This topic is further discussed in Section 15.6.2.

Second, clause deletion allows for a compact simulation of advanced techniques in solvers. For example, the reasonably compact transformation of a PR proof into a DRAT proof [HB18] is facilitated by the clause deletion step in DRAT. Several clause addition steps would be invalid if some clauses were not removed first. It is possible to simulate the deletion of clauses with extended resolution and thus its generalizations by making a copy of all the clauses apart from the deleted ones using copies (renaming) of the variables [KRPH18]. However, the number of copied clauses is linear in the size of the formula and thus typically much more expensive compared to removal.

In the context of proofs of unsatisfiability, one only needs to check whether clause addition steps are valid. Clause deletion steps can be performed without

a check, because the validity of the unsatisfiability result only depends on clause addition. However, when checking also the validity of clause deletion steps, i.e., whether clause deletion preserves unsatisfiability, one can construct proofs of satisfiability by showing the equivalence of the input formula with the empty formula. This is not really useful in propositional logic as a satisfying assignment can be used as a certificate for satisfiability. Yet, this approach can be useful for richer logics, such as Quantified Boolean Formulas [HSB14], see Chapter 31.

15.3. Proof Search

The leading paradigm to solve satisfiability problems is the conflict-driven clause learning (CDCL) approach, described in Chapter 4. In short, CDCL adds lemmas, typically referred to as conflict clauses, to a given input formula until either it finds a satisfying assignment or it is able to learn (i.e., deduce) the empty clause (prove unsatisfiability).

CDCL solvers typically use a range of preprocessing techniques, see Chapter 9 for details. Examples of such techniques are bounded variable elimination (also known as Davis-Putnam resolution) [DP60, EB05], blocked clause elimination [JBH12], subsumption, and hyper binary resolution [BW03]. Preprocessing techniques are frequently crucial to solve large formulas efficiently. These techniques can also be used during the solving phase, which is known as *inprocessing* [JHB12]. Most preprocessing techniques can be expressed using a few resolutions, such as bounded variable elimination and hyper binary resolution. Other techniques can be ignored in the context of unsatisfiability proofs, because they weaken the formula, such as blocked clause elimination and subsumption.

Some CDCL solvers, however, use preprocessing techniques that are hard to represent using resolution proofs. Examples of such techniques are bounded variable addition [MHB12], blocked clause addition [JHB12], Gaussian elimination, cardinality resolution [CCT87], and symmetry breaking [ASM06]. These techniques cannot be polynomially simulated using the resolution rule: For example, certain formulas based on expander graphs are hard for resolution [Urq87], meaning that they admit only resolution proofs of exponential size, while Gaussian elimination can solve them efficiently. Similarly, formulas arising from the pigeon hole principle are hard for resolution [Hak85], but they can be solved efficiently using either cardinality resolution or symmetry breaking. Consequently, solvers that can efficiently solve such problems cannot produce resolution proofs that are linear in size of the solving time as all resolution proofs are at least exponential in size.

Techniques such as Gaussian elimination, cardinality resolution, and symmetry breaking, can be simulated polynomially using extended resolution and its generalizations. However, it is not known how to simulate these techniques efficiently or elegantly using extended resolution. One method to translate Gaussian elimination into ER proofs is to convert the Gaussian elimination steps into BDDs and afterwards translate the BDDs to a extended resolution proof [SB06].

An alternative approach to solve satisfiability problems is the look-ahead approach, described in Chapter 5. Look-ahead solvers solve a problem via a binary search-tree. In each node of the search-tree, the best splitting variable is

selected using so-called look-ahead techniques. Although it is possible to extract unsatisfiability proofs from look-ahead solvers, this hardly happens in practice. However, look-ahead SAT solvers can also be used to partition a problem into many subproblems, which is known as the *cube-and-conquer* approach [HKWB11]. The subproblems are solved using CDCL. The proofs produced by the CDCL solvers can be merged into a proof of the original problem. This method was used to produce proofs of the Erdős Discrepancy Theorem [KL14], the Pythagorean Triples Problem [HKM16], and Keller’s Conjecture [BHMN20].

Searching for proofs in the stronger proof systems, such as PR, is more complicated and costly as determining whether a clause is a PR clause with respect to a formula is an NP-complete problem. One approach to computing PR proofs is *satisfaction-driven clause learning* (SDCL) [HKS17], which generalizes CDCL by performing a more aggressive pruning of the search tree via the addition of PR clauses.

15.4. Proof Formats

Proof formats define how the proofs of a given proof system should be represented syntactically so that they can be validated by automated tools. Formats for unsatisfiability proofs come in two flavors: with or without hints. A handful of formats have been designed for resolution proofs [ZM03, ES03, Bie08]. All these proof formats include hints in the form of details that describe how to validate each proof step.

The hints in resolution proofs refer to the antecedents of an application of the resolution rule. These formats differ in several details, such as whether the input formula is stored in the proof, whether resolution chains are allowed, or whether hints in the proofs must be ordered. We will first discuss the two most widely used formats with hints: **TraceCheck** and **LRAT**. The **stc** [Bie08] tool can be used to validate **TraceCheck** files. Various checkers exist for **LRAT** files, including **LRAT-check** and the formally verified tool **ACL2-check** [HHKW17]. The **LRAT** format also supports stronger proof systems, but we will first focus on how to use it for resolution proofs.

For proofs without hints, there is essentially only one format, which lists the redundant clauses using the same syntax as **DIMACS**. Such proofs can be extended with clause deletion information [HHW13a], and with a generalization of extended resolution [HHW13b]. The format that supports both extensions is **DRAT** [WHH14], which corresponds to the **DRAT** proof system; it is backward compatible with the **RUP** proof format, which corresponds to the **RUP** proof system. The **DRAT-trim** [WHH14] tool can efficiently validate proofs without hints in the various proof systems.

15.4.1. Formats with Hints

There exist two popular proof formats that include hints: **TraceCheck** and **LRAT**. For resolution proofs, the syntax of both formats is the same. The **TraceCheck** format is restricted to resolution, while the **LRAT** format also allows proofs in stronger proof systems. An important difference between **TraceCheck** and **LRAT**

is that only the former includes the input clauses as part of the proof. In contrast, checkers for LRAT proofs also require the formula as input. The other difference between these formats is that **TraceCheck** allows an arbitrary order of the lines and the hints, while for LRAT the order of lines and hints is strict. These difference can be explained by historical considerations: **TraceCheck** was proposed in 2006, when it was not possible to efficiently validate proofs without hints and when it was also difficult to compute the right order of hints for some techniques. The LRAT format was proposed more than a decade later and was designed to make the format strict to make it easy to develop formally-verified checkers.

The proof checker `tracecheck` can be used to check whether a trace represents a *piecewise regular input resolution proof*, which is also known as a *trivial proof* [BKS04]. A proof is *regular* if variables are resolved at most once along any path in the directed acyclic graph (DAG) formed by the proof. It is an *input resolution* proof if each resolution step resolves at most one non-input clause. Therefore it is also linear and has a degenerated graph structure of a binary tree, where each internal node has at least one leaf as child. A *trace* is just a compact representation of general resolution proofs. The **TraceCheck** format is more compact than other resolution formats, because it uses resolution chains, and because the resulting resolvent does not need to be stated explicitly. The parts of the proof which are regular input resolution proofs are called chains in the following discussion. The full trace consists of original clauses and the chains.

Note that input clauses in chains can still be arbitrary derived clauses with respect to the overall proof and do not have to be original clauses. We distinguish between original clauses of the CNF, which are usually just called input clauses, and input clauses to the chains. Since a chain can be seen as new proof rule, we call its input clauses *antecedents* and the final resolvent just *resolvent*.

The motivation for using this format is that learned clauses in a CDCL solver can be derived by regular input resolution [BKS04]. A unique feature of **TraceCheck** is that the chains do not have to be sorted, neither between chains (globally) nor between their input clauses (locally). If possible the checker will sort them automatically. This allows a simplified implementation of the trace generation.

A chains is simply represented by the list of its antecedents and the resolvent. Intermediate resolvents can be omitted, which saves quite some space if the proof generator can easily extract chains.

Chains can be used in the context of searched-based CDCL to represent the derivations of learned clauses. Computing the chains can become challenging when more advanced learned clause optimizations are used. Shrinking or minimization of learned clauses [SB09] are examples of these optimizations. The difficult part is to order the antecedents correctly. The solver can leave this task to the trace checker instead of changing the minimization algorithm [Van09].

Moreover, both **TraceCheck** and LRAT facilitate a simple encoding of hyper resolution proofs. A hyper resolution step can be simulated by a chain. General resolution steps can also be encoded in this format easily by a trivial chain consisting of the two antecedents of the general resolution step. Finally, extended resolution proofs can directly be encoded, since variables introduced in extended resolution can be treated in the same way as the original variables. Checkers

for TraceCheck don't validate the clauses introduced by the extension rule, while LRAT checkers validate the definition clauses introduced via the extension rule by treating them as blocked-clause-addition steps.

The syntax of a trace is as follows:

$$\begin{aligned} \langle \text{trace} \rangle &= \{ \langle \text{clause} \rangle \} \\ \langle \text{clause} \rangle &= \langle \text{pos} \rangle \langle \text{literals} \rangle \langle \text{antecedents} \rangle \\ \langle \text{literals} \rangle &= "*" \mid \{ \langle \text{lit} \rangle \} "0" \\ \langle \text{hints} \rangle &= \{ \langle \text{pos} \rangle \} "0" \\ \langle \text{lit} \rangle &= \langle \text{pos} \rangle \mid \langle \text{neg} \rangle \\ \langle \text{pos} \rangle &= "1" \mid "2" \mid \dots \mid \langle \text{maxidx} \rangle \\ \langle \text{neg} \rangle &= "-" \langle \text{pos} \rangle \end{aligned}$$

where ‘|’ means choice, ‘{...}’ is equivalent to the Kleene star operation (that is, a finite number of repetitions including 0) and $\langle \text{maxidx} \rangle = 2^{28} - 1$ (originally).

The interpretation is as follows. Original clauses have an empty list of antecedents and derived clauses have at least one antecedent. A clause definition starts with its index and a zero terminated list of its literals, which are represented by integers. This part is similar to the DIMACS format except that each clause is preceded by a unique positive number, the index of the clause. Another zero terminated list of positive indices of its antecedents is added, denoting the chain that is used to derive this clause as resolvent from the antecedents. In TraceCheck, the order of the clauses and the order of the literals and antecedents of a chain is arbitrary. The list of antecedents of a clause should permit a regular input resolution proof of the clause with exactly the antecedents as input clauses. The LRAT format enforces a strict order which will be described below.

input formula (DIMACS)	proof without hints (DRUP)	proof with hints (TraceCheck)
<pre>p cnf 3 6 -2 3 0 1 3 0 -1 2 0 -1 -2 0 1 -2 0 2 -3 0</pre>	<pre>-2 0 3 0 0</pre>	<pre>1 -2 3 0 0 2 1 3 0 0 3 -1 2 0 0 4 -1 -2 0 0 5 1 -2 0 0 6 2 -3 0 0 7 -2 0 4 5 0 8 3 0 1 2 3 0 9 0 7 6 8 0</pre>

Figure 15.3. An input formula (left) in the classical DIMACS format which is supported by most SAT solvers. A proof without hints for the input formula in DRUP format (middle). In both the DIMACS and DRUP formats, each line ending with a zero represents a clause, and each non-zero element represents a literal. Positive numbers represent positive literals, while negative numbers represent negative literals. For example, $-2 \ 3 \ 0$ represents the clause $(\bar{b} \vee c)$. A TraceCheck file (right) is a resolution graph that includes the formula and proof with hints. Each line begins with a clause identifier (bold), then contains the literals of the original clause or lemma, and ends with a list of clause identifiers (bold) as hints.

Consider, for example, the trace shown in Fig. 15.3 (right), which consists of the six clauses from our example CNF formula E , which we introduced on page 638. The corresponding DIMACS file is shown in Fig. 15.3 (left). This proof in `TraceCheck` can easily be converted into LRAT by simply removing the first few lines, which represent the input formula. This is possible as the order of the clauses in the DIMACS file is the same as the order of the original clauses in the trace (which is not required).

The first derived clause in the trace starts with index **7**. This is the unary clause which consists of the literal -2 (\bar{b}). It is obtained by resolving the original clause **4** against the original clause **5** on variable 1 (a).

A chain for the last derived clause, which is the empty clause \perp , can be obtained by resolving the antecedents **7**, **6**, and **8**: first **7** is resolved with **6** to obtain the intermediate resolvent -3 (\bar{c}), which in turn can be resolved with clause **8** to obtain the empty clause \perp .

The LRAT format enforces a strict ordering of the hints. Checking a proof step starts with the assignment that falsifies all literals in the clause. For example, for line **8** it starts with the assignment that makes variable 3 (c) false. The hints are read from left to right and each hint is required to be a unit clause under the current assignment. That assignment is extended by making the unit literal true. The last hint is an exception: the current assignment needs to falsify it. So when checking line **8**, the first hint points to clause $(\bar{b} \vee c)$, which is unit (\bar{b}) and \bar{b} is added to the assignment. The second hint points to $(a \vee c)$, which again is unit (a) and a is added to the assignment. The final hint points to $(\bar{a} \vee b)$, which is indeed falsified by the current assignment.

As discussed above, the order of the lines (clauses) in `TraceCheck` is irrelevant, in contrast to LRAT. The checker will sort them automatically using the clause identifiers. The same holds for the hints. So, the last two lines of the example trace can be replaced by:

```

9 0 7 8 6 0
8 3 0 1 2 3 0

```

Note that the clauses **7** (\bar{b}) and **8** (c) cannot be resolved with each other, because they do not contain complementary literals. In this case, the checker has to reorder the antecedents as in the original example.

The main motivation for having hints in the proof for each learned clause is to speed up proof validation. While checking a learned clause, unit propagation can focus on the list of specified antecedents. It can further ignore all other clauses, particularly those that were already discarded at the point where the solver learned the clause.

In the `TraceCheck` format, it might be convenient to skip the literal part for derived clauses by specifying a $*$ instead of the literal list. The literals are then collected by the checker from the antecedents. Since resolution is not associative, the checker assumes that the antecedents are correctly sorted when $*$ is used.

```

8 * 1 2 3 0
9 * 7 6 8 0

```

Furthermore, trivial clauses and clauses with multiple occurrences of the same literal cannot be resolved. The list of antecedents is not allowed to contain the same index twice. All antecedents have to be used in the proof for the resolvent.

Beside these local restrictions the proof checker generates a global linear order on the derived clauses making sure that there are no cyclic resolution steps. The roots of the resulting DAG are the target resolvents.

One feature in the LRAT format that is currently not supported in `TraceCheck` is the deletion of clauses. Clause deletion lines in LRAT start with an identifier (typically the same identifier as the previous line), followed by “d” and a list of clause indices to be deleted, and they end with a “0”.

15.4.2. Formats Without Hints

Proof formats without hints are designed to make proof logging easy. Apart from the lack of hints, they also don’t use clause indices. The absence of hints and clause indices results in much smaller proofs, but these proofs are more expensive to validate. To validate proofs without hints in reasonable time, it is common to include deletion information. Adding this information is also easy.

We appeal to the notion that *lemmas* are used to construct a proof of a theorem. Here, lemmas represent the learned clauses and the theorem is the statement that the formula is unsatisfiable. From now on, we will use the term clauses to refer to original clauses, while lemmas will refer to added clauses.

$$\begin{aligned}
 \langle \text{proof} \rangle &= \{ \langle \text{lemma} \rangle \} \\
 \langle \text{lemma} \rangle &= \langle \text{delete} \rangle \{ \langle \text{lit} \rangle \} \text{“0”} \\
 \langle \text{delete} \rangle &= \text{“”} \mid \text{“d”} \\
 \langle \text{lit} \rangle &= \langle \text{pos} \rangle \mid \langle \text{neg} \rangle \\
 \langle \text{pos} \rangle &= \text{“1”} \mid \text{“2”} \mid \dots \mid \langle \text{maxidx} \rangle \\
 \langle \text{neg} \rangle &= \text{“-”} \langle \text{pos} \rangle
 \end{aligned}$$

There exist a few proof formats for proofs without hints; they have a very similar syntax as DIMACS and can all be expressed using the above grammar. The most basic format is DRUP, short for delete reverse unit propagation, which combines RUP (reverse unit propagation) additions [Van08] and clause deletions. A DRUP proof is a sequence of lemmas that are either added or deleted. Each lemma is a list of positive and negative integers (to express positive and negative literals, respectively) that terminates with a zero as in DIMACS. Clause deletion steps are expressed using the prefix `d`. An example is shown in Figure 15.3.

Recall that a clausal proof $P := \{C_1, \dots, C_m\}$ is a valid RUP proof for a formula F if $C_m = \perp$ and for each C_i , it holds that

$$F \wedge C_1 \wedge \dots \wedge C_{i-1} \vdash C_i$$

This means that for each $i \in 1, \dots, m$, unit propagation must derive a conflict on the formula $F \wedge C_1 \wedge \dots \wedge C_{i-1} \wedge \bar{C}_i$. Consider again the example CNF

formula E from page 638. A RUP proof is shown in Figure 15.3. This proof, $P_E := \{(\bar{b}), (c), \perp\}$, is a valid proof for E , because P_E terminates with \perp and

$$\begin{array}{ll} E & \vdash_{\top} (\bar{b}) \\ E \wedge (\bar{b}) & \vdash_{\top} (c) \\ E \wedge (\bar{b}) \wedge (c) & \vdash_{\top} \perp \end{array}$$

15.4.3. Formats with Witnesses

So far we only considered proof formats that validate techniques which can be simulated using resolution. As mentioned earlier, however, some SAT solvers use techniques—such as blocked clause addition or symmetry breaking—that cannot be simulated using resolution. To validate these techniques, proof formats need to support stronger proof systems such as extended resolution or one of its generalizations.

In these formats, a witness is provided for each proof step in addition to the clause and the optional hints. For most proof systems, the witness consists of a single literal that needs to be part of the clause. To minimize overhead, the convention is to place the witness as the first literal in the clause. For the clauses added by the extension rule this means to put the literals referring to the new variable first.

Resolution proofs, as the name suggests, can only be used to check techniques that can be expressed using resolution steps. The `TraceCheck` format partially supports extended resolution in the sense that one can add the clauses from the extension rule using an empty list of antecedents. Hence these clauses are considered to be input clauses without actually validating them.

The `DRAT` proof format [WHH14], which is syntactically the same as the `DRUP` format, supports expressing techniques based on extended resolution and its generalizations. The difference between the `DRUP` and `DRAT` format is in the redundancy check that is computed in the checker for proofs in that format. A checker for `DRUP` proofs validates whether each lemma is a RUP clause, while a checker of `DRAT` proofs checks whether each lemma is a RAT clause [HHW13b].

Example 15.4. Consider the following CNF formula

$$G := (\bar{a}\bar{v}\bar{b}\bar{v}\bar{c}) \wedge (a\vee d) \wedge (a\vee e) \wedge (b\vee d) \wedge (b\vee e) \wedge (c\vee d) \wedge (c\vee e) \wedge (\bar{d}\bar{v}\bar{e})$$

On the left of Fig. 15.4, G is shown in the `DIMACS` format, using the conventional mapping from the alphabet to numbers, where a is mapped to 1, \bar{a} is mapped to -1, b to 2, \bar{b} to -2, and so on. In the middle of Fig. 15.4, a `DRAT` proof for G is shown. The proof uses the earlier-mentioned technique of bounded variable addition [MHB12], which cannot be expressed using resolution steps. Bounded variable addition can replace the first six binary clauses by five new binary clauses using a fresh variable f : $(f\vee a)$, $(f\vee b)$, $(f\vee c)$, $(\bar{f}\vee d)$, and $(\bar{f}\vee e)$. These new binary clauses are RAT clauses. Fig. 15.4 shows how to express bounded variable addition in the `DRAT` format: First add the new binary clauses using the pivot (witness) literal on the first position, followed by deleting the old ones. After the replacement, the proof is short $\{(f), \perp\}$.

Validating proofs based on extended resolution or one of its generalizations requires reasoning about absence. For example, the addition of definition clauses via the extension rule is only valid when the new variable is indeed new and does not occur in the formula. We need to check all clauses that are reduced but not satisfied by the witness. In most cases, the witness is a single literal, so we need to check only the clauses in which the complement of the literal occurs.

Consider the following example of a proof that again uses bounded variable addition. Fig. 15.4 shows the example formula G in DIMACS as well as a DRAT proof and an LRAT proof. The clauses $(f \vee a)$, $(f \vee b)$, and $(f \vee c)$ are trivially redundant with respect to G using witness f , because G does not contain any clause with literal \bar{f} . Making f true would satisfy these three clauses. However, $(\bar{f} \vee d)$ and $(\bar{f} \vee e)$ are not trivially redundant with respect to G using witness \bar{f} after the addition of $(f \vee a)$, $(f \vee b)$, and $(f \vee c)$. For example, the redundancy of $(\bar{f} \vee d)$ depends on the presence of $(a \vee d)$, $(b \vee d)$, and $(c \vee d)$ as the RAT check would fail without these clauses.

Let's recall the definition of RAT clauses from Section 15.2.4.1: A clause C is a RAT on l with respect to a formula F if for all $D \in F$ with $\bar{l} \in D$, it holds that $F \vdash C \diamond D$. In the proof, $(\bar{f} \vee d)$ is claimed to be RAT on \bar{f} . Let G' denote the formula when checking $(\bar{f} \vee d)$: $G' := G \wedge (f \vee a) \wedge (f \vee b) \wedge (f \vee c)$. We can confirm the RAT claim by applying the following three checks:

$$\begin{aligned} G' \vdash (a \vee d) & \quad \text{using } D = (f \vee a) \\ G' \vdash (b \vee d) & \quad \text{using } D = (f \vee b) \\ G' \vdash (c \vee d) & \quad \text{using } D = (f \vee c) \end{aligned}$$

The first check succeeds because $(a \vee d) \in G'$ is reduced to the empty clause, whereas the second and third checks succeed, because $(b \vee d) \in G'$ and $(c \vee d) \in G'$ are reduced to the empty clause. In the LRAT proof format this is expressed as follows: For each clause that is reduced but not satisfied by the witness (the D clauses), in this case $(f \vee a)$, $(f \vee b)$, and $(f \vee c)$, the negated clause index is listed: -9, -10, and -11, respectively. After the negated clause index, the clause indices of the unit clauses are listed and finally the clause that is reduced to the empty clause. For $(f \vee a)$, clause $(a \vee d)$ is reduced to the empty clause, which has clause index 2.

15.4.4. Binary Formats and Proof Compression

It is common practice to store proofs on disk, and we discussed various formats for this purpose. However, in many applications where proofs have to be further processed and are used subsequently or even iteratively, disk I/O is considered a substantial overhead. In this subsection, we discuss light-weight options to compress proofs [HB16]. The variable-byte encoding discussed below is supported by most SAT solvers.

15.4.4.1. Byte Encoding

The ASCII encoding of a proof line without hints in Figure 15.3 is easy to read, but rather verbose. For example, consider the literal -123456789, which requires

DIMACS formula	DRAT proof	LRAT proof
p cnf 5 8		
-1 -2 -3 0	6 1 0	9 6 1 0 0
1 4 0	6 2 0	10 6 2 0 0
1 5 0	6 3 0	11 6 3 0 0
2 4 0	-6 4 0	12 -6 4 0 -9 2 -10 4 -11 6 0
2 5 0	-6 5 0	13 -6 5 0 -9 3 -10 5 -11 7 0
3 4 0	d 1 4 0	14 6 0 1 9 10 11 0
3 5 0	d 2 4 0	14 d 2 4 6 3 5 7 0
-4 -5 0	d 3 4 0	15 0 8 12 13 14 0
	d 1 5 0	
	d 2 5 0	
	d 3 5 0	
	6 0	
	0	

Figure 15.4. Example formula G in the classical DIMACS format (left). A proof without hints for the input formula in DRAT format (middle). The corresponding proof with hints as a LRAT file is shown on the right. Notice that the formula is not included. Each line begins with a clause identifier (bold), then contains the literals of the lemma, and ends with a list of hints (bold).

11 bytes to express (one for each ASCII character and one for the separating space). This literal can also be represented by a signed integer (4 bytes). If all literals in a proof can be expressed using signed integers, only 4 bytes are required to encode each literal. Such an encoding also facilitates omitting a byte to express the separation of literals. Consequently, one can easily compress an ASCII proof with a factor of roughly 2.5 by using a binary encoding of literals.

In case the length of literals in the ASCII representation differs a lot, it may not be efficient to allocate a fixed number of bytes to express each literal. Alternatively, the *variable-byte encoding* [WMB99] can be applied, which uses the most significant bit of each byte to denote whether a byte is the last byte required to express a given literal. The variable-byte encoding can express the literal 1234 (10011010010 in binary notation) using only two bytes: 11010010 00001001. (in little-endian ordering, e.g., least-significant byte first).

15.4.4.2. Sorting Literals

The order of literals in a clausal proof has no influence on the validity or the size of a proof. However, the order of literals can influence the cost of validating a proof, as it influences unit propagation and in turn determines which clauses will be marked in backwards checking (the default validation algorithm used in checkers of proofs without hints), see Section 15.6.2 for details. The order of literals in the proof produced by the SAT solver is typically not better or worse than any permutation for validation purposes. However, experience shows that this is often not the case for SAT solving: the given order of literals in an encoding results in stronger solver performance compared to any permutation.

Sorting literals before compression has advantages in both light-weight and heavy compression. In light-weight compression, one can use delta encoding: store the difference between two successive literals. Clauses in a proof are typically long (dozens of literals) [HHW13a], resulting in a small difference between two

successive sorted literals. Delta encoding is particularly useful in combination with variable-byte encoding.

In heavy compression, off-the-shelf zip tools could exploit the sorted order of literals. Many clauses in proofs have multiple literals in common. SAT solvers tend to emit literals in a random order. This makes it hard for compression tools to detect overlapping literals between clauses. Sorting literals potentially increases the observability of overlap which in turn could increase the quality of the compression algorithm.

Table 15.1. Eight encodings of an example DRAT proof line. The first two encodings are shown as ASCII text using decimal numbers, while the last six are shown as hexadecimals using the MiniSAT encoding of literals. The prefix *s* denotes sorted, while the prefix *ds* denotes delta encoding after sorted. *4byte* denotes that 4 bytes are used to represent each literal, while *vbyte* denotes that variable-byte encoding is used.

encoding	example (prefix pivot lit ₁ ...lit _{k-1} end)	#bytes
ascii	d 6278 -3425 -42311 9173 22754 0\n	33
sascii	d 6278 -3425 9173 22754 -42311 0\n	33
4byte	64 0c310000 c31a0000 8f4a0100 aa470000 c4b10000 00000000	25
s4byte	64 0c310000 c31a0000 aa470000 c4b10000 8f4a0100 00000000	25
ds4byte	64 0c310000 c31a0000 e82c0000 1a6a0000 cb980000 00000000	25
vbyte	64 8c62c335 8f9505aa 8f01c4e3 0200	15
svbyte	64 8c62c335 aa8f01c4 e3028f95 0500	15
dsvbyte	64 8c62c335 e8599ad4 01cb b102 00	14

15.4.4.3. Literal Encoding

In most SAT solvers, literals are mapped to natural numbers. The default mapping function $map(l)$, introduced in MiniSAT [ES03] and also used in the AIGER format [Bie07], converts signed DIMACS literals into unsigned integer numbers as follows:

$$map(l) = \begin{cases} 2l + 1 & \text{if } l > 0 \\ -2l & \text{otherwise} \end{cases}$$

Table 15.1 shows a proof line in the DRAT format and in several binary encodings. For all non-ASCII encodings, we will use $map(l)$ to represent literals. Notice that the first literal in the example is not sorted, because the proof checker needs to know the witness / pivot literal (which is the first literal in each clause). The remaining literals are sorted based on their $map(l)$ value.

15.5. Proof Production in Practical SAT Solving

Proof logging of unsatisfiability results from practical SAT solvers started in 2003, with both resolution proofs *with* hints [ZM03] and resolution proofs *without* hints [GN03]. Proofs with hints are typically hard to produce and tend to require lots of overhead in memory, which in turn slows down a SAT solver. Emitting proofs without hints is easy and requires hardly any overhead in memory. We will first describe how to produce proofs without hints, followed by how to produce proofs with hints, and finally describe parallel proof production.

15.5.1. Proofs Without Hints

For all proof formats without hints, SAT solvers simply emit proofs directly to disk. Consequently, there is no memory overhead. In contrast to proofs with hints, it is easy to emit proofs. For the most simple format of proofs without hints, RUP, one only needs to extend the proof with all clauses learned by the CDCL solver. This can be implemented by a handful lines of code. Below we discuss how to produce proofs without hints that support deletion information and techniques based on generalizations of extended resolution.

Proofs without hints need deletion information for efficient validation, see Section 15.6.2 for details. Adding deletion information to a proof without hints is straightforward. As soon as a clause is removed from the solver, the proof is extended by the removed clause using a prefix expressing that it is a deletion step. Recall that clauses in proofs without hints have no clause index. Hence all literals in the deleted clause are listed. The checker needs to find the deleted clause in the clause database. This can be done efficiently using a hash function. If a solver removes a literal l from a clause C , then $C \setminus \{l\}$ is added as a lemma followed by deleting C .

Most techniques based on extended resolution or its generalizations can easily be expressed in proofs without hints. Similar to techniques based on resolution, one simply adds the lemmas to the proof for most techniques. The RAT and DRAT formats only require that the witness / pivot literal is the first literal of the lemma in the proof. However, as discussed in Section 15.3, there exist some techniques for which it is not known whether they can be expressed elegantly in the DRAT format. As mentioned already, especially Gaussian elimination, cardinality resolution, and symmetry breaking are hard to express in the current formats. Finally, for proof systems that require witnesses, the witness is printed directly after the clause and before the zero that marks the end of the line.

15.5.2. Proofs With Hints

Early work on proofs with hints [ZM03] mostly showed that proofs can be generated in principle, but ignored dealing with practical aspects such as keeping proofs compact and supporting all techniques. The first proof format that took these aspects into account was `TraceCheck`, which we discussed already and which was first supported by `PicoSAT` [Bie08]. The addition of proof logging was motivated by making testing and debugging more efficient. In combination with file-based delta-debugging [BLB10], proof trace generation allows to reduce discrepancies much more than without proof tracing.

The original idea was to use resolution traces. However, for some time it was unclear how to extract resolution proofs during a-posteriori clause minimization [SB09]. This was the reason for using a trace format instead: clause minimization is obviously compatible with reverse unit propagation, since required clause antecedents can easily be obtained. However, determining the right order of the hints for a resolution proof is hard to generate directly and probably needs a RUP style algorithm anyhow. It was shown how clause minimization can be integrated in `MiniSAT` using a depth-first search for the first-unique-implication-point clause [Van09], which at the same time can produce a resolution proof for

the minimized learned clause. Currently it is unsolved how to further extend this approach to work with on-the-fly subsumption [HS09] as well. The solution is also not as easy to add to existing solvers as tracing added and deleted clauses.

As already discussed above, memory consumption of proofs stored in memory (or disk) can become a bottleneck. One way to reduce space requirements is to delete garbage clauses that are not used anymore. This garbage collection was implemented with saturating reference counters in *PicoSAT* [Bie08]. It has been shown that full reference counting can result in substantial reductions [ANORC08]. In principle, it might also be possible to use a simple mark-and-sweep garbage collector, which should be faster, since it does not need to maintain and update reference counters.

15.5.3. Parallel Proof Production

A framework based on the cube-and-conquer paradigm has been used to deal with hard combinatorial problems that require thousands of hours of computation to solve [HKM16]. In short, the framework consists of five phases: *encode*, *re-encode*, *split*, *solve*, and *validate*. The focus of the encode phase is to make sure that encoding the problem into SAT is valid. The re-encode phase reformulates the problem to reduce the computation costs of the later phases. The split phase partitions the transformed formula into many (typically millions of) subproblems. The subproblems are solved in the solve phase. The validation phase checks whether the proofs emitted in the prior phases are a valid refutation for the original formula. Figure 15.5 shows an illustration of the framework.

In recent years, three long-standing open problem in mathematics have been solved using this framework: the Pythagorean Triples Problem (PTP) [HKM16], Schur number five (S5) [Heu18], and Keller's Conjecture [BHMN20]. The encoding of PTP and S5 is natural and can be achieved with about a dozen lines of code. The encoding of Keller is more involved and also included several symmetry-breaking clauses that arise from symmetries of the problem, but these are not symmetries in the encoding. The re-encoding phase of all three problems consists of adding symmetry-breaking predicates. Additionally, about 30% of the clauses of PTP are redundant and they have been removed using blocked clause elimination.

All three problems used a two-layered splitting approach. For PTN and S5, the re-encoded problem was split into a few million subproblems using the look-ahead solver *march.cu*. This can be done in less than an hour of a single CPU. For Keller, the problem was manually split into many thousands of subproblems. All these subproblems were split into even smaller problems using *march.cu*. This second layer of splitting was performed in parallel. It resulted in billions of subproblem for PTN and S5 and millions of subproblems for Keller. The subproblems were solved using a CDCL solver. Most subproblems are very easy and almost any CDCL solver could be used for this purpose.

The proofs of these problems consists of three parts: The *re-encoding proof*, the *implication proof*, and the *tautology proof*. These proof part shows the satisfiability equivalence of three formulas: 1) the encoded formula F , 2) the re-encoded formula R , and 3) the negation of all of cubes that are part of the first layer

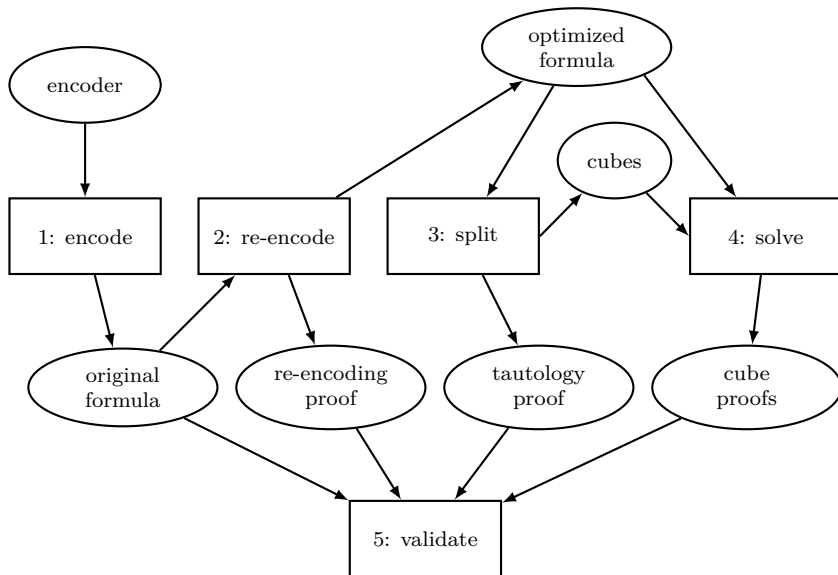

Figure 15.5. Illustration of the framework to solve hard combinatorial problems. The phases are shown in the rectangle boxes, while the input and output files for these phases are shown in oval boxes.

split T . The latter is called T as the cubes need to cover the entire search space, which means that it needs to be a tautology. Together the proof parts show the following relationship:

$$\underbrace{F \models R}_{\text{re-encoding proof}} \models \underbrace{T}_{\text{tautology proof}} \models \perp .$$

implication proof

The re-encoding proof expresses the correctness of the re-encoding phase, which consisted of symmetry breaking and the removal of redundant clauses. The re-encoding cannot be compactly expressed using resolution, so a proof of extended resolution or its generalizations is required. For PTP, S5, and Keller, the re-encoding proof used DRAT.

By far the largest part of the proof (typically over 99%) is the implication proof. It shows that R is unsatisfiable by proving that every clause $C \in T$ is logically implied by R . For each clause $C \in T$ a separate proof piece is produced and these pieces are glued together at the end, which can be done in any arbitrary order. The lack of hints in DRAT proofs make the glueing easy: one can simply concatenate the pieces.

The generation of the final part, the tautology proof, is easy as well as the cubes from the first layer split form a binary tree of assignments by construction. Let m be the number of cubes in our partition, then the tautology proof is a resolution proof consisting of $m-1$ resolution steps.

15.6. Proof Validation and Processing

Although proofs with hints are harder to produce than proofs without hints, they are in principle easy to check and actually needed for some applications, like generating interpolants [McM03]. However, the large size of resolution proofs provides challenges, particularly with respect to memory usage. See [Van12] for a discussion on checking large resolution proofs. The presence of hints makes it easy to implement a checker, especially if the proof format does not allow any ambiguity, such as the LRAT format. This allowed for the implementation of certified (formally verified) checkers, such as ACL2-check [HHKW17].

Proofs without hints are smaller, but validating proofs without hints is more complicated and more costly. Practically all top-tier solvers support the production of proofs without hints, as this is easy to implement, while hardly any of them supports the production of proofs with hints. To obtain the best of both worlds—easy proof production and certified results—there exist tools that turn a proof without hints into a proof with hints. One such tool is DRAT-trim [WHH14], which can turn a DRAT proof into an LRAT proof. DRAT-trim also allows the optimization of proofs, for instance, by removing redundant lemmas. The corresponding tool chain for certifying proofs is shown in Figure 15.6: A SAT solver produces a proof *without* hints, which is turned into an optimized proof *with* hints that is finally validated by a certified checker.

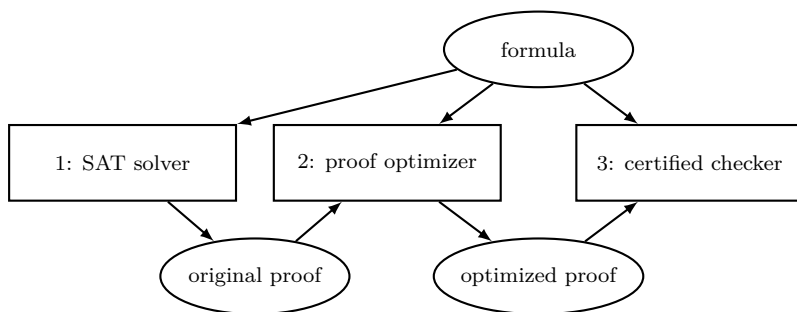

Figure 15.6. Tool chain of certifying proofs.

15.6.1. Proofs With Hints

Resolution proofs can be checked in deterministic logspace [Van08], a very low complexity class. The tool `stc` can efficiently check proofs in the `TraceCheck` format. More details about the format and its use are discussed in Section 15.4.1.

Apart from validation, there exists a vast body of work on compression techniques for resolution proofs [Amj07, BIFH⁺08, Cot10, FMP11, RBST14, Sin07] that go beyond the compression techniques we discussed earlier. One such technique is *RecycleUnits* [BIFH⁺08]: unit clauses in the proof are used to replace some clauses in the proof that are subsumed by the units. The replacement typically makes the proof invalid (i.e., some resolvents are no longer the result of resolving the antecedents). However, the proof can be fixed with a few simple

steps. Figure 15.7 illustrates the RecycleUnits procedure on a derivation of the example CNF formula E from page 638. In the example, notice that replacing a clause by a unit may strengthen the resolvent.

Two other proof compression techniques are *LowerUnits* and *RecyclePivots*. LowerUnits uses the observation that one needs to resolve over a unit clause only a single time. In case a unit clause occurs multiple times in a proof, it is lowered to ensure that it occurs only once. RecyclePivots reduces the *irregularity* in resolution proofs. A proof is irregular if it contains a path on which resolution is performed on the same pivot. Removing all irregularity in a proof may result in an exponential blow-up of the proof [Goe90]. Hence, techniques such as RecyclePivots need to be restricted in the context of proof compression. The tool *Skeptic* [BFP14], which includes most of the compression techniques, can be used to remove redundancy from resolution proofs.

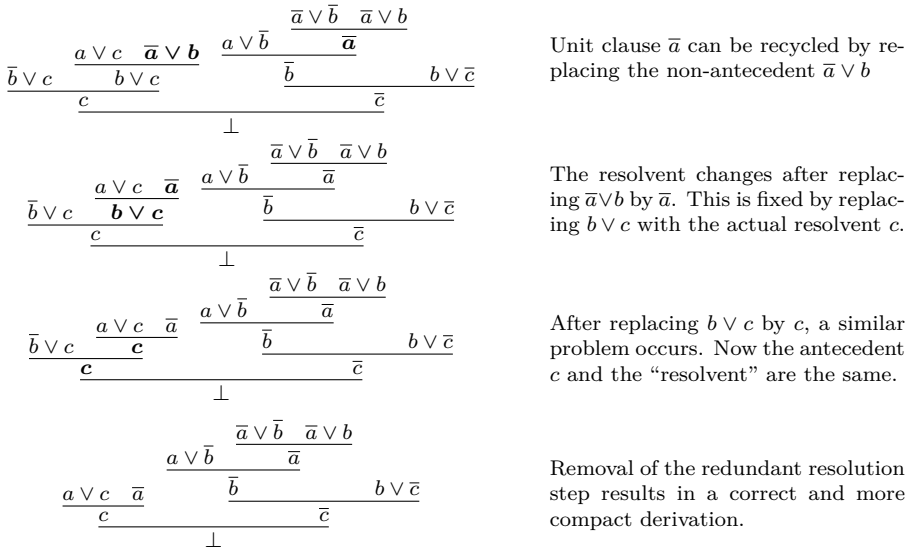

Figure 15.7. An example of the proof compression technique RecycleUnits.

15.6.2. Proofs Without Hints

Proofs without hints are checked using unit propagation. The actual check for each step depends on the proof system. Recall that a RUP proof $\{C_1, \dots, C_m\}$ is valid for formula F , if $C_m = \perp$ and for $i \in \{1, \dots, m\}$, it holds that

$$F \wedge C_1 \wedge \dots \wedge C_{i-1} \vdash C_i.$$

The check for stronger proof systems is more elaborate and thus more expensive. See Section 15.2 for details. The most simple (but very costly) method to validate proofs without hints checks for every $i \in \{1, \dots, m\}$ whether or not the redundancy property of the corresponding proof system holds.

One can reduce the cost of validating proofs without hints by checking them *backwards* [GN03], thereby *marking* clauses that are used for the derivation of other clauses that occur later in the proof: Initially, only the final clause $C_m = \perp$ is marked. Now we loop over the lemmas in backwards order, i.e., C_m, \dots, C_1 . Before validating a lemma, we first check whether it is marked. If a lemma is not marked, it can be skipped, which reduces the computational cost. If a lemma is marked, we check whether the clause satisfies the above redundancy criterion. If the check fails, the proof is invalid. Otherwise, we mark all clauses that were required to make the check succeed (using conflict analysis). For most proofs, this technique allows to skip over half of the lemmas during validation.

The main challenge regarding the validation of proofs without hints is efficiency: Validating a proof without hints is typically much more expensive than obtaining the proof using a SAT solver, even if the implementation uses backwards checking and the same data structures as state-of-the-art solvers. For most other logics, including first order logic, checking a proof is typically cheaper than finding the proof in the first place. There are two main reasons why checking unsatisfiability proofs is more expensive than solving.

First, SAT solvers aggressively delete clauses during solving, which reduces the cost of unit propagation. If the proof checker has no access to the clause deletion information, then unit propagation is much more expensive in the checker than in the solver. This was the main motivation why the proof formats DRUP and DRAT have been developed. These formats support the inclusion of clause-deletion information, thereby making the unit propagation costs between the solver and checker similar.

Second, SAT solvers *reuse* propagations between conflicts whereas proof checkers do not reuse propagations. Consider two consecutive lemmas C_i and C_{i+1} , produced by a SAT solver. In the most extreme (but not unusual) case, the branch that resulted in C_i and C_{i+1} differs only in a single decision (out of many decisions). Hence most propagations are reused by the solver. At the same time, the lemmas might have no overlapping literals, meaning that $C_i \cap C_{i+1} = \emptyset$. Consequently, the checker would not be able to reuse any propagations. In case $C_i \cap C_{i+1}$ is non-empty, the checker could potentially reuse propagations, although no checker implementation for proofs without hints exploits this.

While checking a proof without hints, one can easily produce an unsatisfiable core and a proof with hints. The unsatisfiable core consists of the original clauses that were marked during backwards checking. For most unsatisfiable formulas that arise from applications, many clauses are unmarked and thus not part of the unsatisfiable core. The proof with hints contains for each marked lemma all the clauses that were required during its validation as hints.

The hints that are generated while checking a proof without hints might differ significantly from the hints that would have been produced by the SAT solver. For example, the resolution proof (with hints) for the example formula E might be equal to the resolution graph shown in Fig. 15.1. On the other hand, the resolution proof produced by checking the proofs without hints might be equal to Fig. 15.8. Notice that the resolution graph of Fig. 15.8 (right) does not use all original clauses. Clause $(\bar{b} \vee c)$ is redundant and not part of the core of E .

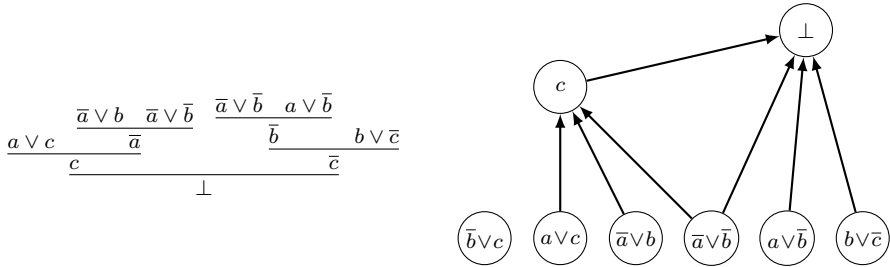

Figure 15.8. A resolution derivation (left) and a resolution graph (right) for the example formula E produced by checking a proof without hints.

15.7. Proof Applications

Proofs of unsatisfiability have been used to validate the results of SAT competitions.² Initially, during the SAT competitions of 2007, 2009, and 2011, a special track was organized for which the unsatisfiability results were checked. For the SAT competitions of 2013 and 2014, proof logging became mandatory for tracks with only unsatisfiable benchmarks. The supported formats for the SAT competition 2013 were `TraceCheck` and `DRUP`, but all solvers participating in these tracks opted for the `DRUP` format. For the SAT competition 2014, the only supported format was `DRAT`, which is backwards compatible with `DRUP`. Since 2016, the SAT competition requires proof logging to participate in the main track.

As already mentioned, one motivation for using proofs is to make testing and debugging of SAT solvers more effective. Checking learned clauses online with RUP allows to localize unsound implementation defects as soon they lead to clauses that are not implied by reverse unit propagation.

Testing with forward proof checking is particularly effective in combination with fuzzing (generating easy formulas) and delta-debugging [BB09b] (shrinking a formula that triggers a bug). Otherwise failures produced by unsound reasoning can only be observed if they turn a satisfiable instance into an unsatisfiable one. This situation is not only difficult to produce, but also tends to lead to much larger input files after delta-debugging.

However, model-based testing [ABS13] of the incremental API of a SAT solver is in our experience at least as effective as file-based fuzzing and delta-debugging. The online proof checking capabilities to `Lingeling` [Bie14] allow the combination of these two methods (model-based testing and proof checking).

Another important aspect of proof tracing is that it allows to generate a clausal (or variable) core (i.e., an unsatisfiable subset). These cores can be used in many applications, including MUS extraction [NRS13], MaxSAT [MHL⁺13], diagnosis [SKK03, NBE12], and abstraction refinement in model checking [EMA10] or SMT [ALS06, BB09a]. Note that this list of references is subjective and by far not complete. It should only be considered as a starting point for investigating related work on using cores.

²see <http://www.satcompetition.org> for details.

Finally, extraction of interpolants is an important usage of resolution proofs, particularly in the context of interpolation-based model checking [McM03]. Since resolution proofs are large and not easy to obtain, there have been several recent attempts to avoid proofs and obtain interpolants directly, see for instance [VRN13]. Interpolation-based model checking became the state-of-the-art until the invention of IC3 [Bra11]. The IC3 algorithm is also based on SAT technology, and also uses cores, but usually in a much more light-weight way. Typical implementations use assumption-based core techniques as introduced in MiniSAT [ES03] (see also [LB13]) instead of proof-based techniques.

15.8. Conclusions

Unsatisfiability proofs are useful for several applications, such as computing interpolants and MUS extraction. These proofs can also be used to validate results of the SAT solvers that produced them and for tools that use SAT solvers, such as theorem provers.

Proofs of unsatisfiability come in two types: with and without hints. Proofs without hints are useful for various applications, but they are costly and complicated to produce. Therefore few SAT solvers support proof logging with hints. Proof logging without hints is easy and therefore most state-of-the-art solvers support it. However, validating proofs without hints is costly, although recent advances significantly improved performance of checkers.

There are several challenges regarding unsatisfiability proofs. How can one store proofs with hints using much less space on disk and produce them using much less memory overhead? Can the cost of validating proofs with hints be reduced further? Last but not least, research is required to study how some techniques, such as Gaussian elimination, cardinality resolution, and symmetry breaking, can be expressed elegantly in unsatisfiability proofs.

Chapter 16

Worst-Case Upper Bounds

Evgeny Dantsin and Edward A. Hirsch

There are many algorithms for testing satisfiability — how to evaluate and compare them? It is common (but still disputable) to identify the efficiency of an algorithm with its worst-case complexity. From this point of view, asymptotic upper bounds on the worst-case running time and space is a criterion for evaluation and comparison of algorithms. In this chapter we survey ideas and techniques behind satisfiability algorithms with the currently best upper bounds. We also discuss some related questions: “easy” and “hard” cases of SAT, reducibility between various restricted cases of SAT, the possibility of solving SAT in subexponential time, etc.

In Section 16.1 we define terminology and notation used throughout the chapter. Section 16.2 addresses the question of which special cases of SAT are polynomial-time tractable and which ones remain **NP**-complete. The first non-trivial upper bounds for testing satisfiability were obtained for algorithms that solve k -SAT; such algorithms also form the core of general SAT algorithms. Section 16.3 surveys the currently fastest algorithms for k -SAT. Section 16.4 shows how to use bounds for k -SAT to obtain the currently best bounds for SAT. Section 16.5 addresses structural questions like “what else happens if k -SAT is solvable in time $\langle \dots \rangle$?”. Finally, Section 16.6 summarizes the currently best bounds for the main cases of the satisfiability problem.

16.1. Preliminaries

16.1.1. Definitions and notation
